# Ultrasensitive broadband phototransistors based on perovskite/organic-semiconductor vertical heterojunctions

Chao Xie<sup>1</sup>, Peng You<sup>1</sup>, Zhike Liu<sup>1</sup>, Li Li<sup>2</sup> and Feng Yan<sup>1</sup>

Organolead halide perovskites have emerged as the most promising materials for various optoelectronic devices, especially solar cells, because of their excellent optoelectronic properties. Here, we present the first report of low-voltage high-gain phototransistors based on perovskite/organic-semiconductor vertical heterojunctions, which show ultrahigh responsivities of  $\sim 10^9 \text{ A W}^{-1}$  and specific detectivities of  $\sim 10^{14}$  Jones in a broadband region from the ultraviolet to the near infrared. The high sensitivity of the devices is attributed to a pronounced photogating effect that is mainly due to the long carrier lifetimes and strong light absorption in the perovskite material. In addition, flexible perovskite photodetectors have been successfully prepared via a solution process and show high sensitivity as well as excellent flexibility and bending durability. The high performance and facile solution-based fabrication of the perovskite/organic-semiconductor phototransistors indicate their promise for potential application for ultrasensitive broadband photodetection.

## INTRODUCTION

Ultrasensitive photodetectors with a broadband spectral response from the ultraviolet (UV)–visible region to the near infrared (NIR) are highly desirable for a multitude of industrial and scientific applications<sup>1–5</sup>. The key strategy for realizing an ultrasensitive photodetector is to achieve a high gain, which means that one incident photon can induce many carriers to conduct current in the device. Conventional high-gain photodetectors, including avalanche photodiodes and photomultipliers, require strictly controlled and complicated fabrication procedures and are also expensive and bulky<sup>6</sup>. Moreover, these devices need to be operated at high voltages ( $> 100 \text{ V}$ ), leading to high power consumption and inconvenience in many applications<sup>3–5</sup>. To date, various novel materials, including nanoparticles, nanorods, organic-semiconductors, graphene and other two-dimensional materials, have been exploited for the development of highly sensitive photodetectors<sup>3–5,7–17</sup>. To achieve high gain in a photodetector, one promising strategy is based on the photogating effect, which can cause photon-activated carriers to recirculate many times before recombining with opposite charges in the channel of a phototransistor<sup>3,5</sup>. The photogating effect, similar to field-effect gating, refers to the modulation of the carrier density, and thus of the conductivity in the channel, by means of light illumination<sup>13</sup>. The sensitivity of a phototransistor relies on strong light absorption, efficient charge separation, long carrier lifetimes and high carrier mobilities in the channel. For example, graphene phototransistors

modified with PbS colloidal quantum dots or MoS<sub>2</sub> on the surfaces of the graphene have shown responsivities of up to  $10^8 \text{ A W}^{-1}$  and gains of  $\sim 10^8$  as a result of pronounced photogating effects<sup>13–15</sup>. However, the phototransistors with the highest previously reported gains cannot be prepared using facile solution processes. Therefore, it is necessary to explore solution-processable ultrasensitive phototransistors for low-cost and multifunctional applications.

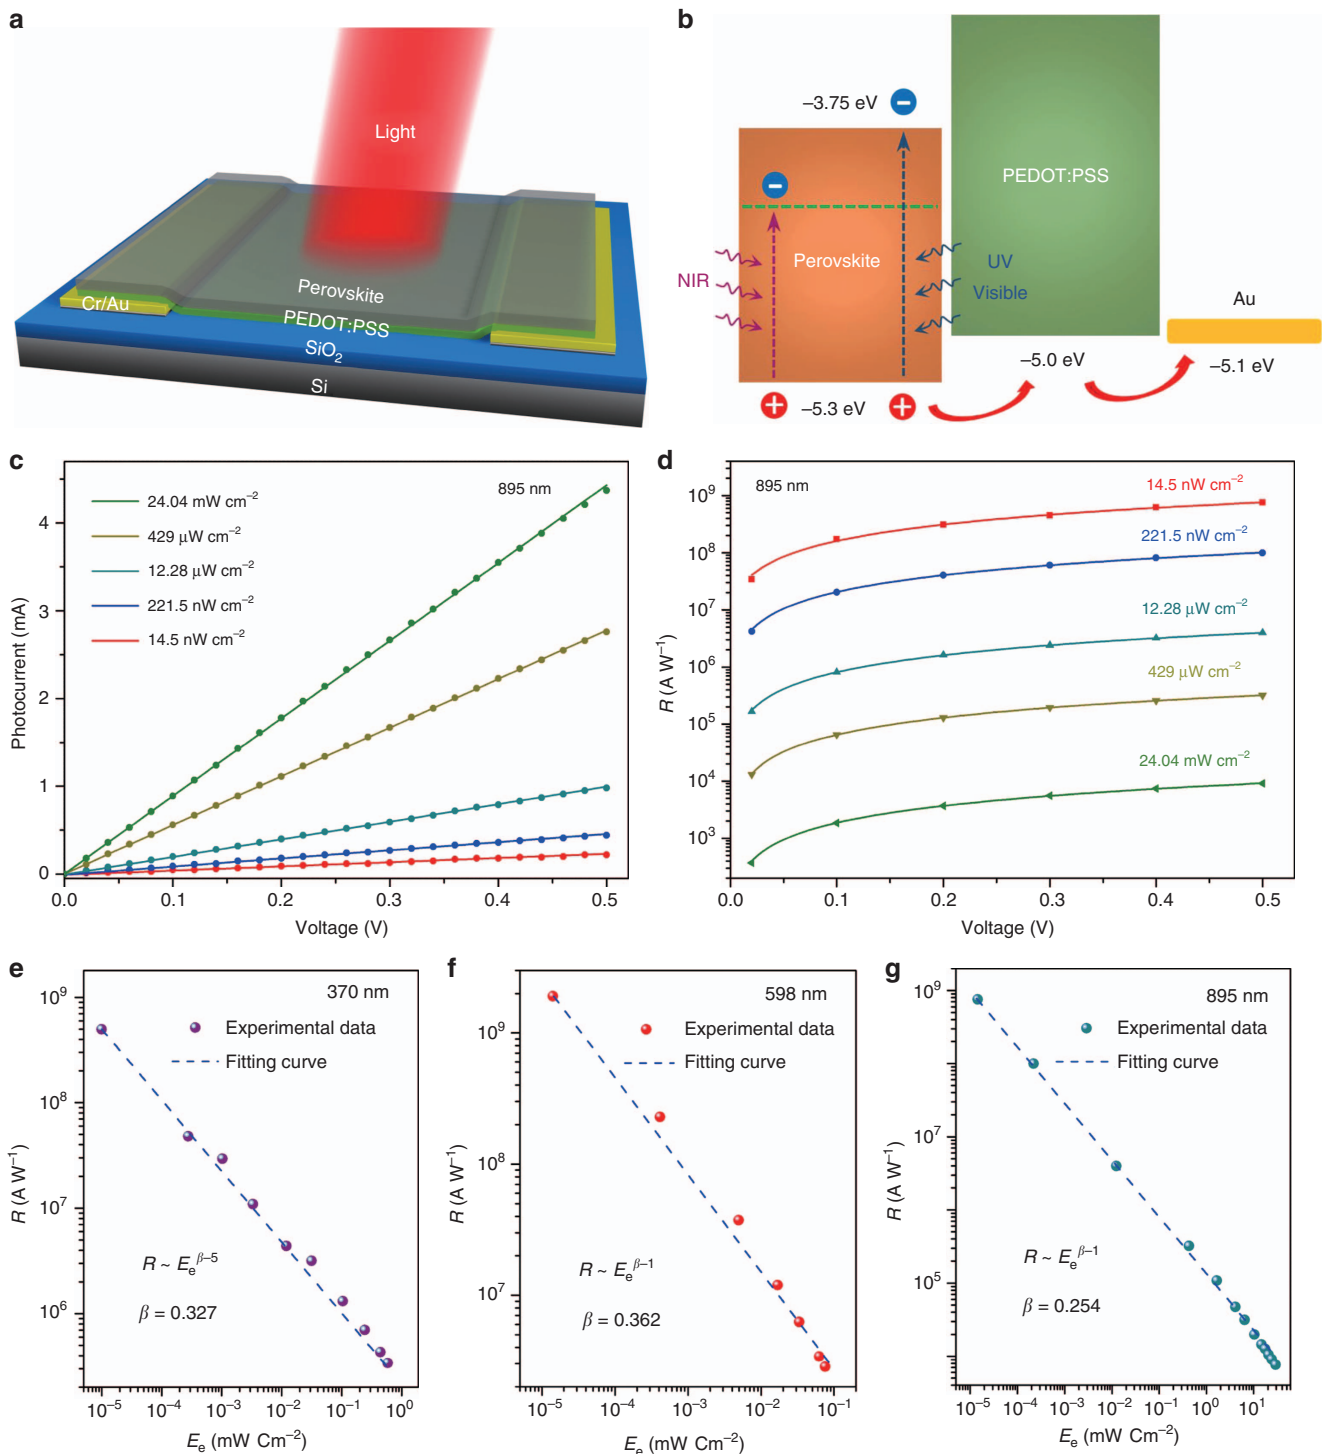

Organolead halide perovskite materials have stimulated considerable research interest in relation to high-efficiency and low-cost perovskite solar cells<sup>18–20</sup>. Their excellent optoelectronic properties, including appropriate direct bandgaps<sup>21</sup>, high light absorption coefficients<sup>22</sup> and long carrier transport lengths<sup>23–25</sup>, render them promising candidate materials for photovoltaics and other optoelectronic devices, including photodetectors, light-emitting diodes and semiconductor lasers<sup>26–30</sup>. Recently, organolead halide perovskites have been successfully used in various types of photodetectors, including photodiodes and phototransistors<sup>31–38</sup>; however, these devices have shown relatively low gain in comparison with phototransistors based on other functional materials. Moreover, previously reported perovskite photodetectors show a detectable wavelength region that is limited by the bandgap of the perovskite material and have not been used for sensing NIR light with wavelengths longer than 800 nm.

Here, we report phototransistors based on perovskite/organic-semiconductor vertical heterojunctions prepared via a solution process. The devices contain double layers of  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$

perovskite and an organic-semiconductor that form staggered heterojunctions. Although perovskite/organic heterojunctions have previously been successfully applied in photovoltaics and even in biological systems as artificial synapses<sup>39</sup>, they have never been used in phototransistors until now. We have found that phototransistors

based on  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$  and poly-(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) exhibit a broadband photore-sponse from the UV–visible region to the NIR region, with a responsivity and specific detectivity of higher than  $10^9 \text{ A W}^{-1}$  and  $10^{14}$  Jones, respectively, at a low operating voltage of only 0.5 V. This

excellent performance is attributed to a significant photogating effect at the vertical heterojunction, mainly due to the long carrier lifetimes and strong light absorption in the perovskite layers.

## MATERIALS AND METHODS

### Device fabrication

A SiO<sub>2</sub> (300 nm)/Si or polyimide (PI) substrate was ultrasonically cleaned sequentially in alcohol, acetone and deionized water and dried under a stream of nitrogen gas. Cr (10 nm)/Au (100 nm) electrodes with a channel width (*W*) and length (*L*) of 1000 and 2 μm, respectively, were patterned via photolithography and magnetron sputtering. Then, a PEDOT:PSS film was deposited onto the substrate via the spin coating of a PEDOT:PSS aqueous solution (Clevios PH 500, Heraeus Precious Metals GmbH & Co. KG, Leverkusen, Germany). The thickness of the PEDOT:PSS film was controlled by adjusting the solution concentration and the spin-coating speed. Afterward, the substrate was transferred into a glovebox filled with high-purity nitrogen gas and baked at 150 °C for 1 h.

Methylammonium iodide (CH<sub>3</sub>NH<sub>3</sub>I) and lead chloride (PbCl<sub>2</sub>) (99.5 wt.%) were dissolved in anhydrous N,N-dimethylformamide (DMF) (99.8 wt.%) at a 3:1 molar ratio of CH<sub>3</sub>NH<sub>3</sub>I to PbCl<sub>2</sub>, and the solution was stirred at 45 °C for 12 h inside a nitrogen-filled glovebox to produce a mixed halide perovskite precursor solution. Then, the precursor solution was spin coated onto the PEDOT:PSS film for 1 min to form a CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3-x</sub>Cl<sub>x</sub> perovskite film. The device was then annealed at 100 °C for 45 min. The thickness of the perovskite film was controlled by adjusting the spin-coating speed while keeping the other conditions unchanged. In this work, perovskite films with approximate thicknesses of 180, 205, 250, 300 and 330 nm were obtained at spin-coating speeds of 6200, 4500, 3300, 2500 and 2000 r.p.m., respectively.

### Material characterization

The morphology of the perovskite/PEDOT:PSS films was characterized using scanning electron microscopy (SEM, FEI Nova 450 Nano, FEI Company, Hillsboro, OR, USA). Transmittance and UV–vis absorption spectra were recorded using a Perkin Elmer (Waltham, MA, USA) Lambda 900 UV/VIS/NIR spectrometer. The PEDOT:PSS surface morphology was characterized by means of atomic force microscopy (AFM, Veeco NanoScope V, Bruker Corporation, Billerica, MA, USA). A surface chemical analysis of the PEDOT:PSS was conducted using an X-ray photoelectron spectrometer (VG ESCALAB 220i-XL, Thermo Fisher Scientific, Waltham, MA, USA).

### Device characterization

Electrical and optoelectrical measurements were performed using a semiconductor parameter analyzer (Agilent 4156 C, Santa Clara, CA, USA) under light illumination at various intensities in a glovebox. The light sources were light-emitting diodes with wavelengths of 370, 598 and 895 nm. The flexible devices were measured both before and after bending tests. In the bending tests, each sample was pressed against a small glass bottle with a radius of 7 mm up to 300 times. Spectral response tests were performed using a standard quantum efficiency measurement system equipped with a xenon lamp (Oriol 66902, 300 W, Newport Corporation, Irvine, CA, USA), a monochromator (Newport 66902, Irvine, CA, USA), a Si detector (Oriol 76175-71580, Newport Corporation), and a dual-channel power meter (Newport 2931-C). Neutral density filters were used to attain light with a constant intensity, and a source meter (Keithley 2420, Cleveland, OH, USA) was used to collect the electrical signals. The devices were wire-

bonded and encapsulated using glass caps and epoxy in the glovebox before the spectral response tests in air.

## RESULTS AND DISCUSSION

Figure 1a presents a schematic diagram of a perovskite photodetector consisting of CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3-x</sub>Cl<sub>x</sub> perovskite and PEDOT:PSS films on a SiO<sub>2</sub>/Si substrate. Cr/Au electrodes were patterned on the substrate by means of photolithography and magnetron sputtering, followed by the sequential coating of PEDOT:PSS and CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3-x</sub>Cl<sub>x</sub> perovskite layers. The surface morphology of the perovskite film on the PEDOT:PSS was observed under SEM (see the Supplementary Information and Supplementary Fig. S1). We found that the perovskite layer exhibited reasonably full coverage on the PEDOT:PSS layer, with only a few pinholes, and cross-sectional SEM imaging showed the film to have a double-layer stacked structure.

Figure 1b shows the band structure of the device<sup>29</sup>, in which a staggered heterojunction is formed between the CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3-x</sub>Cl<sub>x</sub> perovskite and the PEDOT:PSS. Under light illumination, excitons or electron–hole pairs are generated in the perovskite film, depending on the film morphology, as reported by Grancini *et al.*<sup>40</sup>. Moreover, excitons can easily dissociate into electrons and holes at the perovskite/PEDOT:PSS interface or in the perovskite film because of the low-exciton binding energy<sup>41</sup>. Holes tend to diffuse into the PEDOT:PSS layer because of the decreased energy, whereas electrons must accumulate in the perovskite layer since the conduction band level of the perovskite is lower than the lowest unoccupied molecular orbital level of the PEDOT:PSS. Thus, the channel current of the device can be attributed to the electrons and holes in the perovskite and PEDOT:PSS layers, respectively. We found that the electron mobility in the perovskite layer is only  $\sim 1.7 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  (Supplementary Information and Supplementary Fig. S2), whereas the hole mobility in the PEDOT:PSS layer is estimated to be  $\sim 5.6 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  (Supplementary Information, Parts 1 and 2). Therefore, the channel current is mainly due to the hole transport in the PEDOT:PSS layer, and the current across the perovskite layer is negligible.

The current–voltage (*I*–*V*) curves between the two Au electrodes of the perovskite photodetectors were first measured in the dark. The devices exhibited linear *I*–*V* curves, indicating good ohmic contacts between the perovskite/PEDOT:PSS bilayer films and the Au electrodes. Then, the perovskite photodetectors were characterized under light illumination at wavelengths from the UV–visible region to the NIR region. Figure 1c shows the photocurrent ( $I_{\text{ph}} = I_{\text{light}} - I_{\text{dark}}$ ) of a device as a function of the applied voltage between the two Au electrodes under illumination with NIR light (wavelength:  $\sim 895 \text{ nm}$ ) at various intensities. The photocurrents of the same device under UV ( $\sim 370 \text{ nm}$ ) and visible ( $\sim 598 \text{ nm}$ ) light are shown in the Supplementary Information (Supplementary Fig. S3). The photocurrent was found to depend almost linearly on the applied voltage, with a maximum value of  $\sim 4 \text{ mA}$  at an applied voltage of only 0.5 V. To confirm that the photocurrents reported above were not due solely to either the perovskite or the PEDOT:PSS film, control experiments were performed on devices prepared with the individual films. We found that the photocurrent of a transistor based on CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3-x</sub>Cl<sub>x</sub> perovskite alone was  $\sim 10 \text{ nA}$  at a bias voltage of 0.5 V under light illumination at the same intensity (see the Supplementary Information, Supplementary Fig. S4). Another control device, based on pure PEDOT:PSS, exhibited a negligible current response to light illumination. The photocurrents ( $\sim 1 \mu\text{A}$ ) were three orders of magnitude lower than the values observed in the perovskite/PEDOT:PSS phototransistors under the same light intensity from the UV–visible to the NIR region (Supplementary Fig. S5). Therefore, the

increase in the channel current of a perovskite/PEDOT:PSS phototransistor under light illumination can be attributed to a photogating effect, and the photocurrent  $I_{\text{ph}}$  is given by

$$I_{\text{ph}} = I_{\text{light}} - I_{\text{dark}} = \frac{W}{L} q \Delta p \mu V, \quad (1)$$

where  $I_{\text{light}}$  and  $I_{\text{dark}}$  are the currents in the device under light illumination and in the dark, respectively;  $W$  and  $L$  are the channel width and length of the device, respectively;  $q$  is the elementary charge;  $\Delta p$  is the increase in the density of holes per unit area in the PEDOT:PSS layer in the channel;  $\mu$  is the hole mobility in the PEDOT:PSS layer; and  $V$  is the voltage applied to the two Au electrodes.

The responsivity ( $R$ ), which is an essential figure of merit for a photodetector, is given by<sup>6</sup>

$$R(AW^{-1}) = \frac{I_{\text{ph}}}{E_e WL}, \quad (2)$$

where  $E_e$  is the light intensity. Figure 1d shows the device responsivity as a function of the applied voltage for various light intensities (wavelength: 895 nm), exhibiting a maximum value of  $7.6 \times 10^8 \text{ A W}^{-1}$ . Figures 1e–1g show the responsivities to wavelengths of 370, 598 and 895 nm, respectively. The responsivity increased as the light intensity decreased, following a relationship of the form  $R \propto E_e^{\beta-1}$ , as previously observed in many other phototransistors<sup>3,14</sup>. Notably, the highest responsivity at low light intensity was  $1.91 \times 10^9 \text{ A W}^{-1}$  (wavelength:  $\sim 598 \text{ nm}$ ), which is much higher than the corresponding responsivities of previously reported perovskite photodetectors and other state-of-the-art photodetectors<sup>6,13–15,31–38</sup>. Moreover, the gain ( $G$ ) of a phototransistor is given by<sup>42</sup>

$$G = \frac{I_{\text{ph}} hc}{q E_e WL \lambda} = \frac{R hc}{q \lambda} \quad (3)$$

where  $c$  is the speed of light,  $\lambda$  is the wavelength of the incident light and  $h$  is Planck's constant. Thus, the gain corresponding to the maximum responsivity is estimated to be  $4.0 \times 10^9$ .

In addition to the responsivity, the specific detectivity ( $D^*$ ) is another key parameter of a photodetector and is given by<sup>6,42–44</sup>

$$D^* = \frac{(AB)^{1/2}}{NEP} \quad (4)$$

$$NEP = \frac{\overline{i_n^2}^{-1/2}}{R} \quad (5)$$

where  $A$  is the effective area of the photodetector,  $B$  is the bandwidth,  $NEP$  is the noise equivalent power,  $\overline{i_n^2}^{-1/2}$  is the root mean square value of the noise current and  $R$  is the responsivity of the device. The noise level per unit bandwidth (1 Hz) of the perovskite photodetectors was measured to be  $\sim 60 \text{ nA Hz}^{-1/2}$  (see the Supplementary Information, Part 3 and Supplementary Fig. S10). Therefore, the specific detectivities ( $D^*$ ) of a device at an applied voltage of 0.5 V and at wavelengths of 598 and 895 nm were  $1.4 \times 10^{14}$  and  $5.6 \times 10^{13}$  Jones ( $\text{cm Hz}^{1/2} \text{ W}^{-1}$ ), respectively, far superior to those of traditional Si photodetectors<sup>6</sup>.

Figure 2a shows a schematic diagram of a perovskite/PEDOT:PSS phototransistor under light illumination, in which electrons and holes have accumulated in the perovskite and PEDOT:PSS layers, respectively. The density of photocarriers (that is, photo-generated holes) in the PEDOT:PSS layer can be calculated based on the photocurrent. If the hole mobility under light illumination is assumed to be constant, then the density of photocarriers in the PEDOT:PSS layer is given by

the following equation<sup>6</sup>:

$$\Delta n = \frac{L}{W q \mu V} I_{\text{ph}} \quad (6)$$

where  $\mu$  is the hole mobility in PEDOT:PSS. As shown in Figure 2b, the maximum hole density that can be achieved is  $\sim 2 \times 10^{13} \text{ cm}^{-2}$ , which is one order of magnitude higher than that typically induced in a field-effect transistor<sup>6</sup>. Therefore, an extremely strong photogating effect is observed in the devices under light illumination.

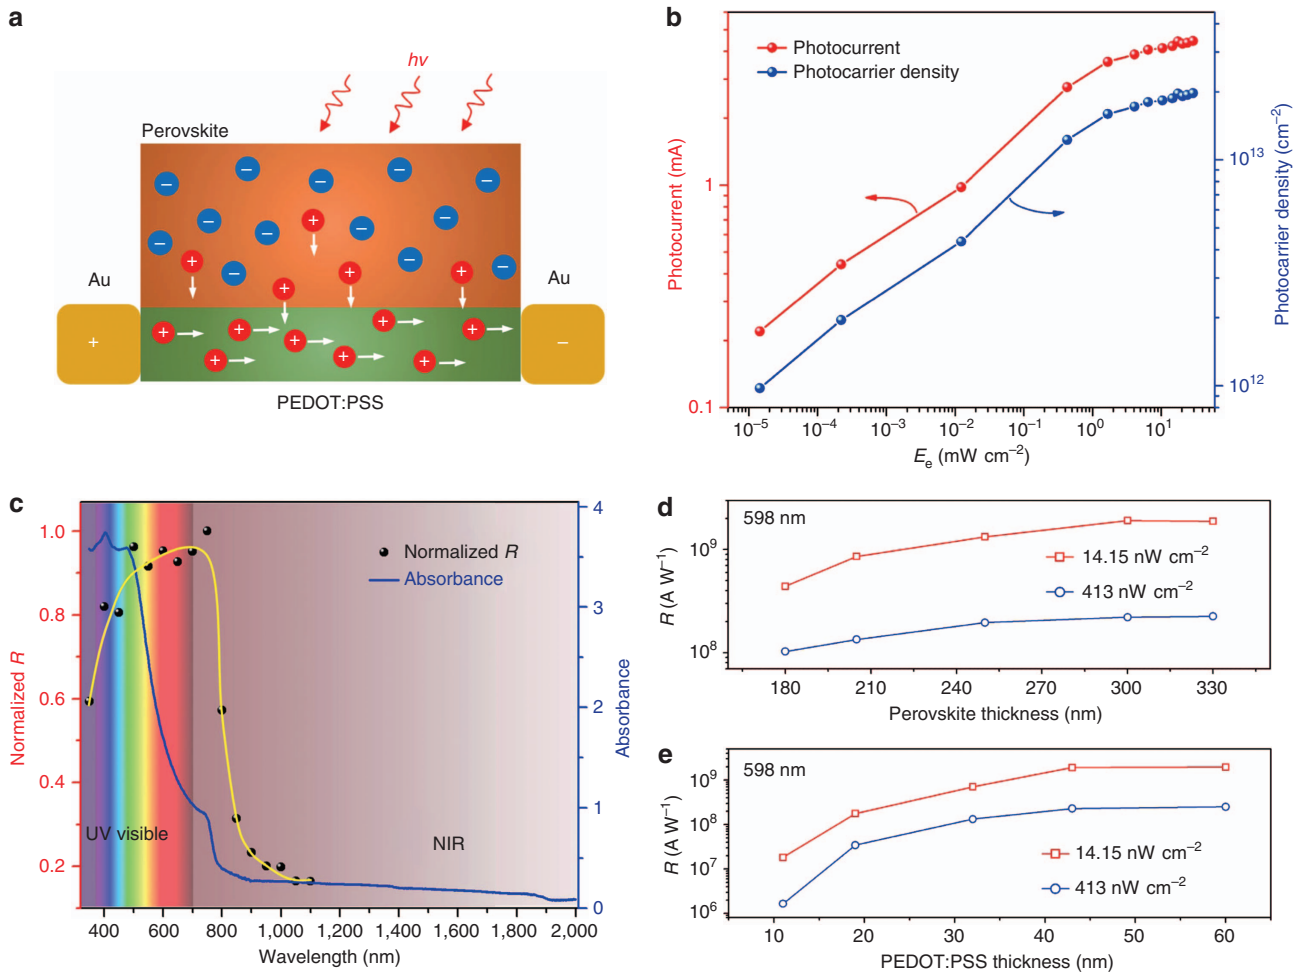

We further characterized the spectral response of the perovskite photodetectors as shown in Figure 2c. The normalized spectral responsivity of a device at a given light intensity exhibits a sharp rising edge near a wavelength of 800 nm, corresponding to the band-edge absorption of the  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$  perovskite ( $\sim 1.55 \text{ eV}$ ), as shown in the same figure. Although the responsivity is rather low at wavelengths longer than 800 nm, it can be as high as  $7.6 \times 10^8 \text{ A W}^{-1}$  at 895 nm, corresponding to a gain of  $1.1 \times 10^9$ . Notably, the spectral response of the phototransistors is different from the external quantum efficiency of a perovskite solar cell, which shows a sharp decrease to 0 for wavelengths longer than 800 nm (see the Supplementary Information and Supplementary Fig. S11)<sup>45</sup>. To better understand this effect, the light absorption of a pure perovskite film was characterized from the UV to the NIR region. As shown in Figure 2c, a perovskite film can absorb light at wavelengths of up to  $1.9 \mu\text{m}$  because of the existence of traps in the film<sup>46</sup>. Therefore, the photoresponse of the devices at wavelengths longer than 800 nm can be attributed to the excitation of carriers from the valence band to the trap states within the perovskite bandgap, as shown in Figure 1b. In such a phototransistor, the photo-generated electrons are not necessarily mobile in the perovskite film, and thus, an ultrahigh responsivity in the NIR region can be achieved, unlike in the case of a solar cell-based photodetector<sup>33,34</sup>.

The photoresponse of a device also depends on the thicknesses of the perovskite and PEDOT:PSS layers, as shown in Figures 2c and 2d. The responsivity increases with increasing perovskite thickness because of the enhanced light absorption and tends to saturate when the perovskite thickness is larger than 300 nm. Similarly, the responsivity increases with increasing PEDOT:PSS thickness and reaches a maximum when this thickness is  $\sim 43 \text{ nm}$ . Therefore, the thicknesses of the perovskite and PEDOT:PSS layers were optimally chosen to be 300 nm and 43 nm, respectively, in our experiments.

The time-dependent photoresponse of the perovskite photodetectors was studied by periodically turning the light illumination on and off. As shown in Figure 3a, the photocurrent of a device increases rapidly during the initial stage (within the first few seconds) of illumination and then increases slowly for several minutes; this behavior can be fitted using a double exponential function with two relaxation times

$$I_{\text{ph}} = A_1 \left( 1 - \exp\left(-\frac{t}{\tau_1}\right) \right) + A_2 \left( 1 - \exp\left(-\frac{t}{\tau_2}\right) \right) \quad (7)$$

where  $\tau_1$  and  $\tau_2$  are two time constants and  $A_1$  and  $A_2$  are magnitudes. As shown in Figure 3b, the time constants  $\tau_1$  and  $\tau_2$  for the fitted curve are 4.5 and 57.5 s, respectively. We note that these response times are relatively long compared with previously reported perovskite photodetectors<sup>31,32,35,36</sup>, which is not strange since slow responses are typically expected in phototransistors with ultrahigh gains<sup>13–15,47</sup>. In our devices, the photoresponse is associated with the accumulation processes of holes and electrons in the PEDOT:PSS and perovskite layers, respectively. During the initial stage, holes diffuse from the perovskite to the PEDOT:PSS layer, and thus, the channel current

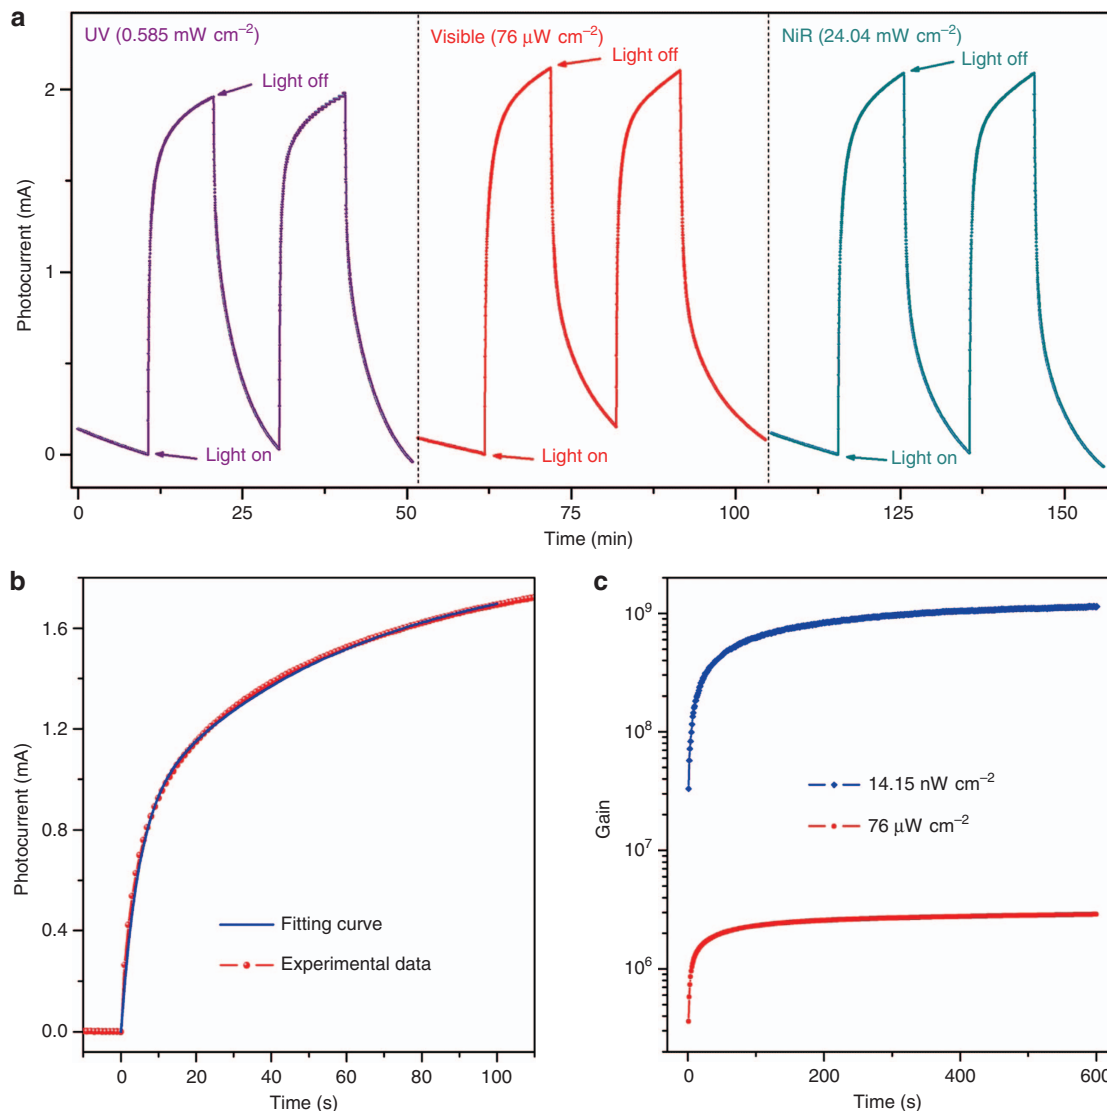

**Figure 2** Photoresponse of  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$  phototransistors. (a) Schematic diagram of a perovskite/PEDOT:PSS phototransistor under light illumination. (b) Plot of the photocurrent and photocarrier density of a phototransistor as functions of the light intensity. Light wavelength: 895 nm. (c) Normalized spectral responsivity of a device (wavelengths: from 350 to 1100 nm) and absorbance spectrum of a  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$  perovskite film on a glass substrate (wavelengths: from 350 to 2000 nm). The black dots represent the experimental data, and the yellow line is a guide for the eye. (d and e) Responsivities of the phototransistors as functions of the perovskite thickness and PEDOT:PSS thickness, respectively. Light wavelength: 598 nm.

rapidly increases with time. As the hole density in the channel increases, more holes will recombine with electrons at the perovskite/PEDOT:PSS interface. Moreover, a reverse electric field induced by the increased number of separated charge carriers will depress the injection rate of holes. Consequently, the increase in channel current subsequently slows under continued illumination for the above reasons. Only once the recombination rate is equal to the rate of injection of holes from the perovskite to the PEDOT:PSS can the device show a stable photocurrent. At the same time, holes will transfer and recirculate many times in the PEDOT:PSS channel throughout their long carrier lifetimes, which explains the ultrahigh gain achieved in our phototransistors.

According to Equation (3), the gain of a device can be calculated based on its time-dependent photocurrent. Figure 3c shows the gain of a device as a function of illumination time for two different light intensities. The gain of the device increased over time and saturated at values of  $1.2 \times 10^9$  and  $2.9 \times 10^6$  for light intensities of 14.15 and  $76 \mu\text{W cm}^{-2}$ , respectively. Thus, the gain decreases with increasing light intensity, which is consistent with the decreased responsivity with increasing light intensity shown in Figure 1.

Since the photoresponse of our devices is due to the accumulation of electrons in the perovskite layer, it is reasonable to consider that the response speed of a device is closely related to the properties of its perovskite layer. We measured a phototransistor with a thinner perovskite layer (thickness:  $\sim 180$  nm) prepared under the same annealing conditions as the other devices (see the Supplementary Information, Part 4 and Supplementary Fig. S12). Although the responsivity of the device was lower, which is consistent with the data shown in Figure 2d, the response speed was dramatically improved, indicating that a thinner perovskite layer can lead to a shorter response time. During the charge accumulation process in the perovskite/PEDOT:PSS heterojunction, electrons will fill the trap states from deeper to shallower levels and will then fill the conduction band in the perovskite. The deep trap states can be filled throughout the entire perovskite layer because of their low-energy levels, whereas the shallow trap states and conduction band will be filled only close to the heterojunction. Consequently, as the film thickness decreases, fewer deep trap states will be involved in the charge accumulation process. Since the capture cross section of deep trap states is typically smaller than that of shallow trap states<sup>6</sup>, a thinner perovskite layer with fewer

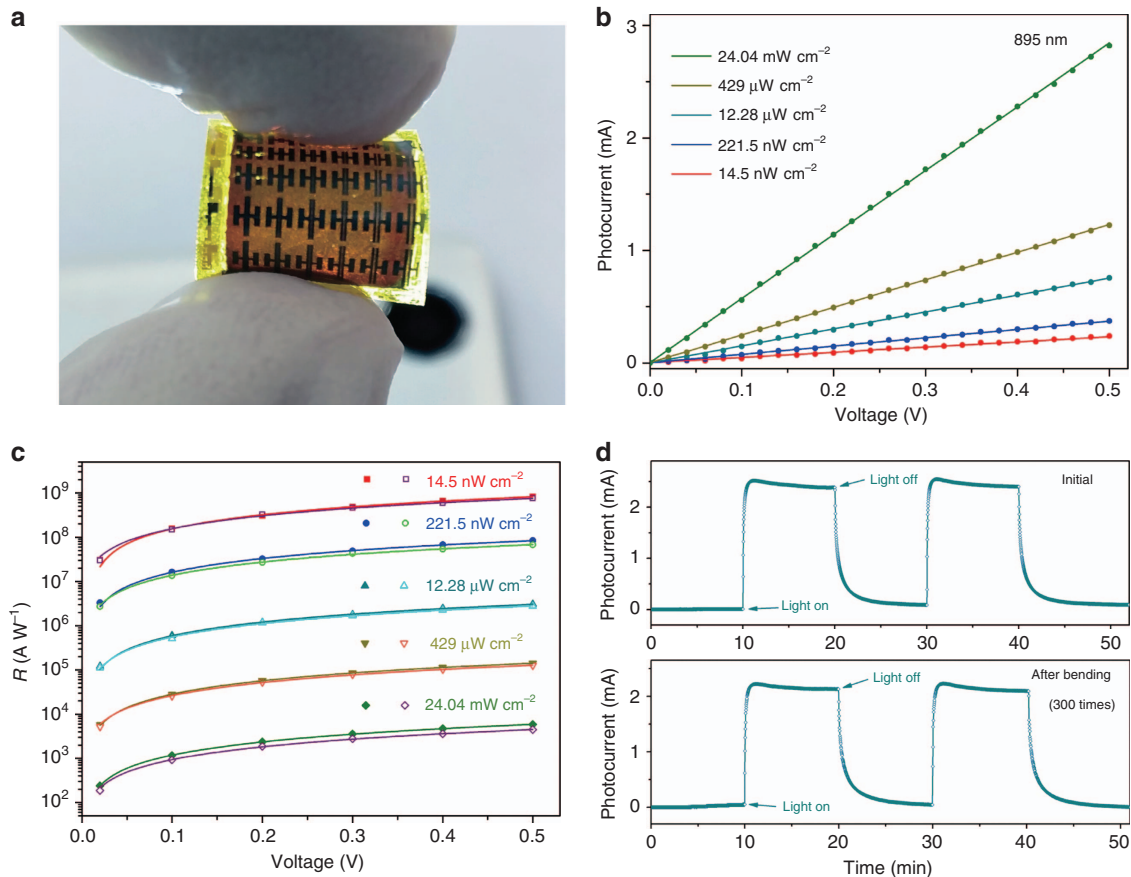

**Figure 3** Transient properties of a  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$  phototransistor. (a) Time-dependent photoresponse of the photodetector to periodic on/off illumination at three different wavelengths of 370, 598 and 895 nm. (b) Enlarged view of the rising edge of the time-dependent photoresponse fitted with a double exponential function. Light wavelength: 598 nm. (c) Gain of the phototransistor as a function of time under light illumination (wavelength: 598 nm) at intensities of  $14.15 \text{ nW cm}^{-2}$  and  $76 \mu\text{W cm}^{-2}$ .

deep trap states can result in a phototransistor with a faster response speed.

Next, we investigated the properties of the perovskite and organic-semiconductor layers that might influence the device responsivity. Although the perovskite material shows strong light absorption and can generate electron-hole pairs with high quantum efficiency, some holes recombine with electrons in the perovskite and are unable to be injected into the PEDOT:PSS layer, especially when a high density of electrons accumulates in the perovskite layer. Therefore, the responsivity and gain of a device strongly depend on the lifetime of holes in the perovskite, which is related to two factors. First, the density of electrons in the perovskite layer increases with increasing light intensity, leading to a decrease in the hole lifetime in the perovskite and, consequently, a decrease in device responsivity. Second, the hole lifetime in  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$  perovskite has been found to be longer than those in many other semiconductors because of the low density of recombination centers in the perovskite<sup>48</sup>. To further confirm this

understanding, we tested phototransistors based on  $\text{CH}_3\text{NH}_3\text{PbI}_3/\text{PEDOT:PSS}$  heterojunctions (see the Supplementary Information, Part 5 and Supplementary Fig. S13) and found that the maximum responsivity was only  $\sim 10^6 \text{ A W}^{-1}$  at the lowest light intensity. It has been reported that the hole lifetime in a  $\text{CH}_3\text{NH}_3\text{PbI}_3$  film is much shorter than that in a  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$  film under the same illumination conditions<sup>23,49</sup>. Therefore, it is reasonable to find that a phototransistor based on  $\text{CH}_3\text{NH}_3\text{PbI}_3/\text{PEDOT:PSS}$  shows a much lower responsivity than a device based on  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$ . This experiment clearly indicates that the ultrahigh responsivity and gain of our phototransistors are due to the long lifetime and diffusion length of holes in the  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$  perovskite films.

To better understand the photogating effect of the perovskite/organic-semiconductor heterojunction, we prepared devices based on another organic-semiconductor, poly(3-hexylthiophene) (P3HT), and  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$ . P3HT is a typical organic-semiconductor with a carrier mobility of up to  $0.1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  (Ref. 50). Under light

illumination, the transfer curve of such a transistor shifts toward higher gate voltages because of the injection of holes into the P3HT layer (see the Supplementary Information and Supplementary Fig. S14). The increase in hole density induced by light illumination is given by  $\Delta n = \frac{C_i \Delta V}{q}$ , where  $C_i$  is the gate capacitance and  $\Delta V$  is the light-induced shift in the gate voltage. The maximum shift is  $\sim 20$  V, corresponding to the increase in the hole density in the channel to  $4 \times 10^{12} \text{ cm}^{-2}$ , which is much lower than the value ( $2 \times 10^{13} \text{ cm}^{-2}$ ) observed for devices based on  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$ . More importantly, the responsivity (see the Supplementary Information and Supplementary Fig. S14 and S15) is several orders of magnitude lower than that of a device based on  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$  for two reasons. First, the hole mobility of P3HT is only  $2.7 \times 10^{-2} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ , which is two orders of magnitude lower than that of PEDOT:PSS. Second, the maximum density of accumulated carriers in a heterojunction is related to the status of the energy level alignment on both sides. Under light illumination, a  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{P3HT}$  heterojunction has band bending on both sides, whereas a  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$  heterojunction has band bending only on the perovskite side because the PEDOT:PSS is highly doped and the Fermi level inside it is pinned by the dopant (see the Supplementary Information and Supplementary Fig. S16). Consequently, a much higher density of electrons can accumulate in the  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$  heterojunction. Meanwhile, the strong photogating effect can be attributed to the high relative dielectric

constant ( $\sim 60$ ) of the perovskite material<sup>41</sup>, which is much higher than that of organic-semiconductors ( $\sim 3$ ) or Si ( $11.9$ )<sup>6</sup>. It has been proven that the density of accumulated carriers is proportional to the dielectric constant under identical band bending conditions<sup>51</sup>. Therefore, the strong photogating effect observed in the  $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x/\text{PEDOT:PSS}$  vertical heterojunction is also due to the high dielectric constant of the perovskite material and the high hole mobility in the PEDOT:PSS layer.

Flexible photodetectors have recently received considerable attention because of their potential applications in several emerging areas, such as wearable electronics and artificial eyes<sup>52</sup>. As shown in Figure 4, perovskite photodetectors were fabricated on flexible polyimide (PI) substrates with a thickness of 50 μm. Figure 4b shows the  $I_{\text{ph}}-V$  relationships for a representative flexible photodetector under infrared light illumination (wavelength:  $\sim 895$  nm) at various light intensities. The device was also characterized after being bent to a radius of 7 mm 300 times. Figure 4c shows the relationships between the responsivity and bias voltage of the device under different light intensities. The maximum responsivity was found to be  $\sim 8.3 \times 10^8 \text{ A W}^{-1}$ , and the performance showed little change before and after the bending test. Figure 4d shows the time-dependent photoresponse of the device under alternating light illumination conditions before and after 300 bending repetitions. Interestingly, the response time of the flexible device was faster than that of a device prepared on a  $\text{SiO}_2/\text{Si}$  substrate under the same processing conditions, and the photocurrent could

reach a stable value within tens of seconds. We characterized the crystalline quality of two perovskite films prepared on PI and SiO<sub>2</sub>/Si substrates and found that the two films showed similar diffraction patterns and peak widths (Supplementary Information and Supplementary Fig. S17). Therefore, the faster response speed cannot be attributed to a different quality of the perovskite in the flexible device. To better understand this effect, we characterized the thickness of the perovskite layer on the flexible substrate using a stylus profiler (Bruker: DektakXT, Billerica, MA, USA). We found that the thickness of the perovskite layer was only ~240 nm, thinner than the perovskite layer (~300 nm) prepared on the SiO<sub>2</sub>/Si substrate. This difference in thickness is presumably due to the different surface morphologies and energies of the substrates. As indicated by the results shown in Supplementary Fig. S12, a thinner perovskite layer can lead to a faster photoresponse. Therefore, the faster response of the flexible device compared with the device prepared on the SiO<sub>2</sub>/Si substrate can be attributed to the thinner perovskite layer of the former.

## CONCLUSIONS

In summary, we have demonstrated ultrasensitive broadband phototransistors with vertical heterojunctions based on CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3-x</sub>Cl<sub>x</sub>/PEDOT:PSS for the first time. Because of the high light absorption coefficient, long carrier lifetime and high dielectric constant of the perovskite, a high density of photo-generated electrons can accumulate in the perovskite layer and induce a pronounced photogating effect on the channel through the following processes. Strong light absorption in the perovskite leads to the creation of excitons or electron-hole pairs. Holes tend to diffuse into the PEDOT:PSS layer because it is energetically favorable for them to do so, leaving electrons trapped in the perovskite layer. The holes will transfer and recirculate many times in the PEDOT:PSS channel throughout their long lifetimes, giving rise to an ultrahigh gain. The devices exhibit an unprecedented responsivity of as high as  $\sim 2 \times 10^9$  A W<sup>-1</sup>, a gain of  $4.0 \times 10^9$  and a high specific detectivity of up to  $\sim 1.7 \times 10^{14}$  Jones under visible light at an operating voltage of only 0.5 V. This responsivity is several orders of magnitude higher than those achieved in previously reported perovskite photodetectors. Although the perovskite material shows weak light absorption above the absorption edge of ~800 nm, the devices still can exhibit high responsivities of close to  $10^9$  A W<sup>-1</sup> under NIR light at wavelengths of up to 1.1 μm because of their extremely high gain. Moreover, high-performance devices that exhibit excellent bending stability can be assembled on flexible plastic substrates. This work opens up the possibility of the application of organolead halide perovskites in highly sensitive, low-cost and flexible photodetectors for broadband detection.

## CONFLICT OF INTEREST

The authors declare no conflict of interest.

## AUTHOR CONTRIBUTIONS

FY, LL and CX conceived of the experiments. CX fabricated and characterized the devices. PY and ZL assisted with experiments on device fabrication. The manuscript was written by CX and FY and was discussed, edited and approved by all authors.
