The WNT pathway has become an attractive target for skeletal therapies. High-bone-mass phenotypes in patients with loss-of-function mutations in the LRP5/6 inhibitor Sost (sclerosteosis), or in its downstream enhancer region (van Buchem disease), highlight the utility of targeting Sost/sclerostin to improve bone properties. Sclerostin-neutralizing antibody is highly osteoanabolic in animal models and in human clinical trials, but antibody-based inhibition of another potent LRP5/6 antagonist, Dkk1, is largely inefficacious for building bone in the unperturbed adult skeleton. Here, we show that conditional deletion of Dkk1 from bone also has negligible effects on bone mass. Dkk1 inhibition increases Sost expression, suggesting a potential compensatory mechanism that might explain why Dkk1 suppression lacks anabolic action. To test this concept, we deleted Sost from osteocytes in, or administered sclerostin neutralizing antibody to, mice with a Dkk1-deficient skeleton. A robust anabolic response to Dkk1 deletion was manifest only when Sost/sclerostin was impaired. Whole-body DXA scans, μ CT measurements of the femur and spine, histomorphometric measures of femoral bone formation rates, and biomechanical properties of whole bones confirmed the anabolic potential of Dkk1 inhibition in the absence of sclerostin. Further, combined administration of sclerostin and Dkk1 antibody in WT mice produced a synergistic effect on bone gain that greatly exceeded individual or additive effects of the therapies, confirming the therapeutic potential of inhibiting multiple WNT antagonists for skeletal health. In conclusion, the osteoanabolic effects of Dkk1 inhibition can be realized if sclerostin upregulation is prevented. Anabolic therapies for patients with low bone mass might benefit from a strategy that accounts for the compensatory milieu of WNT inhibitors in bone tissue.

Introduction

The WNT signaling pathway has important functions in skeletal metabolism. Low-bone-mass phenotypes (e.g., osteoporosis-pseudoglioma syndrome [OPPG], OMIM 259770) observed in patients with loss-of-function mutations in a coreceptor for WNT, LDL receptor-related protein 5 (LRP5) (1–3), and high-bone-mass (HBM) phenotypes (e.g., endosteal hyperosteosis, OMIM 144750) observed in patients with gain-of-function mutations in LRP5 (4–7) both highlight the prominent role that WNT/LRP5 signaling plays in the skeleton. A particularly attractive attribute of the WNT pathway is its effects on anabolic action in bone; consequently, harnessing this pathway to improve skeletal properties in patients with low bone mass represents a major area of investigation for the pharmaceuticals development field.

The anabolic nature of WNT action in bone has been further highlighted by studies focused on the bone overgrowth phenotype among patients with loss-of-function mutations in the SOST gene (sclerosteosis, OMIM 269500), whose protein product, sclerostin, is a potent negative regulator of LRP5 signaling. Sclerostin inhibits LRP5 by directly binding the first β -propeller of LRP5, which disrupts interaction with the WNT1 class of ligands (8). Genetic disruption (9, 10) or transgenic overexpression (11, 12) of Sost in mice results in increased

or decreased bone mass, respectively, which is largely driven by changes in bone formation rate. Further, sclerostin-neutralizing antibodies have dramatic and consistent bone-building effects in mice (13–15), rats (16–18), monkeys (19, 20), and humans (21, 22), leading to significant improvement in bone mass, strength, and fracture susceptibility. These experiments and clinical trials attest to the therapeutic value of targeting sclerostin for improving skeletal properties.

Targeting other secreted inhibitors of WNT signaling that normally disrupt the WNT-LRP5 interaction has appeared less promising for general treatment of low bone mass. For example, the secreted LRP5/6 antagonist Dkk1 is a potent inhibitor of WNT signaling in cultured bone cells (23–25), binding directly to the first and third β -propellers of LRP5/6 and disrupting interaction with WNT1- and WNT3-class ligands (26). Homozygous inactivation of Dkk1 in mice is perinatal lethal, but Dkk1 haploinsufficiency (*Dkk1*^{+/-}) (27) and/or hypomorphic mutation (e.g., doubleridge) (28) results in increased bone mass (29). However, pharmacologic blockade of Dkk1 in rats and mice via neutralizing antibody is only mildly efficacious in young animals and is largely ineffective at improving bone mass in adult animals (30). In light of the strong anabolic effects of sclerostin neutralization, this is a puzzling finding given that Dkk1 is such a potent inhibitor of the WNT-LRP5/6 interaction; at equimolar concentration Dkk1 outcompetes sclerostin for binding to LRP5 and can even displace pre-bound sclerostin from LRP5 receptors (31). Why, then, is Dkk1 neutralization not more anabolic for bone?

We sought to investigate whether we could unlock fuller anabolic potential of Dkk1 neutralization by trying first to better understand the auxiliary molecular events caused by Dkk1 inhibition that might negate its otherwise osteoanabolic effects. Data from human patients with sclerosteosis (32) and from mice treated with sclerostin antibody (33, 34) indicate that sclerostin deficiency results in an increase in Dkk1 protein levels. We investigated whether the opposite compensatory mechanism exists (i.e., Dkk1 deficiency modulates sclerostin levels) and whether this could account for the lack of efficacy of Dkk1 inhibition. Using global and bone-selective *Sost*- and Dkk1-deficient mouse models, in conjunction with neutralizing antibodies to both proteins, the functional studies performed strongly suggest that Dkk1 neutralization is potentially anabolic to bone tissue if the compensatory upregulation of sclerostin is neutralized.

Results

Mice with bone-selective deletion of Dkk1 or WT mice treated with Dkk1-neutralizing antibody exhibit a mild bone phenotype. The skeletal consequences of *Sost* genetic disturbances have been widely studied in mice (9, 10, 13) and humans (35–37), but less is known about the effects of Dkk1 loss — another potent inhibitor of LRP5/6. To understand the magnitude of the potential HBM phenotype generated by Dkk1 deletion in bone, while avoiding the lethal phenotype observed in global Dkk1-knockout mice (27), we bred mice harboring Dkk1 floxed loss-of-function alleles to the ^{10kb}Dmp1-Cre driver strain and quantified the phenotype radiographically. Presence of the ^{10kb}Dmp1-Cre allele reduced Dkk1 expression by more than 80% in cortical bone lysates from *Dkk1*^{f/f} mice (Supplemental Figure 1; supplemental material available online with this article; <https://doi.org/10.1172/jci.insight.98673DS1>). Serial dual-energy x-ray absorptiometry (DXA) revealed a slight but significant increase in whole-body bone mineral content (BMC) among Cre-positive females (12% increase, $P < 0.05$) but not males compared with their respective Cre-negative *Dkk1*^{f/f} littermates (Figure 1, A and B). Cancellous bone volume fraction at 16 weeks of age was 6% greater ($P < 0.05$) among Cre-positive compared with Cre-negative females, but Cre-positive males did not exhibit a significant difference from Cre-negative male controls (Figure 1, C and D). Given previous findings of altered matrix composition in LRP5 and *Sost* mutant mice (38, 39), we also examined bone chemical properties in the conditional Dkk1 mutant mice using Fourier transform infrared imaging (FTIRI). No changes in matrix properties were found when Dkk1 was deleted from bone (Supplemental Figure 2)

To assess whether the surprising absence of a robust HBM phenotype in mice with late-stage bone cell deletion (i.e., in Dmp1-expressing cells) of Dkk1 was perhaps the result of our failure to target the appropriate cell type (e.g., cells earlier in the lineage), we next inhibited Dkk1 more broadly by administering a Dkk1-neutralizing antibody to 10-week-old WT mice. Six weeks of treatment with Dkk1 antibody (25 mg/kg s.c., twice a week) did not significantly change DXA-derived whole-body BMC when compared with vehicle treatment, in either males or females, but a small but significant increase (11%, $P < 0.05$) in BMC as measured by peripheral quantitative CT (pQCT) at the proximal tibia was detected among antibody-treated females (Figure 1, E and F). In summary, neither bone-selective deletion of the Dkk1 gene nor systemic inhibition of extracellular Dkk1 protein increased bone mass consistently or to the extent seen in other

Figure 1. Conditional deletion of *Dkk1* from bone cells or antibody-induced systemic neutralization of *Dkk1* in WT mice has minor effects on the skeleton. (A and B) Longitudinal dual-energy x-ray absorptiometry-derived (DXA-derived) measures of whole-body bone mineral content (BMC) in (A) female and (B) male mice carrying homozygous floxed loss-of-function alleles for *Dkk1*, with (+Cre) or without (-Cre) the ^{10kb}*Dmp1-Cre* transgene. (C and D) μ CT-derived measurements of bone volume fraction in the distal femur secondary spongiosa (C) and representative 3D tomographic reconstructions of the distal and midshaft femur (images shown represent female mice) (D) from *Dkk1^{f/f}* mice with or without the ^{10kb}*Dmp1-Cre* transgene. (E and F) Percent change (from before to after treatment) in DXA-derived whole-body BMC (E) and peripheral quantitative CT-derived total mineral content at the proximal tibia (F) in male and female WT mice treated for 6 weeks with *Dkk1* neutralizing antibody (α *Dkk1*-mAb) or vehicle control. **P* < 0.05 compared with sex-matched control mice. For all experiments, *n* = 11–15 mice/group. Data in A and B were analyzed using repeated-measures ANOVA followed by Fisher's protected LSD post hoc tests. Data in C, E, and F were analyzed using 1-way ANOVA followed by Fisher's protected LSD post hoc tests.

WNT pathway mutants (e.g., LRP5 HBM models, *Sost* models, LRP4 models) (9, 40, 41) and/or pharmacologic inhibition models (e.g., sclerostin neutralization) (13, 16).

Dkk1 levels and/or bioavailability regulate *Sost* — a potential override mechanism of *Dkk1*-mediated control of bone metabolism. Previous reports in mice (33, 42) and humans (32) indicate that *Dkk1* expression is modulated by perturbations in *Sost*/sclerostin expression. We sought to address the reciprocal situation, to understand whether *Sost* expression is modulated by *Dkk1* perturbation. In particular, we asked whether *Sost* expression increases in response to *Dkk1* deletion or inhibition; and whether this potential mechanism might explain the failure of *Dkk1* inhibition/deletion to have robust bone building effects on the skeleton. Mice heterozygous for a LacZ reporter allele knocked into the *Sost* coding sequence (*Sost^{+ / LacZ}* mice) were injected with a single 25-mg/kg dose of *Dkk1* antibody. Two days later, the mice were sacrificed and the femurs dissected, cryosectioned, and stained for LacZ expression. *Dkk1* protein neutralization resulted in a qualitative increase in *Sost* reporter activity in the bone tissue (Figure 2, A and B). Additional, quantitative gene expression experiments were performed using cortical bone lysates from WT mice treated with *Dkk1* antibody; from mice with bone-selective deletion of *Dkk1*; and from transgenic ^{2.3kb}*Col1a1-Dkk1* mice, which overexpress *Dkk1* in bone tissue (Supplemental Figure 1). Bone-selective deletion of *Dkk1* and antibody-mediated neutralization of *Dkk1* protein produced a significant increase in *Sost* expression (Figure 2C). In summary, *Dkk1* protein neutralization or genetic deletion from bone resulted in a compensatory increase in *Sost* expression, which might explain the inefficacy of *Dkk1* inhibition in improving bone properties.

Bone-selective deletion of Dkk1 consistently and robustly improves bone mass when Sost is co-deleted from the same cell population. In light of the compensatory upregulation of *Sost* that occurs when *Dkk1* is inhibited or mutated, we next tested whether *Sost* induction was responsible for the meager skeletal effects of bone-selective *Dkk1* deletion. Our goal was to determine whether *Dkk1* deletion from bone could have a more consistent and robust effect on bone mass if the compensatory increase in *Sost* expression were prevented. To this end, we generated compound mutant mice with floxed loss-of-function alleles for *Dkk1*, with or without co-deletion of *Sost* in the same cells (i.e., *Sost^{f/f}* mice). The *Sost* conditional mice have a floxed conditional by inversion (COIN) module targeted to the single intron of *Sost*, which undergoes inversion upon

Figure 2. Genetically disabling or pharmacologically inhibiting Dkk1 increases Sost expression. (A and B) Representative photomicrographs of β -galactosidase-reacted frozen sections cut from the thigh of female mice heterozygous for a *Sost*-knockin reporter allele (*Sost*^{+/LoxZ}). Mice were given a single injection of vehicle (Veh; A) or Dkk1-neutralizing antibody (α Dkk1-mAb; B) 2 days prior to sacrifice. Blue staining in the cortical bone (CB) indicates endogenous *Sost* promoter activity. Mu, muscle; Ma, marrow. (C) Quantitative PCR of *Sost* transcripts in femoral and tibial cortical bone from female mice with conditional (^{10kb}Dmp1-Cre-mediated) homozygous inactivation of Dkk1 (left), from WT mice treated with α Dkk1-mAb (center), and from ^{2.3kb}Col1a1-Dkk1 mice overexpressing Dkk1 in bone tissue (Dkk1-TG; right). * $P < 0.05$ compared with corresponding controls. $n = 4$ –7 mice/group. Data in C were analyzed using 1-way ANOVA followed by Fisher's protected LSD post hoc tests.

Cre-mediated recombination (43). Again, we used the ^{10kb}Dmp1-Cre driver strain to induce recombination, and we included Cre-negative controls for all *Sost*/*Dkk1* genotypes studied. Mice were scanned periodically using DXA from 4 to 16 weeks of age. Body weight was similar among sex-matched mice regardless of the presence of Cre or *Sost*/*Dkk1* alleles (Supplemental Figure 3), and no significant differences in DXA properties were detected among Cre-negative control *Sost*/*Dkk1* genotypes (Figure 3, A, C, and E; and Supplemental Figure 4). Among Cre-positive female mice, BMC was not significantly different between *Dkk1* mutants and WT controls, but *Sost* mutants exhibited a significant increase in BMC compared with both WT mice (13%–29% increase, $P < 0.05$) and *Dkk1* mutants (10%–26% increase, $P < 0.05$; Figure 3, B, D, and F). Surprisingly, whereas *Dkk1* deletion from bone had no effect on BMC in *Sost*-replete mice, *Dkk1* deletion in mice that underwent co-deletion of *Sost* in the same cells exhibited very large increases in whole-body BMC compared with both WT mice (24%–75% increase, $P < 0.05$) and *Sost* mutant mice (10%–36% increase, $P < 0.05$). Male mice showed similar genotype effects, with the exception of the *Dkk1* mutants, which exhibited significantly elevated hindlimb BMC (Supplemental Figure 4).

μ CT measurements collected from the spine and femur of these mice (16 weeks of age) revealed an even more striking HBM-generating effect of *Dkk1* deletion in the presence of *Sost* co-deletion (Figure 4). Bone volume fraction in the fifth lumbar vertebral (L_5) spongiosa was significantly increased in male and female *Dkk1* mutant mice (increases of 7% and 12%, respectively; $P < 0.05$ for both) compared with WT mice (Figure 4, A–C and Supplemental Figure 5). *Sost* mutant mice exhibited 35% and 27% increases over WT controls in L_5 trabecular bone volume fraction (BV/TV) among male and female mice, respectively ($P < 0.05$ for both). *Dkk1* deletion in mice that underwent co-deletion of *Sost* exhibited a very large increase in L_5 BV/TV, reaching 70%–80% ($P < 0.05$) beyond that in WT mice and ~45% ($P < 0.05$) beyond that in *Sost* mutant mice. Similar effects were found for other μ CT measurements from the distal femur cancellous envelope (Figure 4, D–F, and Supplemental Figure 5) and from the midshaft femur cortex (Figure 4, G–I, and Supplemental Figure 5). Three-point bending tests on femurs taken from these mice revealed that the improved cortical bone properties observed consistently in *Sost* but not *Dkk1* mutants, and to a much greater extent in *Dkk1*/*Sost* mutants, translated into improved mechanical properties (Figure 5, A–C, and Supplemental Figure 6). Histomorphometric measurements of fluorochrome-derived bone formation rates from the midshaft femur were consistent with μ CT and biomechanics results, and revealed potent anabolic action of *Dkk1* deletion when *Sost* was co-deleted (Figure 5, D and E). To assess changes in the WNT/ β -catenin pathway under the different genetic conditions, demineralized histological sections from the mice were prepared and stained for active β -catenin (Supplemental Figure 7). Qualitatively, we found an increase in active β -catenin signaling in all 3 mutants compared with WT controls, though a particularly strong signal was

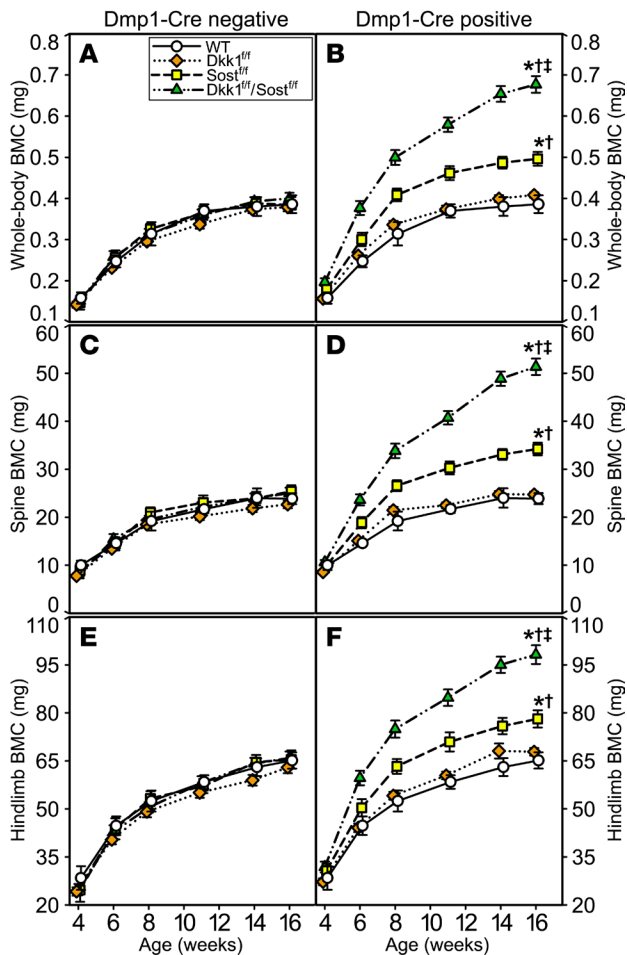

Figure 3. Conditional deletion of *Dkk1* from bone consistently increases bone mineral content when *Sost* is co-deleted in the same bone cell population. Serial in vivo DXA scans of WT (*Dkk1*^{+/+} *Sost*^{+/+}), *Dkk1*-floxed (*Dkk1*^{fl/fl} *Sost*^{+/+}), *Sost*-floxed (*Dkk1*^{+/+} *Sost*^{fl/fl}), and compound floxed (*Dkk1*^{fl/fl} *Sost*^{fl/fl}) mice, collected every 2–3 weeks and analyzed for (A and B) whole-body BMC, (C and D) lumbar spine BMC, and (E and F) BMC of the right hindlimb distal to the acetabulum. Data in A, C, and E show data from Cre-negative mice only; data in B, D, and F show data from Cre-positive mice only. Results in all panels are based on data from female mice; corresponding data from male mice are provided in the supplemental material. **P* < 0.05 compared with WT mice; †*P* < 0.05 compared with *Dkk1*^{fl/fl} mice; ‡*P* < 0.05 compared with *Sost*^{fl/fl} mice. For all curves, *n* = 6–14 mice/group. All panels were analyzed using repeated-measures ANOVA followed by Fisher's protected LSD post hoc tests.

observed in the single *Dkk1* mutant mice. In summary, *Dkk1* deletion from bone cells had little to no effect on skeletal properties, but the same *Dkk1* mutations had dramatic osteoanabolic effects when moved onto a bone-selective *Sost* mutant background. These results suggest that the inability of *Dkk1* deletion to consistently and robustly improve skeletal properties is at least partially explained by a compensatory increase in *Sost* expression.

Dkk1-neutralizing antibody consistently and robustly improves bone mass and strength when administered to *Sost*^{-/-} but not *Sost*^{+/+} mice. Having found that *Dkk1* conditional loss-of-function alleles improved bone properties only when moved onto a bone-selective *Sost* mutant background, we next applied this concept to *Dkk1* antibody efficacy, to determine whether we could create a condition where the otherwise inefficacious *Dkk1* antibody (e.g., Figure 1, D–F) is significantly anabolic. To address this possibility experimentally, global *Sost*-knockout (*Sost*^{-/-}) and WT (*Sost*^{+/+}) female mice were generated, raised to 8 weeks of age, and administered a *Dkk1* antibody treatment regimen (25 mg/kg s.c., twice a week for 8 weeks). *Dkk1* antibody therapy increased DXA-derived whole-body BMC by 12% (*P* < 0.05) among WT mice, but the same therapy in *Sost*^{-/-} mice produced a 63% (*P* < 0.05) increase in BMC (Figure 6A and Supplemental Figure 8). pQCT-derived changes in proximal tibia BMC were not significantly affected by *Dkk1* antibody in WT mice, but in *Sost*^{-/-} mice, *Dkk1* antibody increased BMC by 32% (*P* < 0.05; Figure 6B and Supplemental Figure 8). μ CT properties of the femur after 8 weeks of antibody treatment revealed a small but significant increase in cancellous bone volume fraction at the distal femur among WT mice treated with *Dkk1* antibody, compared with WT mice treated with vehicle (2% difference, *P* < 0.05). A much greater difference was observed among *Sost*^{-/-} mice treated with *Dkk1* antibody versus vehicle (47% increase, *P* < 0.05; Figure 6, C and D, and Supplemental Figure 8). No effect of *Dkk1* antibody was found among WT mice for midshaft femur and parietal μ CT properties, whole femur mechanical properties, or periosteal bone formation rates (Figure 6, E–I, and Supplemental Figure 8), but each of these end points exhibited significant antibody-induced increases when

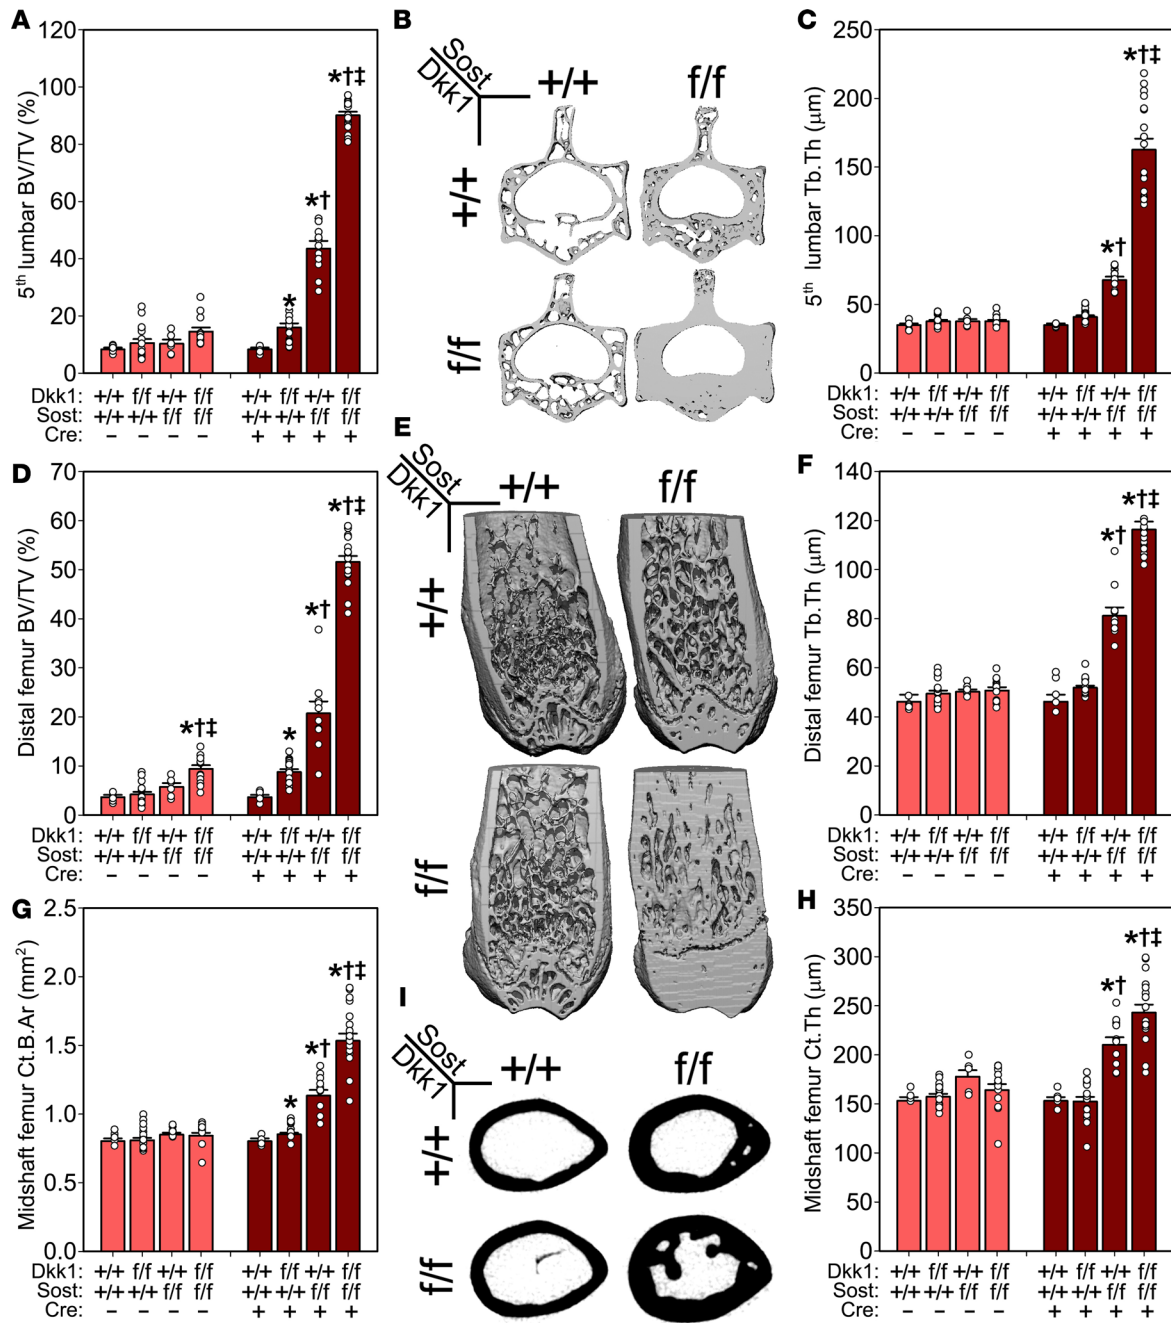

Figure 4. Conditional deletion of Dkk1 from bone improves cancellous and cortical bone architecture dramatically when Sost is co-deleted in the same bone cell population. μ CT-derived measurement of L₅ vertebral body cancellous bone, distal femur metaphyseal cancellous bone, and mid-femur cortical bone from WT (*Dkk1*^{+/+} *Sost*^{+/+}), Dkk1-flox (*Dkk1*^{f/f} *Sost*^{+/+}), Sost-flox (*Dkk1*^{+/+} *Sost*^{f/f}), and compound flox (*Dkk1*^{f/f} *Sost*^{f/f}) mice, with (maroon bars) and without (red bars) the ^{10kb}Dmp1-Cre transgene. Quantitative differences in L₅ trabecular bone volume fraction (BV/TV; **A**) and thickness (Tb.Th; **C**) can be appreciated from representative 3D tomographic reconstructions (**C**) of the central 30% of the vertebra from Cre-positive mice. Quantitative differences in distal femur trabecular (**D**) bone volume fraction and (**F**) thickness can be appreciated from (**E**) representative 3D reconstructions of the caudal half of the distal femur (the ventral half was digitally removed) in Cre-positive mice. Quantitative differences in midshaft femur cortical bone area (Ct.B.Ar; **G**) and thickness (Ct.Th; **H**) can be appreciated from (**I**) representative 2D slices taken from the femur mid-diaphysis of Cre-positive mice. Results in all panels are based on data/images from female mice; corresponding data/images from male mice are provided in the supplemental material. **P* < 0.05 compared with Cre-matched WT mice; †*P* < 0.05 compared with Cre-matched *Dkk1*^{f/f} mice; ‡*P* < 0.05 compared with Cre-matched *Sost*^{f/f} mice. For all panels, *n* = 6–14 mice/group. All data panels were analyzed using 1-way ANOVA followed by Fisher's protected LSD post hoc tests.

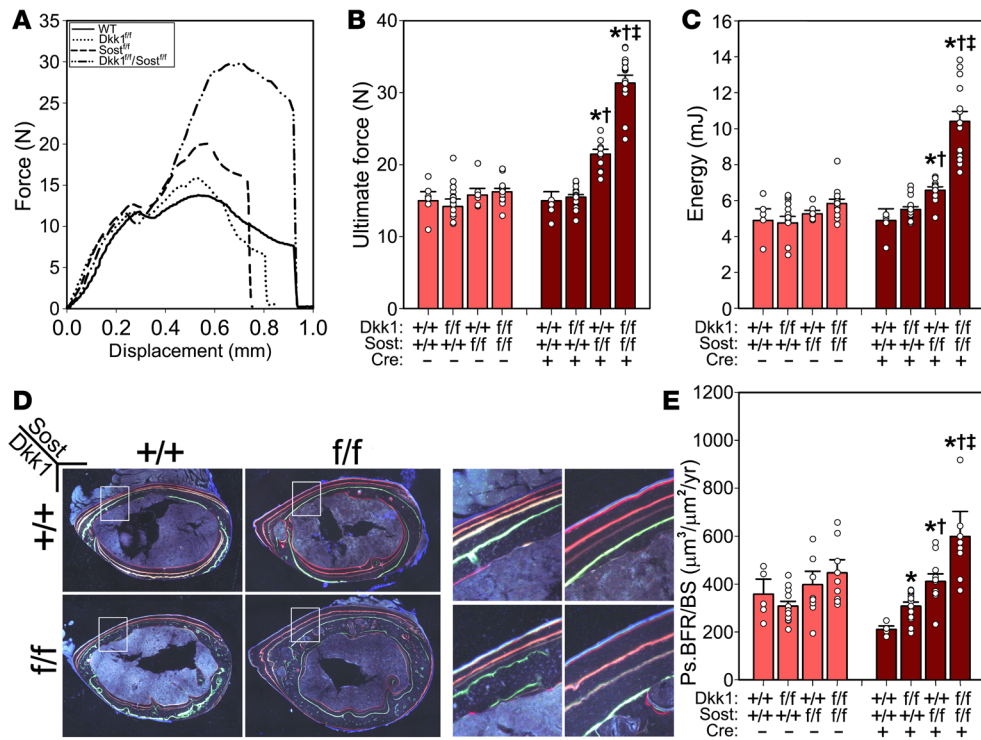

Figure 5. Conditional deletion of Dkk1 from bone improves mechanical properties and increases anabolic action significantly when Sost is co-deleted in the same bone cell population. (A–C) Three-point monotonic bending tests to failure conducted on whole femurs from WT ($Dkk1^{+/+} Sost^{+/+}$), Dkk1-flox ($Dkk1^{f/f} Sost^{+/+}$), Sost-flox ($Dkk1^{+/+} Sost^{f/f}$), and compound flox ($Dkk1^{f/f} Sost^{f/f}$) mice, with (maroon bars) and without (red bars) the $^{10kb}Dmp1$ -Cre transgene. (A) Representative force-displacement curves from tests conducted on Cre-positive mice reveal differences in mechanical properties among genotypes; quantification of (B) ultimate force (peak height of the curve) and (C) energy absorbed (area under the curve). (D) Midshaft femur histologic sections from fluorochrome-labeled Cre-positive mice, calculated from 4 to 14 weeks, reveal differences in bone formation rates, which can be appreciated by noting the distance between each of the 4 unique labels injected intermittently during the experimental period (calcein [green] at 4 weeks; oxytetracycline [yellow] at 6 weeks; demeclocycline [orange] at 8 weeks; alizarin [red] at 14 weeks). Panels on the right are magnifications of the indicated regions in the left panels. Width of white inset boxes, 350 μ m. (E) Quantification of anabolic action on the periosteal surface (Ps), calculated as the bone formation rate per unit bone surface (BFR/BS). Results in all panels are based on data/images from female mice; corresponding data/images from male mice are provided in the supplemental material. For A–C, $n = 6$ –14 mice/group. For E, $n = 6$ –9 mice/group. * $P < 0.05$ compared with Cre-matched WT mice; $^{\dagger}P < 0.05$ compared with Cre-matched $Dkk1^{f/f}$ mice; $^{\ddagger}P < 0.05$ compared with Cre-matched $Sost^{f/f}$ mice. Data in B, C, and E were analyzed using 1-way ANOVA within each Cre grouping, followed by Fisher’s protected LSD post hoc tests.

tested in $Sost^{-/-}$ mice. In summary, Dkk1 antibody is highly effective at increasing bone mass and anabolic action in the skeleton when sclerostin upregulation is prevented; failure to suppress sclerostin upregulation renders Dkk1 antibody therapy ineffective.

Co-administration of antibodies against sclerostin and Dkk1 to WT mice generates a synergistic effect on bone properties that far exceeds additive effects. Our results to this point indicated that Dkk1 antibody is highly osteoanabolic if Sost upregulation is prevented at the genomic level. To take those findings into a more translational setting, we investigated the potential of pharmacologically inhibiting sclerostin action using neutralizing antibody to sclerostin (Sclr-mAb) during Dkk1 antibody administration. For these experiments, we used 8-week-old female WT C57BL/6 (B6) mice and treated them with sclerostin antibody, Dkk1 antibody, or both (simultaneously), each at 25 mg/kg s.c., twice a week for 8 weeks. Consistent with our previous experiments, Dkk1-mAb treatment alone resulted in little to no improvement in bone properties (Figure 7, A–G, and Supplemental Figure 9), but Dkk1-mAb administration in the presence of Sclr-mAb (combination treatment) improved whole-body BMC by 43% compared with Sclr-mAb alone (Figure 7A); improved distal femur bone volume fraction and trabecular thickness by 26% and 74%, respectively (Figure 7, B–D); and improved femoral cortical thickness and ultimate force by 7% and 11%, respectively (Figure 7, E and F). The improvements in bone properties generated by combination therapy were driven by both increased anabolic action (Figure 7G) and a reduction in resorption (Supplemental Figure 9). No obvious side effects of single or dual antibody treatments were observed (e.g., body weight or behavioral changes). In summary, Dkk1 antibody is potentially anabolic

Figure 6. Dkk1 neutralizing antibody has negligible skeletal effects in WT mice but has potent anabolic effects in *Sost*^{-/-} mice. Percent change in (A) whole-body bone mineral content (BMC) and (B) proximal tibia BMC, calculated from just prior to the start of treatment (at 8 weeks of age) to sacrifice at 16 weeks of age, capturing 8 weeks of Dkk1 mAb (α Dkk1-mAb) or vehicle injection in WT (red bars) and *Sost*^{-/-} (purple bars) mice. (C–E) Femoral μ CT properties in the distal metaphyseal spongiosa (bone volume fraction [BV/TV]) and midshaft cortex (cortical thickness [Ct.Th]) measured in 16-week-old mice, after 8 weeks of vehicle or Dkk1 antibody treatment. Note the increase in bone mass induced by Dkk1 inhibition in *Sost*^{-/-} but not WT mice. (G–I) Quantification of (G) ultimate force from 3-point bending tests of the femoral diaphysis and (I) bone formation rates from the same region, revealing increased bone strength and formation rates induced by Dkk1 inhibition in *Sost*^{-/-} but not WT mice. Representative fluorochrome-labeled sections (H) illustrate the increase in bone formation over the experimental period (from yellow to red label). All panels are based on data/images from female mice. **P* < 0.05 compared with genotype-matched vehicle-treated mice. For all experiments, *n* = 9–12 mice/group. Data in A, B, C, E, G, and I were analyzed using unpaired *t* tests within each *Sost* background.

when sclerostin protein function is disabled by neutralizing antibody, supporting our previous observations that the skeletal efficacy of Dkk1 inhibition can be unlocked if the compensatory effects of sclerostin upregulation are countered.

Discussion

Our main objective in the current communication was to understand why neutralization of Dkk1 — a potent LRP5/6 antagonist — fails to generate a robust osteoanabolic response. We found that Dkk1 inhibition via

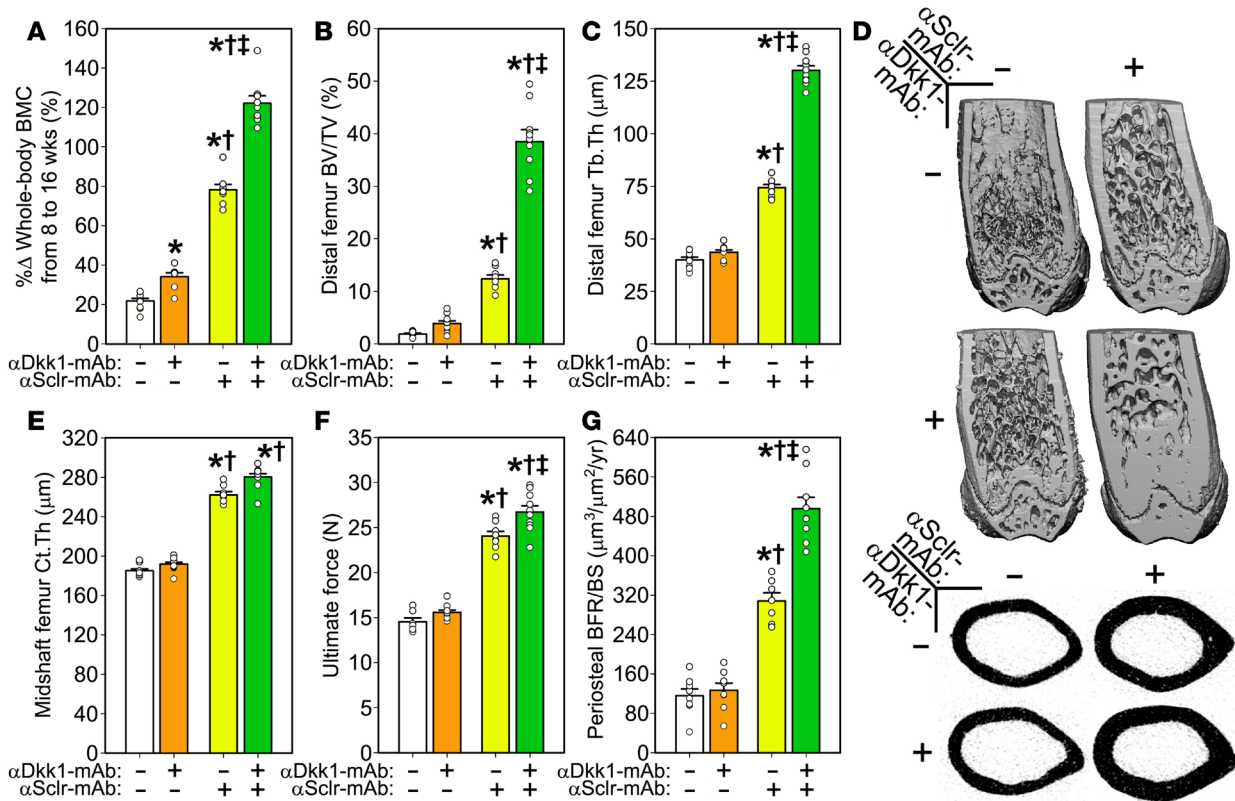

Figure 7. Dkk1-neutralizing antibody has potent osteoanabolic effects in WT mice when sclerostin is pharmacologically inhibited. (A) Percent change in whole-body bone mineral content (BMC) calculated from just prior to the start of treatment (at 8 weeks of age) to sacrifice at 16 weeks of age, capturing 8 weeks of Dkk1 mAb (αDkk1-mAb; orange bars), sclerostin mAb (αSclr-mAb; yellow bars), co-injection with both antibodies (green bars), or vehicle (white bars) in female WT mice. Femoral μCT properties (B–E), biomechanical properties (F) and bone formation rates (G) were quantified for all treatment groups as described above. **P* < 0.05 compared with vehicle-treated mice; †*P* < 0.05 compared with αDkk1-mAb-treated mice; ††*P* < 0.05 compared with αSclr-mAb-treated mice. For all panels, *n* = 10–12 mice/group. Data in all panels were analyzed using 1-way ANOVA, followed by Fisher’s protected LSD post hoc tests. BV/TV, trabecular bone volume fraction; Ct.Th, cortical thickness; Tb.Th, and thickness; BFR/BS, bone formation rate per unit bone surface.

either selective genetic deletion in osteocytes, or antibody-based neutralization, resulted in increased *Sost* expression, as revealed by *in vivo* *Sost* reporter activity and quantitative PCR. To determine whether the increase in *Sost* was responsible for impaired anabolic action of Dkk1 neutralization, we deleted *Sost* in osteocytes, deleted *Sost* globally, or neutralized sclerostin with antibody; in all 3 contexts, Dkk1 genetic deletion from bone or pharmacologic Dkk1 inhibition was significantly and potently anabolic. In other words, the skeletal effects of Dkk1 inhibition are strong but are only manifest when *Sost*/sclerostin is disabled. Those observations suggest that the increase in *Sost*/sclerostin that occurs under Dkk1-disabling conditions acts to restrain the otherwise potently anabolic action of Dkk1 inhibition. These data, in conjunction with those from other groups showing the reciprocal phenomenon (i.e., that Dkk1 expression is increased under *Sost*/sclerostin-disabling conditions [refs. 32–34]), indicate that sclerostin and Dkk1 might exhibit mutual compensatory regulation, where one molecule can become more highly expressed when the other is selectively suppressed. Given that outcome, a larger question emerges: why does sclerostin neutralization result in such abundant increases in bone mass, despite the concurrent upregulation of Dkk1, yet Dkk1 neutralization is largely ineffective because of the concurrent upregulation of *Sost*?

One potential explanation for differences in sclerostin- versus Dkk1-mediated inhibition of osteoanabolism might be related to selectivity of local facilitator proteins. Recent work on the role of LRP4 in bone indicates that the receptor serves as a facilitator of sclerostin but not Dkk1 action on WNT1/β-catenin signaling (44). Although both sclerostin and Dkk1 interact with LRP4 (44, 45), neither overexpression nor knockdown of LRP4 impacts Dkk1’s ability to impair WNT signaling in bone cells. Further, mice that express HBM-causing mutations in LRP5 (e.g., A214V or G171V) exhibit protection from bone-driven sclerostin overexpression but not Dkk1 overexpression (46, 47). Thus, while the biology of sclerostin- and

Dkk1-mediated effects on bone mass are not well understood, it is clear that these two molecules engage different mechanisms to affect WNT signaling and bone mass.

Previous genetic models of Dkk1 loss of function have relied on global heterozygous inactivation of the gene (+/−) or on naturally occurring global hypomorphic alleles (e.g., doubleridge) to assess skeletal consequences of Dkk1 genetic impairment (29). Our experiments are the first to our knowledge to selectively target Dkk1 in bone tissue, using mice with homozygous Dkk1 floxed alleles that were recombined using the ^{10kb}Dmp1-Cre transgene. Those mice have a very mild skeletal phenotype, as most skeletal end points collected indicate either no difference from Cre-negative mice or, if differences were detected, the effect size was small. One potential explanation for the meager effect on phenotype could be the choice of Cre driver. Dkk1 expression has been detected in tissues other than bone (e.g., skin, bladder, prostate), so our approach which selectively inactivated Dkk1 in Dmp1-expressing cells could have “missed” a more relevant cell type capable of producing a stronger phenotype (e.g., early osteoblasts). However, three observations are noteworthy regarding our choice to use Dmp1-Cre for these experiments: (i) a body-wide screen of Dkk1 expression in young adult mice found that Dkk1 expression was restricted largely to bone (i.e., osteocytes), where very strong expression was detected (48); (ii) both fluorescence-activated cell sorting (49) and laser capture microdissection (50) approaches revealed that Dkk1 is highly upregulated in the osteocyte compared with the osteoblast; and (iii) our data indicate that Dkk1 deletion from Dmp1-expressing cells is highly anabolic if Sost is inhibited, suggesting that inhibiting Dkk1 in this cell type can generate major effects if the right conditions (e.g., Sost inhibition) are achieved. If the osteoanabolic Dkk1 inhibition alone were demonstrable, the mouse would likely be the most robust model to detect the effect given that mice have 10–20 times more circulating Dkk1, and 2–5 times less circulating sclerostin, than rats, cynomolgus monkeys, or humans (Monica Florio, Amgen Inc., personal communication).

It has also been noted that Dkk1 expression is more abundant in bone from young mice, and decreases dramatically in adolescent and adult mice, which might explain why Dkk1 antibody is more efficacious in young versus old mice (i.e., there is more target available to inhibit). However, mice in our Dmp1-Cre × *Dkk1^{fl/fl}* experiments had Dkk1 deleted from bone since conception, and therefore effects should be manifest in young mice, when Dkk1 is more highly expressed and potentially more active. Moreover, inspection of DXA data at 4 weeks of age and beyond into adulthood (effects during growth should be cumulative) revealed no changes in BMC. Another potential explanation for differences in sclerostin- versus Dkk1-mediated inhibition might be related to selectivity of facilitator proteins. Recent work on the role of LRP4 in bone indicates that the receptor serves as a facilitator of sclerostin but not Dkk1 action on LRP5/6.

Despite its modest effect on bone gain in unperturbed, intact mice, Dkk1 antibody has proven efficacious in certain pathological contexts, such as fracture healing (30, 51), multiple myeloma (52, 53), and inflammatory arthritis (54, 55). Our data suggest that Dkk1 inhibition is highly anabolic in a healthy, intact adult mouse, if the compensatory mechanisms are disabled. The Amgen group approached the Dkk1-sclerostin compensatory regulation phenomenon from a different angle, by looking to make anti-sclerostin antibody more efficacious (33). They reported that Dkk1 levels were increased in sclerostin antibody-treated mice, which they surmised might be restraining a fuller anabolic potential of sclerostin inhibition. That observation prompted them to develop a bispecific antibody that targets both sclerostin and Dkk1, which shows synergistic osteoanabolic action similar to what they (33) and we report for the combined use of individual antibodies to sclerostin and Dkk1. Importantly, the two studies are consistent in finding a synergistic effect of compound sclerostin/Dkk1 inhibition that far exceeds any potential additive effects. The molecular mechanisms that control transcriptional compensation/upregulation between Sost and Dkk1 are unknown. Sost transcription is regulated by a number of pathways and factors, including *Osx* (56), *Bmps* (57), *Tgf-β* (58), histone deacetylases (HDACs) (59), cAMP/PKA (60), and hypoxia (61), among others (reviewed in ref. 62). Dkk1 transcription is regulated by some of these same mechanisms (63, 64), but the mechanisms that confer reciprocal maintenance of WNT inhibition remain to be elucidated.

In summary, the osteoanabolic effects of Dkk1 inhibition can be unleashed when sclerostin upregulation is prevented. The role of other secreted inhibitors in the compensatory expression mechanism are unknown. Canonical WNT signaling antagonists such as WISE (65), sFRP4 (66), and NOTUM (67), are associated with skeletal phenotypes in mice when mutated either globally or selectively in bone cells, and sclerostin inhibition enhances a number of these transcripts in mouse bone (68). Whether pharmacologic modulation of these or other members of the secreted WNT inhibitory milieu can improve or otherwise tailor the efficacy of sclerostin and/or Dkk1 neutralizing therapy is not known.

Methods

Mice. Development of the conditional Dkk1-flox mouse model has been reported elsewhere (69). Briefly, these mice harbor head-to-toe loxP sequences flanking exons 1 and 2 of the endogenous Dkk1 gene. Development of the conditional Sost-flox mouse model has been reported elsewhere (43). Briefly, these mice harbor a COIN module in the single Sost intron, flanked by mutant loxP sequences introduced in a head-to-head arrangement. Development of the Sost-LacZ knockin reporter/null mouse model has been reported elsewhere (43). Briefly, these mice harbor a LacZ-neo cassette in place of the endogenous Sost coding sequence. Development of the ^{10kb}Dmp1-Cre transgenic mouse model has been reported elsewhere (70). Briefly, these mice harbor a transgene expressing Cre recombinase, driven by a 9.6-kb fragment of the mouse dentin matrix protein 1 (Dmp1) promoter. Development of the ^{2.3kb}Col1a1-Dkk1 transgenic mouse model has been reported elsewhere (48). Briefly, these mice harbor a transgene expressing a mouse Dkk1 cDNA, driven by a 3.2-kb fragment of the rat collagen 1A1 promoter. All mouse colonies were on a mixed background of B6 and 129/SvJ, ranging from 93.8% to 100% B6, depending on the colony. For all experiments, littermate controls were used to stabilize the effect of genetic background within experiments.

Antibodies. Details of the development of Dkk1- and sclerostin-neutralizing antibodies have been reported elsewhere (16, 54). Briefly, the Dkk1 antibody is a neutralizing rat mAb raised against mouse Dkk1, and the sclerostin antibody, which neutralizes mouse sclerostin, is a version of a mouse mAb in which the amino acid sequence has been modified for use in rats. Antibodies were injected into mice s.c. at 25 mg/kg, twice per week. Vehicle treatment was the buffer in which the antibodies were made. Treatment duration is indicated in the figure legend for each experiment.

DXA. Collection of serial DXA measurements on live mice are described and validated elsewhere (13). Briefly, isoflurane-anesthetized mice were scanned periodically on a PIXImus II (GE Lunar). BMC was measured from the scans for the whole body, lumbar spine (L₃-L₅), and right lower limb.

μCT. Formalin-fixed femurs, L₅ vertebrae, and craniums were scanned, reconstructed, and analyzed as previously described (13, 71, 72) using either 13-μm resolution, 50-kV peak tube potential and 151-ms integration time (femur and vertebra) or 20-μm resolution, 50-kV peak tube potential and 125-ms integration time (cranium). Standard parameters (73) related to cancellous and cortical bone architecture were measured.

pQCT. Collection of serial tibial pQCT measurements in live mice is described elsewhere (74). Briefly, a single slice through the proximal tibia and one through the midshaft tibia were collected on isoflurane-anesthetized mice using a Stratec x-ray microscope (Stratec Inc.) at 70-μm resolution. Slices were analyzed for BMC using Stratec software in peel mode 2.

Histology. Mice were given various combinations of oxytetracycline HCl (80 mg/kg, s.c.), calcein (12 mg/kg, i.p.), alizarin complexone (20 mg/kg, i.p.), and demeclocycline (40 mg/kg, i.p.) to label mineralizing bone, at the time points indicated for each experiment (see figure legends). After sacrifice, femurs were processed, and cut, for plastic-embedded histomorphometry as previously described (72). Briefly, the periosteal bone formation parameters mineralizing surface (MS/BS; %), mineral apposition rate (MAR; μm/d), and bone formation rate (BFR/BS; μm³/μm²/yr), were calculated using standard protocols (75). Frozen sections of unfixed Sost-LacZ reporter mouse thighs were cut and reacted for β-galactosidase activity as previously described (65). Demineralized paraffin-embedded longitudinal thin sections cut through the proximal tibia were immunolabeled for active β-catenin and counterstained for DAPI as previously described (65).

Mechanical properties. Parameters related to whole bone strength were measured using 3-point bending tests as previously described (41). Briefly, each femur was loaded to failure in monotonic compression, during which force and displacement were collected every 0.01 seconds. From the force/displacement curves, ultimate force and energy to failure were calculated using standard equations (76).

Serum C-terminal telopeptide (CtX). Serum concentration of the resorption marker CtX was measured by a commercially available ELISA (RatLaps; IDS Inc.) as previously described (13, 72). Briefly, blood samples were collected from the retromandibular vein, permitted to clot at room temperature for 30 minutes, spun at 5,000 g to separate the serum, and frozen at -80°. Thawed serum samples were assayed for CtX in triplicate according to the manufacturer's instructions.

Gene expression via quantitative PCR. Snap-frozen femur and tibia diaphyses were pulverized in liquid N₂ and processed for total RNA isolation as previously described (77). Briefly, total RNA was reversed transcribed into cDNA using random hexamers; measured; then reacted for Sost, Dkk1, and the housekeeping

gene *Hprt1* using quantitative PCR-based Taqman Assay-on-Demand kits. The $\Delta\Delta\text{CT}$ method was used to calculate relative expression, which was normalized for each sample using *Hprt1*.

Bone matrix properties. Humerus midshaft samples were processed and measured for bone matrix composition as previously described (78). Briefly, fixed bone samples were embedded in resin, cut, mounted to plastic slides, polished, and measured using FTIRI at the National Synchrotron Light Source at the Brookhaven National Laboratory (U10B beamline). A total of 64 scans were collected and averaged for each spectra, which were subsequently processed using previously published spectral analysis methods (79).

Statistics. Statistical analyses were computed with JMP (version 4.0, SAS Institute Inc.). The radiographic, histomorphometric, and biomechanical endpoints were analyzed using 1- or 2-way ANOVA, with genotype and/or antibody treatment as main effects. Time series data were analyzed with repeated-measures ANOVA. When at least one main effect was significant, interactions terms were calculated and tested for significance. Differences among groups were tested for significance with Fisher's protected least significant difference (LSD) post hoc test. Statistical significance was taken at $P < 0.05$. Two-tailed distributions were used for all analyses. Data are presented as mean \pm SEM.

Study approval. All mouse procedures were performed in accordance with the IACUC guidelines and approvals.

Author contributions

PCW, WAB, and ALA conducted the genetic experiments involving compound flox mice. SER and AGR conducted the antibody studies in *Sost*^{-/-} and WT mice. DJH and KEL conducted the μCT analysis and histomorphometry work. KSK performed the LacZ studies and biomechanical testing. RDR conducted the FTIRI measurements at the Brookhaven National Laboratory. GGL contributed intellectual input. AGR designed the experiments and wrote the manuscript.

Acknowledgments

Financial support was provided by the NIH (AR053237 to AGR; DK075730 to GGL; AR070624 to WAB), the US Department of Veterans Affairs (BX001478 to AGR) the US Department of Energy (DE-AC52-07NA27344 to GGL). Sclerostin and *Dkk1* antibodies were provided by Amgen Inc. and UCB (Brussels, Belgium). Monica Florio provided comparative data on serum sclerostin and *Dkk1* levels in humans, monkeys, rats, and mice. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.
