ABSTRACT

Objective Oesophageal cancer is the seventh most common cause of cancer-related death worldwide. Disease relapse is frequent and treatment options are limited.

Design To identify new biomarker-defined therapeutic approaches for patients with oesophageal cancer, we integrated the genomic profiles of 17 oesophageal tumour-derived cell lines with drug sensitivity data from small molecule inhibitor profiling, identifying drug sensitivity effects associated with cancer driver gene alterations. We also interrogated recently described RNA interference screen data for these tumour cell lines to identify candidate genetic dependencies or vulnerabilities that could be exploited as therapeutic targets.

Results By integrating the genomic features of oesophageal tumour cell lines with siRNA and drug screening data, we identified a series of candidate targets in oesophageal cancer, including a sensitivity to inhibition of the kinase BTK in *MYC* amplified oesophageal tumour cell lines. We found that this genetic dependency could be elicited with the clinical BTK/ERBB2 kinase inhibitor, ibrutinib. In both *MYC* and *ERBB2* amplified tumour cells, ibrutinib downregulated ERK-mediated signal transduction, cMYC Ser-62 phosphorylation and levels of MYC protein, and elicited G₁ cell cycle arrest and apoptosis, suggesting that this drug could be used to treat biomarker-selected groups of patients with oesophageal cancer.

Conclusions BTK represents a novel candidate therapeutic target in oesophageal cancer that can be targeted with ibrutinib. On the basis of this work, a proof-of-concept phase II clinical trial evaluating the efficacy of ibrutinib in patients with *MYC* and/or *ERBB2* amplified advanced oesophageal cancer is currently underway (NCT02884453).

Trial registration number NCT02884453; Pre-results

INTRODUCTION

Oesophageal carcinoma is the seventh leading cause of cancer-related mortality and represents an area of unmet clinical need.¹ Over 450 000 people worldwide are affected with this disease, and the incidence of oesophageal adenocarcinoma (EAC) continues to rise rapidly, although oesophageal squamous cell carcinoma (ESCC) is the most common histology.² Integrated genomic characterisation of oesophageal carcinoma has revealed

Significance of this study

What is already known on this subject?

- Oesophageal cancer is the seventh leading cause of cancer-related mortality and represents an area of unmet clinical need.
- Additional targeted approaches to treating this disease are urgently required, particularly in patients who progress after first-line therapy.
- Genomic profiling of oesophageal cancers has highlighted the presence of amplifications in oncogenes including *CCND1*, *ERBB2* and *MYC*, and efforts are required to exploit this information to identify therapeutic targets that could be used to treat biomarker-selected groups of patients with oesophageal cancer

What are the new findings?

- By analysing large-scale in vitro functional genomic profiling data and drug data from tumour cell models of oesophageal cancer and integrating this with genomic profiling of these models, we have identified a series of candidate genetic vulnerabilities associated with cancer driver gene alterations common in oesophageal cancers.
- One of the most profound effects identified was an addiction to the kinase BTK in *MYC* amplified oesophageal tumour cells, which could be elicited with the kinase inhibitor ibrutinib and which also targeted oesophageal tumour cells with *ERBB2* amplification.

How might it impact on clinical practice in the foreseeable future?

- As the result of the observations made in this study, a proof-of-concept phase II clinical trial evaluating the efficacy of ibrutinib in patients with *MYC* and/or *ERBB2* amplified advanced oesophageal cancer is currently underway (NCT02884453).

a separation between EAC and ESCC. This is demonstrated by a closer resemblance of genomic sequencing data from ESCC with squamous cell carcinomas of other anatomical sites than when compared with genomic profiles from primary EAC.³ EAC and ESCC are also distinct in terms

To cite: Chong IY, Aronson L, Bryant H, et al. *Gut* 2018;**67**:1780–1792.

of their aetiology in that EAC may originate from Barrett's oesophagus, a premalignant condition that arises as a complication of chronic gastro-oesophageal reflux disease,⁴ whereas ESCC does not. Overall, 5-year survival rates over the past 30 years have improved from 5% to 19%. However, the prognosis for patients diagnosed with oesophageal cancer remains poor.^{5,6} Patients with EAC frequently present with advanced, inoperable disease, but even in those patients with operable disease the frequency of disease recurrence after surgery remains high.² Treatment options for patients with oesophageal cancers are extremely limited. Platinum-based chemotherapy remains the mainstay of treatment for EAC in the perioperative and metastatic setting,⁷⁻¹¹ and although taxanes and camptothecin analogues have been introduced into treatment regimens, these have not delivered large improvements in median survival.¹²⁻¹⁴

A small number of targeted therapeutic approaches exist for patients with EAC; these include the antivascular endothelial growth factor receptor 2 (anti-VEGFR2) therapeutic antibody ramucirumab, used in patients who progress after fluoropyrimidine or platinum-containing chemotherapy,^{15,16} and the Erb-B2 receptor tyrosine kinase (ERBB2) antibody, trastuzumab, used in combination with platinum-based chemotherapy as a first-line therapy in patients whose tumours exhibit *ERBB2* oncogene amplification and/or overexpression.¹⁷ However, there are no licensed targeted therapies for patient with ESCC. Therefore, there is a clear need to identify additional targeted approaches to treating this disease, particularly in those patients who progress after first-line therapy.

One approach to this problem has been to define the molecular make-up of the disease, with the ultimate aim of using this information to inform the design of novel biomarker-stratified therapeutic approaches. For example, genomic profiling of oesophageal cancers has defined the mutational landscape of the disease.^{3,18-24} This work has highlighted the presence of a number of recurrent somatically occurring mutations in the disease, including amplifications of several well-known oncogenes including *cyclin D1* (*CCND1* 15% in EAC³ and 46% in ESCC²³), *ERBB2* (32% in EAC³ and up to 11% in ESCC²⁵) and *MYC* (32% in EAC and 23% in ESCC³). Building on this work, efforts are now required to exploit this information to identify therapeutic targets that could be used to treat biomarker-selected groups of patients with oesophageal cancer. Here, we describe an analysis of large-scale in vitro functional genomic profiling of tumour cell models of oesophageal cancer. Integrating this functional profiling with genomic profiling of these models, we identify a series of candidate genetic vulnerabilities associated with cancer driver gene alterations common in oesophageal cancers. One of the most profound effects identified in this way was an addiction to the kinase BTK in *MYC* amplified oesophageal tumour cells; this addiction could be exploited with the kinase inhibitor ibrutinib, which also targeted oesophageal tumour cells with *ERBB2* amplification, suggesting a novel candidate therapeutic approach in EAC and ESCC.

RESULTS

Identification of genetic dependencies in oesophageal tumour cell lines that are associated with cancer driver gene alterations

We aimed to identify genetic dependencies (GD) (ie, gene addiction and synthetic lethal effects) in oesophageal cancer that are associated with the presence of alterations in known oncogenic driver genes. To do this, we (1) compiled copy number and

mutation profiles of 17 oesophageal tumour-derived cell lines using array comparative genomic hybridisation (aCGH) and exome sequencing data; (2) used these data to classify tumour cell lines according to the presence or absence of alterations in specific cancer driver genes, and then (3) interrogated recently described RNA interference (RNAi) screen data for the same tumour cell lines²⁶ to identify RNAi reagents that selectively targeted oesophageal tumour cell lines with cancer driver gene alterations. In addition, we carried out small molecule inhibitor drug sensitivity profiling in the same oesophageal tumour cell line panel, and by integrating these data with the genomic profiles of the tumour cell lines identified drug sensitivity effects associated with alterations in specific cancer driver genes (figure 1A).

Genomic profiling of oesophageal tumour cell lines

We selected 17 tumour cell lines, eight of which were derived from EAC (OE19, OE33, OACP4C, FLO-1, SK-GT-4, KYAE-1, ESO26 and JH-EsoAd1) and nine of which were derived from ESCC (KYSE70, TE1, TE5, TE6, TE8, TE9, TE10, TE11 and TE14; table 1). We used in-house aCGH data (32K based array CGH array platform²⁷) and publicly available single nucleotide polymorphism genotyping data (<http://cancer.sanger.ac.uk/cosmic>, <https://portals.broadinstitute.org/ccle/home>; online supplementary tables 1-17) to determine the copy number profile of each tumour cell line and used publicly available exome sequencing data to identify coding sequence variants in each model. We then cross-referred these tumour cell line genomic profiles to those from primary oesophageal tumours^{3,21,23,24,28-34} to annotate tumour cell lines in the panel according to the presence or absence of mutations in genes known to be recurrently mutated, amplified or deleted in primary oesophageal tumours. Cancer driver genes harbouring coding mutations or copy number alterations in two or more oesophageal tumour cell lines are illustrated in figure 1B and online supplementary table 18.

Consistent with the mutational spectrum of the clinical disease, we found that mutations in genes such as *TP53* (mutated in 72% of primary EAC¹⁹ and 83% of ESCC²³) were highly prevalent in the oesophageal tumour cell line panel. Six cell lines (OE19, OACP4C, SK-GT-4, KYSE70, TE9 and TE14) were predicted to have premature truncating *TP53* mutations and 11 cell lines were predicted to have missense *TP53* mutations (OE33, FLO-1, KYAE-1, ESO26, JH-EsoAd1, TE1, TE5, TE6, TE8, TE10 and TE11). The *SYNE1* gene (spectrin repeat containing nuclear envelope protein 1 gene), mutated in approximately 25% of primary treatment-naïve EAC tumours,¹⁹ was mutated in six oesophageal cell lines (FLO-1, KYAE-1, KYSE70, TE5, TE9 and TE10). Nine out of the 17 oesophageal tumour cell lines harboured homozygous copy number deletion of *CDKN2A* (cyclin-dependent kinase inhibitor 2A, p16/p14 gene), found to be deleted in 76% of EAC and ESCC of the oesophagus.³ In addition, 35% of the tumour cell line panel exhibited *ERBB2* amplification events, a frequency comparable to the *ERBB2* amplification rate in primary EACs.³ Furthermore, amplification of *CCND1* (*Cyclin D1* gene) was present in seven oesophageal models (JH-EsoAd1, TE6, TE8, TE9, TE10, TE11 and TE14), and *MYC* amplification was present in five oesophageal cancer cell lines (OACP4C, KYAE-1, TE8, TE9 and TE10); in the clinical disease *CCND1* amplification events are found in 15% of primary EAC³ and 46% of primary ESCC²³ cases, whereas *MYC* is amplified in 23% in EAC and 32% in ESCC.³ In total, we identified 35 genes that were recurrently mutated in primary oesophageal tumours that were also mutated in at least 3 out of 17 oesophageal tumour cell line models.

EAC, oesophageal adenocarcinoma; SCC, squamous cell carcinoma.

a further 5 days, at which point cell viability was estimated using CellTiter-Glo reagent (figure 2A). Each tumour cell line was screened in triplicate, with 15 of the 17 tumour cell lines generating highly reproducible data (median correlation coefficients of >0.9 between replicates; online supplementary figure 1) and suitable dynamic range quality control criteria (estimated by Z' calculations). The cell viability measurements for each drug titration (online supplementary table 19) were used to generate area under the curve (AUC) dose response data for each tumour cell line, illustrated as a heatmap in figure 2A and in online supplementary table 20.

We found the vast majority of oesophageal tumour cell lines to be sensitive to conventional cytotoxic agents including gemcitabine, camptothecin and paclitaxel, as well as the HSP90 inhibitor 17-AAG, the polo-like kinase 1 (PLK1) inhibitor BI2536, the cyclin-dependent kinase modulator flavopiridol and the P21 activated kinase 4 inhibitor, PF03758309 (figure 2A and online supplementary table 20). We then assessed if drug sensitivity effects differed according to whether tumour cell lines were derived from EAC or ESCC (online supplementary table 21) and found that ESCC cell lines were more sensitive to four drugs including dasatinib ($p=0.032$, median permutation (MP), t-test, figure 2B), a multitarget tyrosine kinase inhibitor and Src family tyrosine kinase inhibitor, and BI2536 ($p=0.033$, MP test, figure 2C), a small molecule inhibitor of PLK1. Compared with EAC cell lines, the ESCC cell lines were more sensitive to the epidermal growth factor receptor (EGFR) small molecule inhibitor, gefitinib ($p=0.034$, MP test, figure 2D), a finding that was consistent with data from a subgroup analysis of the cancer oesophagus gefitinib (COG) trial that revealed an HR in favour of gefitinib treatment in patients with ESCC.³⁵ In addition, ESCC cell lines were found to be more sensitive to the pan-ErbB inhibitor, canertinib ($p=0.038$, MP test, figure 2E), compared with EAC cell lines.

We integrated the data from the small molecule inhibitor screen with the genomic profiles of the tumour cell line panel to identify drug sensitivity effects associated with likely cancer driver gene alterations (figure 1A, online supplementary table 22). As expected, this analysis indicated that *ERBB2* or *EGFR* amplified

tumour cell lines were preferentially sensitive to the Erb-family kinase inhibitor lapatinib ($p=0.038$, Mann-Whitney U test, figure 2F), providing proof of principle that this approach could identify drug sensitivities associated with molecularly defined subgroups of oesophageal cancer. We also noted that oesophageal tumour cell lines that harbour missense mutations predicted to result in amino acid changes in the PI3KCA helicase domain exhibited the greatest sensitivity to the PI3-kinase/AKT signalling pathway inhibitor BEZ235 ($p=0.018$, MP test, figure 2G). Oesophageal tumour cell lines harbouring mutations within the PI3KCA helicase domain also exhibited preferential sensitivity to the 3-phosphoinositide-dependent protein kinase 1 inhibitor GSK-2334470A ($p=0.021$, MP test) and vinorelbine ($p=0.032$, MP test, figure 2H).

Integration of genomic profiles with siRNA data

Using a similar data integration scheme as for the drug sensitivity data, we cross-referred the genomic profiles of the tumour cell line panel to in-house generated data describing the sensitivity of each of the 17 oesophageal tumour cell line models and an additional 103 tumour cell lines to siRNAs designed to target a panel of 714 genes encoding kinases and kinase-related proteins (the 'Campbell *et al* data set'²⁶) as a means to identify candidate GDs in oesophageal cancers (online supplementary figure 2 and supplementary table 23). As kinases represent a pharmacologically tractable family of enzymes, we reasoned that doing so might also identify targetable vulnerabilities associated with molecularly defined subsets of the disease (figure 1A).

Initially, we used this integrated analysis to identify those kinases that when targeted with siRNA selectively targeted the oesophageal tumour cell lines, as opposed to the other 103 tumour cell lines that we also profiled by siRNA screening in our data set.²⁶ This analysis suggested that, compared with non-oesophageal tumour cell lines, those derived from oesophageal cancers exhibited dependencies on *NEK9* ($p=0.00026$, MP test), *PACE1* ($p=0.00027$, MP test), *MGC42105* ($p=0.0003$, MP test) and *CDKN2C* ($p=0.00058$, MP test) (figure 3A and online supplementary table 24). When ESCC-derived cell lines were compared with EAC-derived cell lines, we found *EGFR* to be the most profound GD associated with ESCC histology ($p=0.000006$, MP test, figure 3B and online supplementary table 25). This observation confirms the enhanced sensitivity of ESCC cell lines to the EGFR small molecule inhibitor, gefitinib, and the pan-ErbB inhibitor, canertinib, seen in the small molecule drug screen (figure 2E). When using the genomic profiles of the oesophageal tumour cell lines to identify GD associated with alterations in specific cancer driver genes (online supplementary table 26), we found that, as expected, siRNA designed to target *ERBB2* itself preferentially targeted *ERBB2* amplified oesophageal tumour cell lines ($p=0.019$, MP test, figure 3D,E), supporting the hypothesis that *ERBB2* amplification can lead to an oncogene addiction effect.¹⁷ We found that *ERBB2* amplified oesophageal tumour cell lines also exhibited GDs on members of the mitogen-activated protein kinase family that signal downstream of *ERBB2*³⁶ including *MAPK2K2* ($p=0.0073$, MP test, figure 3D), *MAP2K3* ($p=0.0082$, MP test, figure 3F) and *MAPK6* ($p=0.0082$, MP test, figure 3D).

MYC is amplified in 23% of EAC and 32% of ESCC.³ We found *MYC* amplified oesophageal tumour cell lines to exhibit GDs on *CLK1* (*Cdc2-like kinase* gene, $p=0.02$, MP test, figure 3G), *BTK* (*Bruton agammaglobulinaemia tyrosine kinase* gene, $p=0.017$ MP test, figure 3H), *ALK* (*anaplastic*

$p=0.0056$ MP test, [figure 3M](#)) and *TGFBR1* (*TGF β receptor1* gene, $p=0.013$, MP test, [figure 3L](#)).

Ibrutinib sensitivity in *MYC* and *ERBB2* amplified oesophageal cancer

Analysis of the oesophageal kinase dependency profiles revealed that one of the most profound associations was between *MYC* amplification and sensitivity to BTK siRNA ($p=0.017$, MP test, [figure 3H](#)). Although BTK has been most studied within the context of B cell malignancies³⁷ and comprises a key component downstream of BCR signalling,³⁸ BTK isoforms are also present in epithelial tumours including breast,³⁹ prostate,⁴⁰ colon⁴¹ and gastric cancers.⁴² We assessed BTK protein and mRNA expression across the panel of oesophageal tumour cell lines and found that canonical BTK is expressed in these models, although at low levels ([figure 4A,B](#)). We also confirmed that a splice variant, BTK-C, is expressed in the oesophageal tumour models ([figure 4C,D](#)).

We validated the BTK/*MYC* synthetic lethal interaction in *MYC* amplified oesophageal tumour cell lines using multiple, different BTK-targeting siRNAs ([figure 4E,F,G](#)), suggesting that this was unlikely to be an off-target effect. In addition, we observed decreased cell viability ([figure 4H](#)) and a reduction of BTKC mRNA expression after transfection with individual siRNAs specifically targeting BTK-C ([figure 4I](#) and online supplementary figure 3), suggesting that the BTK-C isoform is essential in oesophageal tumour models. To investigate whether small molecule inhibition of BTK could mimic these effects, we exposed the panel of oesophageal tumour cell lines to increasing concentrations (0.1–10 μ M) of the clinical BTK inhibitor ibrutinib, a drug that has durable single-agent efficacy in relapsed mantle cell lymphoma, Waldenstrom's macroglobulinaemia and chronic lymphocytic leukaemia.^{43–44} While ibrutinib is a potent BTK inhibitor, it also directly inhibits *ERBB2*.^{45–46} Consistent with this, our analysis of ibrutinib sensitivity in oesophageal tumour cell lines revealed that there was preferential sensitivity to ibrutinib in both *MYC* amplified and/or *ERBB2* amplified oesophageal tumour cell lines ($p=0.018$, Mann-Whitney U test, [figure 5A,B](#)).

We wanted to examine the mechanism of ibrutinib sensitivity in *MYC* amplified oesophageal cell lines. We found that *MYC* protein levels were reduced by ibrutinib exposure in both KYAE-1 (*MYC* amplified) and TE8 (*MYC* and *ERBB2* amplified) oesophageal tumour cell lines ([figure 5C,D](#)). Transfection of siRNA targeting *MYC* confirmed that these tumour cell lines were addicted to *MYC* ([figure 5E,F](#)). Ibrutinib exposure also caused an increased G_1 fraction in *MYC* amplified and *MYC/ERBB2* coamplified oesophageal tumour cell lines ([figure 5G,H](#)) but not in tumour cell lines without these amplification events ([figure 5I](#)). In *MYC* amplified and also *MYC/ERBB2* coamplified oesophageal tumour cell lines, ibrutinib exposure caused a reduction in phosphorylated Rb, total Rb and cyclin D1 protein levels ([figure 5J,K](#)) not seen in non-amplified tumour cell lines ([figure 5L](#)), consistent with the increased G_1 fraction. Ibrutinib exposure also increased annexin V and cleaved PARP1 levels in sensitive tumour cells ([figure 5M,N](#)), suggesting that the G_1 arrest caused by ibrutinib might eventually drive an apoptotic response.

ERK1/2 is downregulated by ibrutinib

BTK is known to signal via the ras/mitogen-activated protein kinase (RAS-RAF-MEK-ERK) pathway.⁴¹ To investigate whether this contributed to the ibrutinib-dependent reduction of *MYC*

protein levels in oesophageal tumour cells, we evaluated changes in p-ERK protein expression after ibrutinib exposure. We observed a reduction in p-BTK ([figure 6A](#)), indicating decreased catalytic activity of BTK and p-ERK levels ([figure 6B,C](#)) after ibrutinib exposure. As ERK is a known mediator of *MYC* phosphorylation at serine 62,⁴⁷ we assessed changes in p-*MYC* S62 protein expression after exposure to ibrutinib and observed a decrease in p-*MYC* S62 levels in oesophageal tumour cell lines that were either *MYC* amplified or *MYC/ERBB2* coamplified ([figure 6D,E](#)). Phosphorylated *MYC* at serine 62 (p-*MYC* S62) is required for stabilisation of *MYC* protein levels.⁴⁸ Consistent with this, we observed a reduction in *MYC* protein levels ([figure 6D,E](#)). Taken together, these results suggested that exposure to ibrutinib resulted in a reduction in *MYC* in oesophageal tumour models by reduction of BTK-dependent, ERK-mediated, *MYC* phosphorylation.

DISCUSSION

In this study, we show how integration of functional genomic profiling data with genotypic data from oesophageal cancer tumour cell lines may be used to identify candidate GDs. By undertaking high-throughput small molecule drug screening, we provide a public resource for the identification of biomarker driven therapies in a disease that currently has very limited treatment options.

By interrogating drug and siRNA data with copy number profiling data, we identified an addiction to BTK in *MYC* amplified oesophageal tumour cell line models that may represent an induced essentiality where the gain of *MYC* function induces a dependency on BTK.⁴⁹ We exploited this addiction with the small molecule inhibitor ibrutinib that targets both BTK and *ERBB2*, and found increased sensitivity in *MYC* and/or *ERBB2* amplified oesophageal tumour models to ibrutinib. Ibrutinib exposure also resulted in downregulation of c*MYC*. Mechanistically, one model that is consistent with these data might be that BTK and *ERBB2* inhibition with ibrutinib results in downregulation of c*MYC*, likely via deregulation of ERK signalling. The use of ibrutinib in this context exemplifies how molecular and functional profiling data might be used to design novel therapeutic approaches for patients with oesophageal cancer.

Ibrutinib already has Food and Drug Administration approval for the treatment of patients with Waldenstrom's macroglobulinaemia,⁵⁰ mantle cell lymphoma⁴⁴ and chronic lymphocytic leukaemia⁴³ based on the demonstration of durable responses in single-arm multicentre clinical studies that enrolled patients with previously treated disease. Considering the known safety profile of ibrutinib, we have initiated a proof-of-concept single-arm phase II trial of ibrutinib in patients with advanced oesophagogastric cancer harbouring *MYC* and/or *ERBB2* amplifications (ibrutinib in *MYC* amplified oesophageal cancer (iMYC) trial — NCT02884453) who have progressed after first-line treatment. Patients recruited to the iMYC trial undergo prescreening for *MYC* and *ERBB2* amplification by fluorescence in situ hybridisation criteria. The role for ibrutinib in *ERBB2* amplified EAC may be clinically relevant as there are currently no approved anti-*ERBB2* therapies in the second-line setting; approximately half of patients with advanced EAC have de novo resistance to first-line trastuzumab, and the median time to progression following initial response to chemotherapy and trastuzumab is only 7.1 months.¹⁷ Exploratory molecular and functional imaging biomarker analyses have been incorporated into the iMYC trial where serial tumour biopsies and blood samples are retrieved at screening, during treatment and

at progression. Whole exome sequencing and RNA sequencing of serial tumour samples will be undertaken to assess genetic determinants of response and resistance to ibrutinib. Sequential tumour samples will be evaluated for expression of phosphorylated kinases in the ERBB2, AKT and RAS-RAF-MEK-ERK-MYC

signalling pathways as part of pharmacodynamic biomarker assessment. In addition, we will assess the expression of phosphorylated proteins that signal downstream of BTK, including 1-phosphatidylinositol-4,5-bisphosphonate phosphodiesterase gamma and protein kinase C. Given that we observed greatest

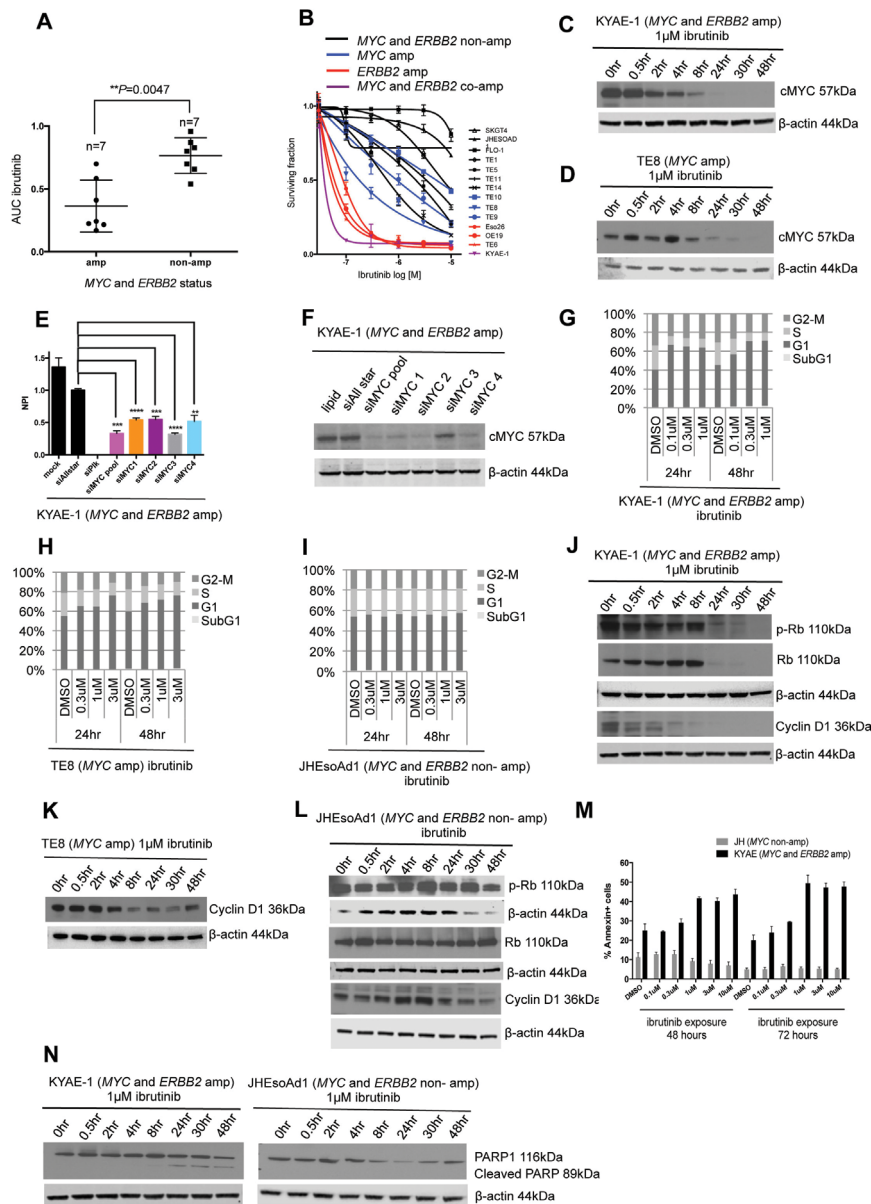

Figure 5 Ibrutinib sensitivity in *MYC* and/or *HER2* amplified oesophageal tumour cell lines. (A) Box plot depicting area under the curve values for ibrutinib. Preferential sensitivity to ibrutinib is observed in oesophageal cancer cell lines harbouring *MYC* and/or *ERBB2* amplification. (B) Ibrutinib drug sensitivity curves across the panel of oesophageal tumour cell lines. Cell lines that are not *MYC* or *ERBB2* amplified are depicted in black, *MYC* and *ERBB2* amplified in purple, *MYC* amplified alone in blue and *ERBB2* amplified alone in red. (C) Western blots showing decreased expression of cMYC in *MYC* amplified KYAE-1 tumour cell line after exposure to 1 μM ibrutinib. (D) Western blot showing decreased expression of cMYC in *MYC* amplified TE8 tumour cell line after exposure to 1 μM ibrutinib. (E) Bar chart showing decreased cell viability in KYAE-1 (*MYC* and *ERBB2* amplified) following transfection with siMYC oligonucleotides. (F) Western blot showing decreased protein expression of cMYC following transfection of siMYC oligonucleotides in KYAE-1 (*MYC* and *ERBB2* amplified). (G) Cell cycle analysis after 24 and 48 hours of ibrutinib exposure in KYAE-1 (*MYC* and *ERBB2* amplified), (H) TE8 (*MYC* amplified) and (I) JHEsoAd1 (*MYC* and *ERBB2* non-amplified) tumour cell lines. Prolongation of the G₁ phase is observed with increasing doses of ibrutinib in cell line harbouring *MYC* amplification. G₁ arrest was not observed in JHEsoAd1 (*MYC* and *ERBB2* non-amplified) cell line. (J) Western blot showing decreased expression of p-Rb, Rb and cyclin D1 following ibrutinib exposure in KYAE-1 (*MYC* and *ERBB2* amplified). (K) Western blot showing decreased expression of cyclin D1 following ibrutinib exposure in TE8 (*MYC* amplified). (L) Western blot showing no change in protein expression of p-Rb, Rb and cyclin D1 following ibrutinib exposure in JHEsoAd1 (*MYC* and *ERBB2* non amplified). (M) Bar chart showing the apoptotic cell fraction (percentage of annexin-positive cells) after exposure to increasing doses of ibrutinib (24 and 48 hours). An increase in apoptosis is observed in KYAE-1 (*MYC* and *ERBB2* amplified) that is not seen in JHEsoAd1 (*MYC* and *ERBB2* non-amplified). (N) Western blot showing expression of cleaved PARP1 after ibrutinib exposure in the KYAE-1 (*MYC* and *ERBB2* amplified). Cleaved PARP1 is not seen in JHEsoAd1 after ibrutinib exposure (*MYC* and *ERBB2* non-amplified).

sensitivity to ibrutinib in *MYC/ERBB2* coamplified models (4% of EAC³) and that *ERBB2* amplification only occurs in up to 11% of ESCC²⁵ compared with up to 32% in EAC,³ it is likely that a therapeutic approach utilising ibrutinib will be clinically

relevant to a larger proportion of patients with EAC within the context of this study.

Our aim in providing these data and illustrating its potential utility is to present testable hypotheses for future work that

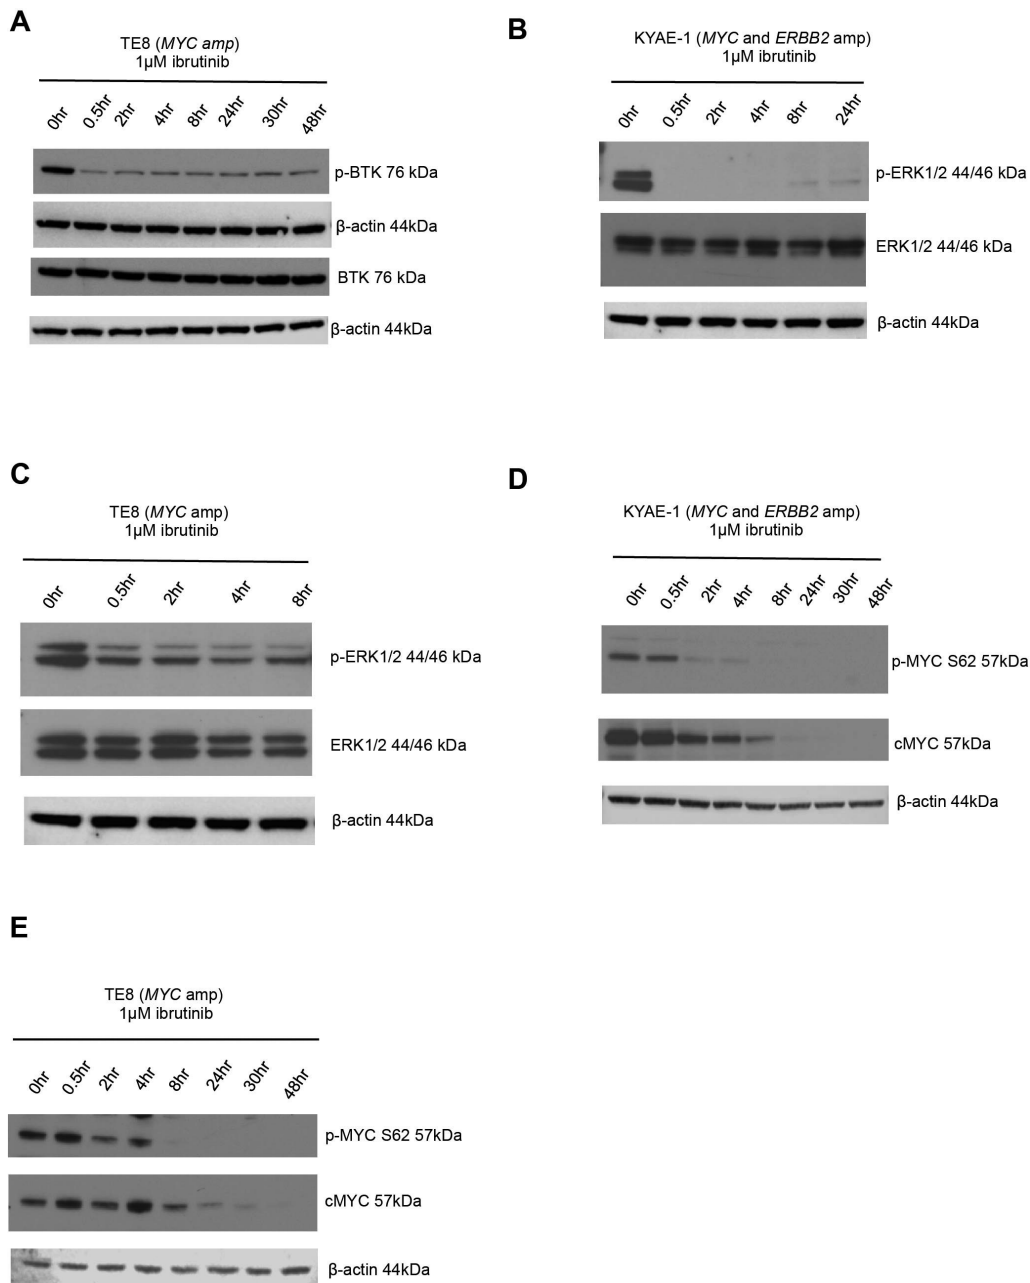

Figure 6 ERK1/2 is downregulated by ibrutinib. require orthogonal validation. We recommend that subsequent work based on the siRNA analysis incorporates the use of individual siRNAs designed to target a gene, CRISPR-Cas9-mediated gene targeting or small molecule inhibitors given the well-documented off-target effects associated with RNAi reagents.⁵¹ We are also mindful of the limitations of using tumour cell lines in terms of modelling the human disease and would recommend that future work relating to oesophageal cancer should be validated using patient-derived tumour organoids (PDTOs) and xenografts (PDXs). PDXs, where surgically resected tumour samples are engrafted directly into immunocompromised mice, offer many advantages over standard cell-line xenograft models, including the preservation of the

molecular heterogeneity frequently observed in human oesophageal tumours, and represent a genomically characterised platform with which to analyse drug sensitivity in relation to driver mutations for the purposes of biomarker discovery. In addition to commercially available PDX collections, patient-derived in vitro and in vivo models have also been propagated through academic collaboration.⁵² Going forward, it would be important to use such platforms to identify the dynamic response to ibrutinib in relevant oesophageal cancer PDTOs and PDXs as a route to identifying mechanisms of resistance to BTK inhibition that might emerge. Finally, candidate predictive biomarkers identified from drug screening should be evaluated in oesophageal tumour tissues within the context of prospective

clinical studies utilising targeted therapies and correlated with clinical outcome.

Supplementary tables

All online supplementary tables have been made publicly available and can be accessed using the following link: <https://doi.org/10.5281/zenodo.826575>.

MATERIALS AND METHODS

Cell lines

Tumour cell lines were obtained from the American Type Culture Collection, European Collection of Cell Cultures and Deutsche Sammlung von Mikroorganismen und Zellkulturen, and maintained as per the supplier's instructions. Short tandem repeats (STR) geno typing of 10 loci was performed using the GenePrint 10 system (Promega) and used to confirm the identity of cell lines prior to storage. At monthly intervals, mycoplasma testing was carried out using MycoAlert Mycoplasma Detection Kit (Lonza).

Array comparative genomic hybridisation

All cell line and tumours were subjected to aCGH (Breakthrough Breast Cancer Research Centre) 32K BAC array platform and profiled as previously described.²⁷ siRNA screening and processing 17 oesophageal cancer cell lines were optimised for siRNA screening conditions by titrating cell number and transfection lipid. Each cell line was transfected with a plate-arrayed siRNA library targeting 714 kinases and kinase-related genes (Dharmacon in a 384-well plate format) as described in Campbell *et al.*²⁶

Association testing

An MP test was used to identify associations between specific features (histotype or driver gene mutation) and sensitivity to specific siRNAs. For each kinase we compared the observed difference between the median Z score of the interest group (mutant, tissue of interest or other grouping variable) and the median Z score of the 'other' group (wild-type, non-tissue of interest or inverse of other grouping variable) to that expected based on random permutation.

Small molecule kinase inhibitor growth assays

The compound screens comprised an in-house library of 80 small molecule inhibitors (0.5, 1, 5, 10, 50, 100, 500 and 1000 nM). Five hundred cells were seeded in 384-well plates. Twenty-four hours post seeding, drug treatment was initiated and cells were continuously exposed to the drugs (6 days), at which point

cell viability was estimated using CellTiter-Glo (Promega). Luminescence values were normalised to the median of the per-plate dimethyl sulphoxide (DMSO) negative control wells and the dose–response relationships modelled using three-parameter logistic regression provided by the drc R package. AUC scores are represented as a proportion of the maximum area under curve (calculated as: $\log_{10}(500000) - \log_{10}(500) = 3$).

BTK and BTK-C PCR

RNA was extracted from untreated cells using RNeasy Mini Kit (Qiagen). One microgram of RNA was converted to cDNA using reverse transcriptase with the iScript cDNA synthesis kit (BioRad) as per manufacturer's instructions. The cDNA was used to detect BTK or BTK-C with the following primers: BTK forward 5'-GGGGTTTGCTCAGACTGTCC-3', BTK-C forward 5'-AATGAAGGGGTCCTCCACCT-3' and BTK/BTK-C reverse 5'-AATCACTGCGGCCATAGCTT-3'. PCR was performed using Platinum Green Hot Start PCR 2x Master mix (Thermo Fisher) as per manufacturer's instructions.

BTK and BTK-C real-time PCR

RNA was extracted and converted to cDNA. Real time PCR was carried out using PowerUp SYBR Green Master mix (Thermo Fisher) and 20x PrimePCR primers for BTK and Actin (BioRad). For BTK-C, the primers used were those described by Eifert *et al* (Genes, Chromosomes and Cancer, 2013) and actin primers were forward 5'-CCCTGGCACCACAGCAC-3' and reverse 5'-GCCGATCCACACGGAGTAC-3'.

Reverse transfections and cell viability assay

Fifteen microlitres of each siRNA species were mixed with 750 μ L of optimum and incubated at RT (10 min). Fifty microlitres of RNAiMax (Invitrogen) were incubated with 2.5 mL optimum (10 min). Two hundred fifty microlitres of transfection mix were added to the siRNA mix and incubated at RT (30 min). Of the transfection/siRNA mix, 17.5 μ L was plated in triplicate in 96-well plate format, then 80 μ L cells/well (0.025×10^6 cells/mL) were then seeded. After 5 days, 35 μ L CellTiter-Glo was added per well. The de-convoluted siRNA target sequences used are as follows:

siMYC1 AACGUUAGCUUCACCAACA siMYC2 GGAACU-AUGACCUCGACUA siMYC3 GAACACACAACGUCUUGGA siMYC4 CUACCAGGCUGCGCGCAA siBTK1 GCUAUG-GGUGCCAAAUUU siBTK2 GAAAGCAACUACCAUGGU siBTK3 GGUAAACGAUCAAGGAGUU siBTKC1 GGUUAUUG GAUGCCCAUUUUU siBTKC2 GGGAGAGCACACAGGU GAAUU

Table 2 Genetic dependencies in oesophageal cancer: Chong *et al*

| Ab | 1 Ab dilution | 2 Ab dilution | | Company | Product code |
|------------------------|---------------|-----------------|--------|----------------|--------------|
| BTK | 1:1000 (BSA) | 1:2000 | Rabbit | Abcam | ab32555 |
| P BTK (Y223) | 1:1000 (BSA) | 1:2000 | Rabbit | Cell Signaling | 50825 |
| MYC | 1:5000 (BSA) | 1:5000 | Rabbit | Abcam | ab32072 |
| P MYC (Ser62) | 1:1000 (BSA) | 1:5000 | Rabbit | Cell Signaling | 13 748 |
| PARP 1 | 1:1000 (Milk) | 1:5000 | Mouse | Santa Cruz | sc-8007 |
| Cyclin D1 | 1:2000 (BSA) | 1:2000 | Rabbit | Cell Signaling | 2922 |
| P Rb (Ser780) | 1:5000 (BSA) | 1:5000 | Rabbit | Cell Signaling | 8180 |
| Total Rb | 1:2000 (Milk) | 1:5000 | Mouse | Cell Signaling | 9309 |
| P-ERK (Thr202/Tyr2014) | 1:1000 (BSA) | 1:5000 | Rabbit | Cell Signaling | 4370 |
| Total ERK | 1:1000 (BSA) | 1:5000 | Rabbit | Cell Signaling | 9102 |
| Actin | 1:2000 (milk) | 1:10 000 (milk) | Mouse | Santa Cruz | Sc-47778 |

Apoptosis assay

Apoptotic cells were identified using an FITC Annexin V Kit (BD Bioscience). Cells were plated and treated the following day with ibrutinib for 48 or 72 hours, trypsinised, washed in phosphate-buffered saline (PBS) and resuspended in 1x Annexin binding buffer. Five microlitres of FITC Annexin V and 5 µL propidium iodide (PI) and 400 µL of 1x Annexin binding buffer were added. Data were analysed on a BD LSRII flow cytometer.

Cell cycle assay

Cells were plated and treated the following day with ibrutinib for 24 or 48 hours. Cells were trypsinised, washed in PBS and fixed in 70% ethanol, then treated with 50 µg/mL RNase A. PI was added (50 µg/mL) and data were analysed on a BD LSRII flow cytometer.

Western blotting

Cell lysates were separated using 4%–12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) Bis-Tris gel, transferred to nitrocellulose membrane, blocked in 5% milk and blotted with antibodies (table 2).

BTK overexpression in MYC amplified oesophageal cancer cell lines

BTK was overexpressed using a lentiviral vector containing the BTK ORF (Source Bioscience). Five micrograms of this plasmid with 4 µg psPAX2 packaging plasmid and 1.5 µg pMD2.G envelope plasmid were combined with Lipofectamine 3000 and P3000 (Thermo Fisher) and used to transfect 2×10^6 293 T cells.

Acknowledgements This work was funded by a Cancer Research UK programme grant to CJL (grant number C347/A8363) and Janssen and Pharmacyclis Pharmaceuticals as part of a sponsored research agreement with IYC. AA is funded by a Department of Defence grant. We acknowledge NHS funding to the NIHR Royal Marsden Hospital Biomedical Research Centre. We thank the Thornton Foundation, Cadogan Foundation and the Royal Marsden Cancer Charity for their financial support.

Contributors Data generation and analysis: IYC, LA, HB, AG, JC, RE, AR, MBL, PW, CJL. Data interpretation: IYC, LA, HB, SP, JSRF. Obtained funding: IYC, DC, IC, AA, CJL. Manuscript drafting: IYC, LA, SP, MD, IC, DC, AA, CJL. Approval of final manuscript: All authors.

Disclaimer IYC has received research funding from Janssen and Pharmacyclis as part of a sponsored research agreement. DC accepts research funding from the following institutions: Amgen, AstraZeneca, Bayer, Celgene, Merrimack, Medimmune, Merck Serono and Sanofi Oncology. IC is on the Advisory Board for Sanofi Oncology, Eli Lilly, Bristol Myers Squibb, MSD, Roche and Five Prime Therapeutics, accepts research funding from Janssen-Cilag, Sanofi Oncology, Merck Serono and Novartis, and has received honorarium from Taiho, Pfizer, Amgen, Eli Lilly and Gilead Science.

Competing interests IYC has received research funding from Janssen and Pharmacyclis as part of a sponsored research agreement. IC accepts research funding from Janssen-Cilag.
