Correspondence: [kjacobse@gmu.edu](mailto:kjacobse@gmu.edu)

Increased economic interdependence, social integration, and other aspects of globalization are contributing to significant changes in hepatitis A epidemiology. Globally, the incidence of hepatitis A virus (HAV) infection is decreasing, the age at midpoint of population immunity (AMPI) is increasing, and the proportion of symptomatic cases is increasing as the average age at infection increases. In low-income countries, HAV remains endemic but improved water and sanitation systems are reducing transmission rates among young children. In high-income countries, most adults remain susceptible to HAV and foodborne outbreaks are becoming more frequent. Middle-income countries have diverse epidemiological profiles, and they play important roles in the global spread of HAV through international trade and travel. Future changes in the epidemiology of hepatitis A will be heavily influenced by globalization processes.

Globalization is a process characterized by countries and people around the world becoming more interdependent and integrated across economic, political, cultural, and other domains. Evidence for globalization can be observed in the increasing rates of cross-border trade, the growing complexity of international supply chains, the rising pace of international travel and migration, and the social and cultural changes that are occurring as online communication makes it easy for people from different parts of the world to interact. The globalization of economic markets and sociocultural practices is influencing human behaviors, altering the ways people interact socially and with the environment, and modifying the ways people conceive of health and seek health services (Huynen

et al. 2005). For infectious diseases generally, and for hepatitis A specifically, the globalization of trade and travel are important drivers of epidemiological change (Suk et al. 2014; Semenza et al. 2016).

This article summarizes the current epidemiology of hepatitis A in countries with different income levels and endemicity patterns, describes the major socioeconomic and environmental changes that are contributing to hepatitis A epidemiological transitions, examines the specific roles of international food trade and international travel on hepatitis A epidemiology, and uses globalization theory to predict the changes that are likely to occur in hepatitis A epidemiology over the next several decades.

## HEPATITIS A VIRUS (HAV) EPIDEMIOLOGY

Tens of millions of individuals worldwide contract HAV through fecal–oral transmission each year, usually via ingestion of contaminated food or water or through contact with an infectious person (Rein et al. 2014). Young children who are exposed to the virus usually have no symptoms of disease, but older children and adults often experience several weeks of jaundice and a lengthy convalescence, and they are at risk of acute liver failure and death. Symptomatic hepatitis A patients typically miss several weeks of work or school, and the costs of medical care can be substantial (Berge et al. 2000). Globally, the HAV incidence rate is decreasing and the average age at infection is increasing (Rein et al. 2014). However, there are major differences in the profiles of countries with different socioeconomic profiles (Jacobsen 2009).

Low-income countries typically have high HAV incidence rates. Surveillance for incident hepatitis A cases can be difficult in high-incidence areas because the majority of cases occur in young children who remain asymptomatic. However, even asymptomatic infections confer long-term immunity against HAV that can be detected with serologic tests. Seroprevalence studies in low-income countries typically show that nearly 100% of older children and adults have anti-HAV immunoglobulin (Ig)G levels indicating prior infection with HAV and that the majority of young children already have serologic evidence of past infection (Jacobsen 2009). The age at midpoint of population immunity (AMPI) is the youngest age at which half of the birth cohort has serologic evidence of prior exposure to HAV. In most sub-Saharan African countries and other very low-income areas, the AMPI is less than 5 years (Jacobsen and Wiersma 2010), which means that more than half of preschool-aged children have already contracted HAV and developed immunity as a result of their infection. These prevalence statistics in children provide ample evidence of high HAV incidence rates in low-income countries.

High-income countries usually have low or very low HAV incidence rates, and seroprevalence studies typically show an AMPI that is in

middle adulthood. For example, in many Western and Northern European countries, the AMPI is above 50 years, which means that more than half of 50-year-olds and the vast majority of children and younger adults remain susceptible to HAV infection (Kurkela et al. 2012; Carrillo-Santistevé et al. 2017). When a large proportion of hepatitis A cases occur among adolescents and adults, the case detection rate is usually fairly high because nearly all infected individuals in these age groups develop jaundice. A reasonable estimation of the annual HAV incidence rate can be calculated from mandatory notifications of cases to public health authorities. When outbreaks occur and the incidence rate spikes, these situations often can be detected soon after the first cases become symptomatic. Even outbreaks that spread through childcare facilities usually can be detected, because caregivers who contract the virus from asymptomatic infected children are likely to develop jaundice after the 15- to 50-day incubation period (Staes et al. 2000). However, the long incubation period, averaging about 4 weeks, means that it is often difficult for investigators to identify the specific original source of HAV outbreaks.

In middle-income countries in which incomes are rising, urbanization is occurring, and nearly all members of the population (especially in urban areas) now have access to clean water, the incidence of HAV is decreasing and the median age at infection is rising. Significant increases in the AMPI were observed between 1990 and 2005 in East Asia, Southeast Asia, Eastern and Central Europe, Latin America, and parts of the Middle East and North Africa (Jacobsen and Wiersma 2010). Paradoxically, a lower HAV incidence rate often initially causes an increase in the number of hospitalizations and deaths from hepatitis A in the population, because older hepatitis A patients tend to be much sicker than young children who become infected. Mathematical models of HAV in upper-middle-income countries, like Brazil, Mexico, and Thailand, have found that a decrease from an intermediate to a low overall incidence rate may not have a significant impact on reducing the rate of symptomatic disease for several de-

ades, in the absence of vaccination, because the proportion of symptomatic cases increases as the overall incidence rate decreases (Van Effelterre et al. 2017a,b). However, these countries are expected to eventually shift to the low-incidence, nonendemic profiles currently observed in high-income countries. This transition has already occurred in many upper-middle-income countries.

### RISK FACTORS FOR HAV

HAV incidence rates are decreasing in most countries. Many high-income countries are now nonendemic for HAV, many middle-income countries are shifting from intermediate to low endemicity, and many low-income countries are shifting from very high to high or intermediate endemicity (Jacobsen and Koopman 2005). Several factors are influencing these changes in HAV epidemiology.

One contributor is improved access to clean drinking water sources and to sanitation and hygiene facilities. The incidence of HAV decreases when everyone in a community has access to a toilet and a handwashing facility, especially food handlers, caregivers of young children who are not yet toilet-trained, and others who are at elevated risk of playing a role in the transmission of HAV within communities. Meta-analysis has confirmed the association between higher rates of access to a safe drinking water source and a lower HAV incidence rate (Jacobsen and Koopman 2005). Hepatitis A has an unusual risk profile because a lower incidence rate can raise the number of symptomatic cases occurring in a population by postponing the age at which the typical individual contracts the virus. This characteristic of the disease means that increased access to water and sanitation can initially increase the population burden from HAV (Mohd Hanafiah et al. 2011), although the case numbers will decrease as continued infrastructure development further reduces the incidence rate.

Water and sanitation access do not adequately explain the differences in HAV endemicity levels between countries with moderate or high water-access rates. In these locations, economic

indicators such as the gross national income per capita or the human development index (which combines economic, education, and life expectancy data into one metric) appear to be better predictors of HAV endemicity than water access (Itani et al. 2014; Koroglu et al. 2017). This relationship between socioeconomic status and HAV risk is also observed at the individual and household levels, with higher incomes, higher levels of education, smaller family sizes and less crowding in the home, and other indicators of higher socioeconomic status associated with a reduced likelihood of exposure to HAV (Jacobsen and Koopman 2004). Thus, socioeconomic development appears to be a factor in changing HAV epidemiology trends in ways that extend beyond environmental improvements.

Another set of factors relates to human demographics. One important driver of HAV epidemiology in middle-income countries appears to be rural-to-urban migration (Van Effelterre et al. 2017a). Rural areas tend to be poorer and have less developed water and sanitation infrastructure, so they tend to have higher HAV incidence and prevalence rates (Jacobsen and Koopman 2004). When a rural resident of a middle-income country who is shedding HAV as a result of acute infection travels to a city, that infectious individual may infect many urban residents who are susceptible to HAV, especially if the rural resident is in the city to sell produce or other food items.

A similar process may occur in higher-income countries as a result of refugee migration. Child refugees originating in places with intermediate or high HAV endemicity who contract HAV at the start of their journey or during their travels may become contagious several weeks later, after the family has relocated to a new country. If the housing available to refugees is substandard and residents do not have sufficient access to hygiene facilities, one infected child may spark an outbreak within the refugee community. Outbreaks have occurred recently in several refugee camps in Europe that are hosting people who have fled from the conflict in Syria, including camps in Germany and Greece (Mellou et al. 2017; Michaelis et al. 2017). These outbreaks have generally remained within the

refugee community, and vaccination strategies have been successful at preventing spread to other local populations (Mellou et al. 2017; Michaelis et al. 2017). However, it is possible for migrants and other travelers to initiate chains of local transmission of HAV in low-endemicity countries.

An additional demographic process influencing HAV epidemiological patterns is population aging. In nations designated as “least developed countries,” young children who are not yet toilet-trained account for up to 10% of the total population; in high-income countries, this proportion is usually about 3% (UN DESA 2017). In communities with a relatively large proportion of young children in their populations, child-to-child transmission plays a key role in sustaining endemic levels of hepatitis A. Countries with older populations rarely have endemic HAV, but they are vulnerable to outbreaks of hepatitis A because a sizeable proportion of their residents remain susceptible to HAV.

Globalization may play a role in all of these risk scenarios. In particular, economic globalization processes are enabling financial and infrastructural development in many parts of the world and are driving increased rural-to-urban and international migration and trade. For hepatitis A, international food trade and greater human mobility are critical components of the epidemiological changes that are occurring globally.

#### HAV AND INTERNATIONAL FOOD TRADE

In low-income countries, HAV is spread through contaminated water, direct contact with infectious individuals, and consumption of contaminated foods. Because these transmission pathways all relate to water, sanitation, and hygiene, it may be impossible to isolate the particular exposure responsible for causing a cluster of hepatitis A cases. In high-income countries, where safe drinking water is routinely available, it is more feasible to identify the specific food items that cause outbreaks. The two primary food groups linked to outbreaks of hepatitis A are produce and seafood (Greig and Ravel 2009), including frozen berries, green onions, lettuce,

oysters, clams, and mussels (Acheson and Fiore 2004). The World Health Organization’s Foodborne Disease Burden Epidemiology Reference Group estimated that more than 90,000 people worldwide died of hepatitis A disease in 2010 and that nearly 30,000 of those deaths could be directly attributed to foodborne acquisition of HAV (Kirk et al. 2015).

Although most foodborne outbreaks of hepatitis A are small, affecting only a few dozen or several hundred people, these outbreaks can become widespread. In 1988, nearly 300,000 people in Shanghai contracted HAV by eating raw clams, a popular delicacy that had been consumed by nearly one-third of the city’s residents in the month before the outbreak began (Halliday et al. 1991). In 2003, more than 600 people contracted HAV from a single restaurant in Pennsylvania, in the United States, by eating contaminated green onions that had been imported from Mexico (Wheeler et al. 2005).

International trade in foods is accelerating. For example, in the United States, the proportion of consumed food that is imported from other countries increased from 12% in 1990 to 20% in 2013; this proportion increased from 56% to 97% for fish and shellfish, from 31% to 49% for fruits and nuts, and from 4% to 20% for vegetables (Jerardo 2016). The number of foodborne outbreaks in the United States rose steadily as the proportion of food that is imported increased (Gould et al. 2017). Although not all foodborne outbreaks of hepatitis A in high-income countries are caused by imported foods, the risk of HAV contamination is elevated when foods are procured from low- or middle-income countries that are HAV-endemic.

Globalization is expected to increase the number of foodborne outbreaks in high-income countries, and there is already evidence of this change occurring. For example, frozen berries have caused numerous outbreaks of hepatitis A in Europe. In one large outbreak that occurred between January 2013 and August 2014, more than 1100 people in Italy, Germany, Norway, and 10 other European countries were hospitalized with hepatitis A disease. Some of the cases were travelers to Italy, but most were people who had not traveled outside of their home countries

in the months before they became ill. Molecular characterization and trace-back investigations linked the outbreak to Bulgarian blackberries and Polish red currants that had been added to mixed berry products (Severi et al. 2015). Bulgaria is classified as an upper-middle-income country, unlike its high-income neighbors, and the 86% rate of access to improved sanitation facilities in Bulgaria in 2015 was considerably lower than the 99% European average (UNICEF/WHO 2015). The fruit products likely became contaminated as a result of poor worker hygiene or the spraying of produce with irrigation water that contained raw sewage (Tavoschi et al. 2015). At the same time that this large outbreak was occurring, separate multicountry hepatitis A outbreaks in other parts of Europe were linked to strawberries imported from Egypt and Morocco (Gossner and Severi 2014). Foodborne outbreaks of HAV in other parts of the world have also been reported with increasing frequency. A multistate outbreak in the United States in 2013 was attributed to imported frozen pomegranate arils from Turkey, which is classified as an upper middle-income country (Collier et al. 2014). Pomegranate seeds from Egypt were implicated in an HAV outbreak in Canada in 2012 (Swinkels et al. 2014). Hundreds of Australians contracted HAV from imported sundried and semidried tomatoes in 2009, and the same strain also caused a tomato-borne outbreak in the Netherlands in 2009–2010 (Donnan et al. 2012).

Preventing HAV cases caused by imported foods requires improving food-processing practices in source countries. Globalization provides opportunities to establish, strengthen, and enforce international food safety regulations and to improve information sharing about hazards (Käferstein et al. 1997). Strategies for reducing the threat from foodborne infections usually require both exporting and importing countries to be willing to invest resources in supporting enhanced food protections. Corporations involved in international food production, manufacturing, and trade can also be incentivized to take steps to better guarantee the quality and safety of food products. Without improvements, many residents of high- and middle-income countries

face an increasing risk of contracting HAV from food products as global food trade accelerates.

## HAV AND INTERNATIONAL TRAVEL

Modern transportation networks and other developments stemming from the globalization of human movement have enabled infectious diseases to spread more quickly across international borders (Gushulak and MacPherson 2000). The number of international trips increased from 25 million worldwide in 1950 to 278 million in 1980, 674 million in 2000, and 1186 million in 2015; this number is projected to reach 1.8 billion trips per year by 2030 (UNWTO 2016). These trips are distributed across the globe. In 2015, about 51% of international destinations were European countries, 24% were in the Asia-Pacific region, 16% were in the Americas, 5% were in Africa, and 5% were in the Middle East (UNWTO 2016).

Hepatitis A is one of the vaccine-preventable diseases that is most common among tourists and other international travelers (Boggild et al. 2010). The majority of travel-associated hepatitis A cases occur when residents of high-income countries (and some urban residents from middle-income countries) travel to places with higher levels of HAV endemicity. Unvaccinated travelers may contract the virus and then become ill after they have returned to their home countries. These imported viral infections may then be transmitted within households, schools, workplaces, and other social networks, and those secondary cases may cause subsequent waves of transmission. The accelerated rates of global travel that are projected to occur in the coming years could increase the number of travel-associated outbreaks in high-income and middle-income countries.

Hepatitis A vaccines can protect travelers from nonendemic and low-endemicity countries who are likely to be exposed to HAV during trips to HAV-endemic locations. An added benefit is that vaccinated travelers will not bring HAV home and cause secondary cases in non-traveling contacts. Vaccination is typically recommended for high-risk populations from high-income countries, including travelers to

higher endemicity areas as well as, in some situations, immunocompromised individuals, men who have sex with men, people who inject drugs, and healthcare workers (ACIP 2006; WHO 2012; Gossner et al. 2015). However, too many travelers are unaware of the recommendations for hepatitis A vaccination or choose to disregard advice from health professionals and other information sources. A study of people from Australia, Canada, Finland, Germany, Norway, Sweden, and the United Kingdom who were traveling to HAV-endemic countries found that a large minority of travelers had never been vaccinated against hepatitis A (Heywood et al. 2016). Hepatitis A vaccination rates have also been found to be low among travelers from Japan (Namikawa et al. 2010) and suboptimal among travelers from France, Italy, South Korea, Spain, and the United States (Chin et al. 2016; Pedersini et al. 2016; Lammert et al. 2017).

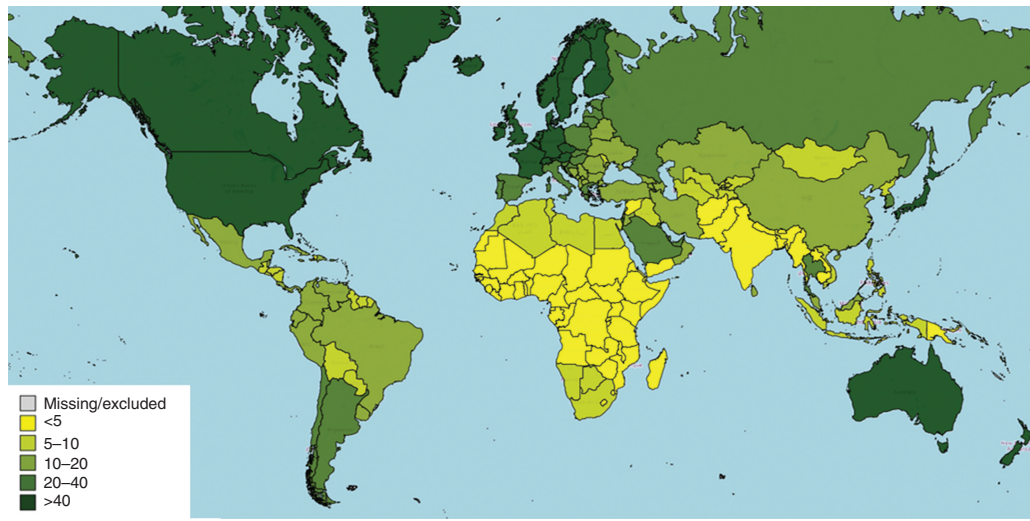

Of the cases of hepatitis A in international travelers reported between 2007 and 2011 to GeoSentinel, the global surveillance network of the International Society of Travel Medicine (ISTM), which is operated in partnership with the U.S. Centers for Disease Control and Prevention (CDC), about half of the cases were tourists engaging in leisure travel to India, Morocco, Egypt, Mexico, or other locations, about 10% were traveling for business, and about one-third were people visiting friends or relatives (VFRs) in another country (Leder et al. 2013). The VFR designation typically refers to foreign-born individuals and their children who return to the migrants' countries of origin to visit their extended families (Barnett et al. 2010). The majority of people who resettle in a new country move from a middle-income country to a high-income country (UN DESA 2016). Immigrants from places with endemic HAV will have developed natural immunity to HAV as children following asymptomatic infection, and they may not realize that their offspring who were born and raised in nonendemic areas are vulnerable to HAV and could become very ill from the virus. VFRs are significantly less likely than non-VFR travelers to be protected against HAV through vaccination, and they are more likely to report engaging in risky behaviors such as

drinking tap water and eating raw shellfish (van Genderen et al. 2012). The risks of under-vaccination of VFRs, especially children and adolescents, are apparent in travel health reports. For example, more than half of hepatitis A cases among returning international travelers living in Quebec between 2004 and 2007 were VFRs, and the majority of those cases were pediatric infections even though children accounted for only about 10% of VFRs (Bui et al. 2011).

International tourism is a sizeable proportion of the global economy, generating more than \$1.2 trillion in spending each year (UNWTO 2016). Nearly 40% of this spending—about \$500 billion—is expended in low- and middle-income countries, and travel is an important part of the economic growth strategies in many of these destinations. The proportion of international travelers heading to a low- or middle-income country is expected to grow over the coming decades (UNWTO 2016). As the proportion and number of travelers from higher-income countries who remain susceptible to HAV increase, the number of international travelers who contract HAV while abroad may increase.

## HEPATITIS A PREDICTIONS FOR A GLOBALIZING WORLD

A map showing the estimated AMPI for each country worldwide in 2015 is presented in Figure 1. AMPI values derived from serological studies are available for many countries in Europe (Carrillo-Santistevé et al. 2017) and the Middle East (Koroglu et al. 2017) as well as for Argentina (Yanez et al. 2014), Brazil (Ximenes et al. 2014), China (Lu et al. 2009), Mexico (Lazcano-Ponce et al. 2013), South Korea (Lee et al. 2011), Thailand (Sa-nguanmoo et al. 2016), the United States (Klevens et al. 2011), and several other locations. For countries without recent population-based surveys of hepatitis A seroprevalence rates by age, an estimated AMPI value was imputed based on the country's human development index and other socioeconomic and environmental indicators. Limited data availability means that there is uncertainty about the assigned values for some countries, especially in low- and middle-income areas.

**Figure 1.** Map of estimated age (in years) at midpoint of population immunity (AMPI) to hepatitis A by country in 2015.

However, regional trends are apparent. In many low-income countries, HAV continues to be highly endemic and most children contract the virus before their fifth birthday. In many high-income countries, the HAV infection rate has been so low for several decades that the AMPI now exceeds 40 years of age. Middle-income countries generally have an AMPI in middle childhood or adolescence.

Most of the world's lowest-income countries are located in sub-Saharan Africa. Lower-middle-income countries are also scattered across sub-Saharan Africa, South and Southeast Asia, and parts of Central America, Central Asia, the Middle East, and Oceania (World Bank 2017). Many of these low- and lower-middle-income countries have high HAV incidence rates. Nearly all adult residents of these countries became infected as very young children and developed life-long immunity. However, the incidence rate is decreasing in lower-middle-income regions and may decrease in low-income areas during the coming decades as the countries' economies and infrastructure develop. The Millennium Development Goals (MDGs) launched in 2000 spelled out a poverty-reduction strategy that provided low-income countries and their partners with specific targets for improving population-level socioeconomic, environmental, and

health metrics. Between 1990 and 2015, the percentage of the world's people living on less than \$1.25 per day dropped from 47% to 14%, while access to an improved drinking water source increased from 76% to 91% (United Nations 2015a). The Sustainable Development Goals (SDGs) that will guide global development strategies between 2016 and 2030 promote further reductions in poverty and increases in access to water, sanitation, hygiene, vaccination, medication, clinical care, and other tools for health (United Nations 2015b). The SDG targets for water and sanitation may be especially important drivers of reduced HAV burden in lower-income countries. Access to an improved sanitation facility only increased from 54% to 68% between 1990 and 2015, and rural areas continue to lag behind urban areas in both water and sanitation access (United Nations 2015a). Under the SDGs, access to utilities will increase and disparities between regions are expected to decrease.

As the HAV incidence rate decreases and a larger pool of young children avoid exposure to the virus, a growing number of children, adolescents, and young adults in lower-income countries will remain vulnerable to HAV into their school years and beyond. This trend is already being observed in some relatively wealthy urban

areas within lower-middle-income countries. For example, a study of 3683 military recruits from across India in 2010–2011 found that >7% of these young adults remained susceptible to HAV (Kotwal et al. 2014). There may also be some small pockets of vulnerability to HAV emerging in higher-income urban areas of lower-middle-income countries in West Africa (Jacobsen 2014). This could indicate that an HAV epidemiological transition is starting in these regions. This shift toward a lower level of endemicity will likely be gradual, in part because HAV survives so well in water and soil (Sobsey et al. 1986). As this transition occurs, the number of cases of symptomatic hepatitis A in these countries is likely to increase.

At present, the lowest-income countries are not major exporters of food, so they are playing a limited role in trade-related HAV exportation. As these countries' economies grow, they may become food exporters and play a greater role in foodborne outbreaks of HAV in other world regions. Low-income countries already receive a sizeable number of international travelers, including tourists and heritage visitors as well as business travelers, and the number of international guests will increase in the coming years. If these travelers are not protected against HAV by vaccination or prior infection, they are likely to contract the virus and bring it home.

The world's highest-income countries are located primarily in Europe, North America, and Australasia, and they are also found in parts of the Middle East and East Asia, including Japan and the Republic of Korea (World Bank 2017). HAV is not endemic in these areas, and because these countries have had very low incidence rates for several decades they have populations that are highly susceptible to hepatitis A. The number and magnitude of outbreaks of hepatitis A is likely to increase somewhat as a result of globalization processes. Travel vaccines prevent hepatitis A cases in international travelers and limit the number of secondary cases that could occur among the contacts of infected travelers. However, most hepatitis A cases in high-income countries occur among people who have not traveled internationally in the months before the onset of symptoms (Gossner et al. 2015;

CDC 2017). Few adults who live in high-income countries have been vaccinated against HAV, and a large proportion of older adults remain susceptible to HAV (Jacobsen and Wiersma 2010). Outbreaks from imported foods can affect hundreds or thousands of people, and infected adults may miss many weeks of work and require costly hospitalizations. Large, expensive multicountry outbreaks of hepatitis A attributable to imported foods are occurring more frequently than they did in previous decades (Gossner et al. 2015; Tavošchi et al. 2015). If hepatitis A outbreaks become more common, it may be helpful for economists to examine the potential value of hepatitis A vaccination for protecting members of the workforce in high-income countries from the lengthy absences that could be caused by severe acute hepatitis.

The world's middle-income countries are located in Central and South America, East Asia, and parts of North Africa, the Middle East, Central Asia, Southeast Asia, Southern Africa, and Eastern Europe (World Bank 2017). Middle-income countries have diverse patterns for HAV, with even small differences in economic status linked to different HAV profiles. The AMPI is shifting into adolescence and early adulthood in many countries, but there are often significant rural–urban and other differences within subpopulations (Van Effelterre et al. 2017a,b). For example, there is an east-to-west gradient of decreasing levels of HAV endemicity in Turkey (Demiray et al. 2016) and a north-to-south gradient of lowering risk in Brazil (Ximenes et al. 2014). Geographic differences in risk have also been observed in other upper-middle-income countries.

Middle-income countries are the places where universal childhood vaccination is most likely to be recommended, because there is still a moderate risk of infection for residents through contaminated food, water treatment system failures, intracountry travel to rural areas, and other exposures, and the increasing AMPI means that many of the people who contract HAV are old enough to be at risk of acute liver failure. In upper-middle-income countries, universal childhood vaccination against hepatitis A is often

found to be a cost-effective public health intervention (Suwantika et al. 2013), in addition to protecting vaccinated children and the adults in their families from the direct and indirect household costs associated with infection. For example, cost-effectiveness analyses have suggested that universal childhood vaccination would be a good investment in countries as diverse as Brazil (Sartori et al. 2012), Indonesia (Suwantika et al. 2014), and Mexico (Carlos et al. 2016). Routine childhood vaccination against hepatitis A has already been introduced in several middle-income countries (WHO 2017).

Middle-income countries play an important role in the global epidemiology of HAV, and they are likely to continue to play a key role in global transmission cycles. Many middle-income countries are food exporters, and they are implicated in a growing number of foodborne outbreaks in higher-income countries. They also are a common destination for international travelers, and the number of flights between high-income and middle-income countries is increasing. As middle-income countries' economies grow, they are likely to switch from being countries that are distributing HAV to other world regions to being nonendemic countries that are vulnerable to HAV outbreaks sparked by international trade and travel originating in lower-income regions.

### CONCLUDING REMARKS

Pandemics of infectious diseases began occurring soon after global trade routes opened in the 16th century. By the early 1800s, widespread cholera outbreaks were occurring in waves (Lee and Dodgson 2000). Starting in 1851, a series of International Sanitary Conferences were convened to establish infectious disease prevention regulations that would protect public health while allowing international trade to continue (Huber 2006). The resulting International Sanitary Regulations formed the foundation for the International Health Regulations that guide global communication about shared threats to health today. Global trade is even more critical for the economic security of countries around the world today than it was when the original

international health treaties were negotiated. Even when countries adopt nationalist policies that seek to limit some aspects of international commerce and migration, it would be impossible and unwise to attempt to block all food imports and stop all international travel (including travel by diplomats and other government officials, military personnel, and other people whose work is critical to national interests). In a globalized world, pathogens easily spread between places and populations. No country will be able to completely eliminate its risk from hepatitis A while HAV remains endemic in any part of the world.

Although the trends in hepatitis A epidemiology point to a steadily decreasing incidence rate at the global level, the distribution of risk is not uniform. The lowest-income countries have a high incidence rate but a low disease burden. The highest-income countries have a very low incidence rate, but the individuals who become infected have a high likelihood of requiring hospitalization and a risk of death from acute liver failure. Middle-income countries that are transitioning toward nonendemic status may temporarily experience an increased burden from severe hepatitis as the age at infection increases. The epidemiological changes in hepatitis A that occur in countries across the income spectrum in the coming decades will be heavily influenced by globalization processes.
