Conflict of Interest:

All the authors contributed to the Review Article and had no conflict of interest with any other party. Hira Peracha, Kazuki Sawamoto, Lauren Averill, Heidi Kecskemethy, Mary Theroux, Mihir Thacker, Kyoko Nagao, Christian Pizarro, William Mackenzie, Hironori Kobayashi, Seiji Yamaguchi, Yasuyuki Suzuki, Kenji Orii, Tadao Orii, Toshiyuki Fukao, Shunji Tomatsu declare that they have no conflict of interests.

Contributions to the project:

Hira Peracha has contributed to the concept and planning of the project, collection of data from the publications, the draft of the manuscript, and reporting of the work described as the primary author.

Kazuki Sawamoto has contributed to the concept and planning of the project, collection of data, data analysis, the draft of the manuscript, and reporting of the work described.

Lauren Averill has contributed to the concept and planning of the project, analysis of images on x-rays, MRI, and CT, and reporting of the work described.

Heidi Kecskemethy has contributed to the concept and planning of the project, analysis of images on DXA, and reporting of the work described.

Mary Theroux has contributed to the concept and planning of the project, data and interpretation on airway, and reporting of the work described.

Mihir Thacker has contributed to the concept and planning of the project, interpretation of x-rays, clinical manifestations of spine and lower extremities, and reporting of the work described. Kyoko Nagao has contributed to the concept and planning of the project, hearing test, and reporting of the work described.

Christian Pizarro has contributed to the concept and planning of the project, tracheal surgery, and reporting of the work described.

William Mackenzie has contributed to the concept and planning of the project, spine and knee surgeries, and reporting of the work described.

Hironori Kobayashi has contributed to the concept and planning of the project, interpretation of GAG data, and reporting of the work described.

Seiji Yamaguchi has contributed to the concept and planning of the project, interpretation of GAG data, and reporting of the work described.

Yasuyuki Suzuki has contributed to the concept and planning of the project, interpretation of clinical data, and reporting of the work described.

Kenji Orii has contributed to the concept and planning of the project, interpretation of clinical data, and reporting of the work described. Tadao Orii has contributed to the concept and planning of the project, interpretation of clinical pictures, images, and GAG data, interpretation of published data and reporting of the work described.

Toshiyuki Fukao has contributed to the concept and planning of the project, interpretation of clinical data, and reporting of the work described.

Shunji Tomatsu is a Principal Investigator for this project and has contributed to the concept and planning of the project, interpretation of published data, and reporting of the work described.

Abstract

Mucopolysaccharidosis IVA (MPS IVA, Morquio A syndrome) is an autosomal recessive disorder caused by the deficiency of N-acetylgalactosamine-6-sulfate sulfatase. Deficiency of this enzyme leads to the accumulation of specific glycosaminoglycans (GAGs), chondroitin-6-sulfate (C6S) and keratan sulfate (KS), which are mainly synthesized in the cartilage. Therefore, the substrates are stored primarily in the cartilage and its extracellular matrix (ECM), leading to a direct impact on bone development and successive systemic skeletal spondylepiphyseal dysplasia. The skeletal-related symptoms for MPS IVA include short stature with short neck and trunk, odontoid hypoplasia, spinal cord compression, tracheal obstruction, obstructive airway, pectus carinatum, restrictive lung, kyphoscoliosis, platyspondyly, coxa valga, genu valgum, waddling gait, and laxity of joints. The degree of imbalance of growth in bone and other organs and tissues largely contributes to unique skeletal dysplasia and clinical severity. Diagnosis of MPS IVA needs clinical, radiographic, and laboratory testing to make a complete conclusion. To diagnose MPS IVA, total urinary GAG analysis which has been used is problematic since the values overlap with those in age-matched controls. Currently, urinary and blood KS and C6S, the enzyme activity of GALNS, and *GALNS* molecular analysis are used for diagnosis and prognosis of clinical phenotype in MPS IVA. MPS IVA can be diagnosed with unique characters although this disorder relates closely to other disorders in some characteristics.

In this review article, we comprehensively describe clinical, radiographic, biochemical, and molecular diagnosis and clinical assessment tests for MPS IVA. We also compare MPS IVA to other closely related disorders to differentiate MPS IVA. Overall, imbalance of growth in MPS IVA patients underlies unique skeletal manifestations leading to a critical indicator for diagnosis.

Keywords

mucopolysaccharidosis IVA; N-acetylgalactosamine-6-sulfate; keratan sulfate; chondroitin-6-sulfate; spondyloepiphyseal dysplasia

1. Introduction: Historical Aspect for MPS IVA

Mucopolysaccharidosis IVA (MPS IVA) also known as Morquio A syndrome is an autosomal recessive disorder caused by the deficiency of N-acetylgalactosamine-6-sulfate sulfatase (GALNS). This enzyme deficiency leads to a progressive accumulation of excessive glycosaminoglycans (GAGs): chondroitin-6-sulfate (C6S) and keratan sulfate (KS).

These excessive GAGs are stored primarily in the cartilage and its extracellular matrix (ECM) because C6S and KS are mainly produced in the cartilage [1]. The storage of GAGs within the lysosomes disrupts cell function and metabolism in cartilage [2], resulting in a direct impact on cartilage and bone development, failure of ossification, imbalance of growth, and successive unique systemic skeletal dysplasia [1,3,14]. Excessive C6S and KS are secreted in blood and excreted in the urine of patients with MPS IVA. Staprans et al. have described that GAGs in plasma are not covalently linked to plasma proteins and are isolated as complexed with plasma proteins in noncovalent linkages [4].

In 1929, Dr. Luis Morquio, a pediatrician in Uruguay, first reported 4 Swedish siblings with unique skeletal dysplasia, later classified as Morquio A syndrome (MPS IVA). Those patients reported had disproportionate short-trunk, hypermobile joints, prominent forehead, abnormal face with a large mandible, short neck, pectus carinatum, kyphoscoliosis, flaring of the rib cage, genu valgum, and pes planus [5]. At that same year, Dr. Brailsford, a radiologist in the UK, also reported a patient with similar skeletal manifestations, except that aortic valve disease and corneal clouding were not described in the original publication [6]. In 1962, Pedrini et al. reported urinary excretion of KS in three patients with Morquio syndrome, showing that this metabolic disorder differs from other mucopolysaccharidoses [6]. In 1965, McKusick et al. classified Morquio as MPS IVA [7]. Dr. Orii et al. reported patients with milder forms of MPS IVA [8,9].

These reports have demonstrated that patients with MPS IVA have a wide range of clinical heterogeneity and that the diagnosis of MPS IVA, especially with the attenuated form, can be difficult and delayed. Clinical phenotype and consequent prognosis are primarily determined by the extent of imbalance of growth between bones (flat bones - skull, hip, sternum, ribs; spine; short and long bones; sesamoid bones), trachea, vessels, and organs, leading to serious morbidity and mortality with spinal cord compression and restrictive lung and obstructive airway [9].

2. Diagnosis

2.1. Clinical Diagnosis

Diagnosis of MPS IVA begins with the development of unique clinical manifestations, which can occur from either clinical findings and/or radiographic findings [10]. Some symptoms that can be noticed at birth include prominent forehead, pectus carinatum, kyphosis (gibbus), and abnormal findings in the lumbar vertebral bodies in X-rays [12–15]. Gibbus, in particular, is often the first sign noticed in MPS IVA [11]. Diagnosis of MPS IVA patients is often not made until a few years of age since the majority of patients seem normal at birth, and normal levels of total urine GAG are observed in some cases [12].

GAG accumulation along the upper airway induces enlarged tongue, adenoidal, tonsillar, and vocal cord hypertrophy, and large mandible. GAG accumulation in the lower airway and cervicothoracic part results in an imbalance of growth between spine, rib, and manubrium vs. trachea and vessels in thoracic inlet causing consequent bulging and twisted narrowing trachea [13]. Respiratory involvement is seen with recurrent respiratory infections, upper and lower airway obstruction, tracheomalacia, restrictive lung, shortness of breath, loud

snoring, look up to the sky position (head and neck maintained in extension), and sleep apnea [14]. Unlike other types of MPS, hypermobile joints (fingers, wrists, neck, and knees) are commonly observed; however, decreased joint mobility can be observed in the large joints including shoulder, elbows, and hips [15].

There is a broad phenotypic spectrum in MPS IVA ranging from a rapid progressive early-onset form (severe) to a slowly progressive late-onset form (attenuated) [16].In patients with the severe phenotype of MPS IVA, spinal cord compression, airway compromise, and later valvular heart disease are the leading causes of high morbidity and mortality, contributing to the shortened lifespan of individuals to the first few decades of life if untreated [13,17]. The severe form is characterized by hypermobile wrist joints, kyphosis, scoliosis, pectus carinatum, deformity of vertebral bodies, disproportionate stature with short trunk, knock knee (genu valgum), and waddling gait [16]. Due to the progressive and often life-threatening nature of the disease [16], early and accurate diagnosis is critical for optimal patient management [10], which provides a better quality of life and prolonged lifespan [17]. Respiratory failure has been shown as the primary cause of death in patients (63%), followed by cardiac failure (11%), post-traumatic organ failure (11%), complications of surgery (11%), and myocardial infarction (4%) [17].

Patients with the attenuated form of the disease can survive for over 70 years if well-managed [18] and might have late-disease onset during late childhood or adolescence, and often first manifests hip problems (pain, stiffness) as the primary symptom [9] (Fig. 1). Clinical features are limited to minor skeletal abnormalities, hip pain, and moderate short stature associated with the early-onset osteoporotic phenotype [19].

According to the International Morquio A Registry, the most common initial signs are short stature (49.9%), genu valgum (45.1%), kyphosis (44.4%), pectus carinatum (43.6%), and abnormal gait (37.8%). The most common current symptoms and the percentage of the present signs and symptoms are short stature (84.7%), genu valgum (78.7%), pectus carinatum (71.4%), kyphosis (70.4%), abnormal gait (64.4%), and laxity of wrist joints (63.2%) [20] (Fig. 2).

As the disease progresses regardless of the phenotype of the disease, more signs and symptoms begin to appear. With increasing age, joint laxity and skeletal deformities become more evident, and patients typically require support by orthopedic interventions [18]. The combination of bone and joint impairment leads to pain and arthritis causing the subsequent inability of walking, restriction of range of motion, and consequently decreased activity of daily living [9].

2.2. Biochemical Diagnosis

2.2.1. Urinary and Blood GAG—Urine-based testing for total GAG is considered only a screen and provides substantial false negatives; it is recommended that KS measurement, as well as enzymatic testing, are used to confirm the diagnosis of MPS IVA [20]. Measurement of urinary GAGs is performed both quantitatively and qualitatively [20]. While a gross elevation of urinary GAGs is normally specific for patients with other types of MPS, borderline or slightly evaluated values are common in those with MPS IVA [21–24].

False negative results are found for almost 15% of all MPS patients [23] and even more for MPS IV patients [21–23]. The urinary excretion of GAGs is high in infants and young children, decreases with age, plateaus by the second decade of life, and remains constant through adulthood [22,23,25–27]. The qualitative analysis of total urinary GAGs is usually performed by spectrophotometric analysis using dimethylmethylene blue (DMMB) [28]. For qualitative urine-based testing methods, the GAGs are first isolated from the urine and then separated by thin layer chromatography or electrophoresis [29–32].

2.2.2. Keratan Sulfate (KS)—KS is mostly synthesized and accumulated in the cartilage and cornea in MPS IVA patients, and excessive accumulation of KS in lysosome leads to disruption of chondrocytes and subsequent increase of KS levels in blood and urine [33]. We had two autopsied cases. The first autopsied case died of respiratory complication with tracheal obstruction after cervical fusion at 20 years old [35]. The second case died of respiratory failure with tracheal obstruction as well. In both casess, the chondrocytes in various bones had accumulation of storage materials [34]. We have analyzed over 20 cases of surgical remnants with various bones. All chondrocytes were vacuolated and were severely affected [13,34–36]. Primary synthesis of KS in chondrocytes and successive storage of KS in chondrocytes because of the deficiency of GALNS enzyme proves the cartilage as the main source of KS in blood circulation.

The detection of KS in biological specimens with tandem mass spectrometry (MS/MS) has been developed first by Oguma et al. [37] and applied to specimens in MPS IVA patients and distinguished between control subjects and MPS IVA patients without the false negatives [38–40]. Blood and urine KS levels are higher in MPS IVA patients, compared with age-matched controls [12, 37–39]. Urine KS levels remain higher or subnormal in MPS IVA patients than those in controls after 20 years of age; however, blood KS levels tend to be normalized by the age of 20 years [38–40].

Using sandwich ELISA [21,41] and LC/MS/MS [37,39] assay, the study was conducted for KS levels in blood and urine from MPS IVA patients and healthy controls to evaluate the comparability of results. Blood, urine, and other biological samples were purified by filtration and GAGs are digested with chrondroitnase ABC and keratanase II to yield disaccharides of C6S and KS, respectively. After digestion, the samples were injected into the LC-MS/MS [38,40,42–45].

The levels of blood and urine KS correlate with clinical severity during the early and progressive stage of the disease, and therefore, it is a good prognostic biomarker at this stage [12]. Blood KS directly displays growth, turnover disruption, and/or repair of cartilage where it is mainly synthesized [12]. The advantage of measurement of KS in dried blood spot (DBS) testing is its convenience for transport of samples and screening purposes [12]. In contrast, urine KS has a broader range of value and may not reflect cartilage condition directly. KS is synthesized mainly in cartilage. Depending upon the extent of destruction of cartilage in MPS (not only IVA but other types), KS level was increased in blood [12,21,46]. The levels of blood and urine KS also correlated with clinical severity during the early and progressive stage of the disease [21] and therefore, it is a good prognostic biomarker at this stage. Urine KS comes via kidney, and urine KS is filtered in kidney. Therefore, only

selected smaller molecules are excreted in urine [12,47]. When MPS IVA patients are treated with ERT, it is likely that urine KS levels are reduced rapidly since the enzyme is delivered to kidney and digests the KS stored in the kidney [48]. Thus, urinary KS is useful to differentiate MPS IVA from other forms of MPS and to demonstrate pharmacodynamic effects of therapy while it does not provide a valuable predictor (biomarker) of skeletal or clinical improvement during these therapies for MPS IVA [49]. It is noteworthy that the origin and character of urinary GAGs are different from those of blood GAGs as seen is KS [50,51].

The ratio of di-sulfated KS to total KS in urine is much higher than that in blood [52]. There is a negative correlation between blood and urine for levels of mono- and di-sulfated KS in ERT-treated MPS IVA patients, suggesting reduction of urine KS level does not reflect blood KS level [52].

GALNS plays a role as galactose-6-sulfatase (G6S) because the enzyme hydrolyzes the sulfated galactose of KS and converts di-sulfated KS to mono-sulfated KS [49,52]. Therefore, deficiency of GALNS activity leads to the accumulation of more di-sulfated KS, and therefore, the ratio of di-sulfated KS to total KS of patients with MPS IVA increases, compared with normal controls especially at an early stage [49]. Levels of both mono-sulfated and di-sulfated KS in blood were measured by LC/MS/MS, and patients with MPS IVA had higher KS with both forms, compared with age-matched controls [53]. The elevation of di-sulfated KS in MPS IVA patients was more significant than that of mono-sulfated KS [49]. The proportion of di-sulfated KS vs. total KS in blood rose with age in control subjects while it was age-independent in patients with MPS IVA. The proportion of di-sulfated KS is better at distinguishing younger MPS IVA patients than older patients from age-matched controls. Levels of mono- and di-sulfated KS in the urine of MPS IVA patients were also higher when compared to those in age-matched controls for all studied ages. A significant difference in sulfation levels of KS between control subjects and patients with MPS IVA indicates that di-sulfated KS is another potential biomarker for MPS IVA [49]. Overall, determination of urine KS concentration provides a potential biomarker to screen for a high risk of MPS IVA patients and to measure pharmacodynamics effects [54]. This is important for assessing the clinical status at the initial progressive stage. Blood KS could be used for 1st tier newborn screening followed by the enzyme essay or vice versa [12] and is a potential biomarker to provide the clinical severity and therapeutic effect for the bone at the initial progressive stage [47].

2.2.3. Chondroitin-6-sulfate (C6S)—The GALNS enzyme plays an important role in converting C6S to CS, by hydrolyzing the sulfate group in C6S. Measurement of C6S has been developed by LC/MS/MS [55]. It is important that the data of C6S and KS are reported together, as the information provided enhances discrimination of patients from controls compared to C6S or KS levels alone [3,55]. Thus, C6S could be another useful biomarker for MPS IVA [55]. Overall, blood and urine KS and its sulfation level should be measured for diagnosis, the prognosis of the phenotype, and assessment of pharmacokinetic efficacy. Blood KS and/or C6S could be a biomarker for therapeutic effect only at presymptomatic to the early progressive stage but not beyond the progressive stage.

2.2.4. Enzyme assay—In 1976, the enzyme deficiency in MPS IVA (GALNS deficiency) was identified [56]. GALNS acts on 2 substrates: N-acetylgalactosamine-6-sulfate (GalNAc-6S) [57] and galactose-6-sulfate (Gal-6S) [58,59].

GalNAc-6S is a component of C6S, and Gal-6S is a component of KS [57–59]. These substrates are both used currently to demonstrate deficient GALNS activity [10]. The GalNAc-6S based assay uses radio-labeled natural substrate [60], and the Gal-6S based assay uses a fluorogenic artificial substrate [61]. GALNS activity is determined based on the amount of radioactivity released from this substrate with a lack of GALNS activity, resulting in the low generation of the signal [61]. The fluorogenic assay uses the 4-methylumbelliferyl-β-D-galactopyranoside-6-sulfate (4MU-Gal6S) substrate [61]. GALNS present in the sample first removes the 6-sulfate, and then exogenous β-galactosidase removes the galactoside, freeing the 4-methylumbelliferone adduct, which will fluorescent under high pH [61]. The addition of exogenous β-galactosidase to the reaction mixture is critical because conditions in which β-galactosidase is deficient would result in significant GALNS activity underestimation and possibly misdiagnoses [61].

To facilitate prenatal diagnosis, prenatal samples, such as dissected chorionic villi, cultured chorionic villus cells, and amniocytes can also be used [62,63]. Fibroblasts and leukocytes are recommended for diagnosis of the deficiency in GALNS activity [64]. Protocols for evaluating GALNS activity in DBS samples have recently been proposed as screening methods [65,66]. Leukocytes that are isolated from whole blood are better for more rapid analysis as cell culture is not required [67].

Fibroblast samples are recommended for enzyme activity analysis due to the impact of environmental and logistical factors during shipment can be minimized and corrected through culturing of the cells [10]. The measurement of GALNS activity in DBS is useful for screening, but it is not as robust as it is in fibroblasts or leukocytes due to the low number of cells present in the sample [10]. More data is needed to evaluate GALNS stability in DBS because DBS samples are more likely to be unprotected to environmental extremes during shipping in comparison to leukocytes [10]. The activity of a reference enzyme with similar stability in the same sample should be measured to confirm that the low GALNS activity is not the cause of sample degradation [10]. If the DBS sample is used, measuring a reference enzyme in the same sample to confirm integrity is recommended, but it may not be enough to rule out an effect of handling on GALNS activity due to the stability of GALNS as compared to other enzymes in a DBS which remains unknown [10].

The MS/MS-based method using a novel substrate has recently been developed [68]. Incorporation of this new assay into a multiplexed lysosomal storage disease panel for use in newborn screening programs is being considered [69].

MPS IVA can also be diagnosed with DNA sequencing methods, where the coding regions of the GALNS gene and small segments of immediately adjacent intronic regions are evaluated. Multiple MPS IVA mutations are believed to be found in only one individual or even one family [70]. DNA sequencing-based methods identify missense and nonsense mutations, small insertions and deletions in the coding regions; however, splicing alterations

or changes in copy number can be missed [71,72]. A variety of methods are available including PCR, comparative genomic hybridization and multiplex ligation-dependent probe amplification [70].

No example of pseudodeficiency allele or complex allelic interaction is currently described for MPS IVA; however, Morrone et al. believes that the possibility warrants caution and the analysis of mutations in the context of complete and accurate patient genotypes [73].

2.3. Radiographic diagnosis

2.3.1. Skeletal Manifestations—When MPS IVA is suspected, radiographic imagining should be performed as a component of the diagnostic process [10]. A patient should obtain a skeletal survey to allow evaluation of the skull, complete spine (including flexion-extension lateral views), chest, hips, and limbs (particularly, hands, wrists, and knees) because of the wide variation and subtleties of radiographic findings in MPS IVA [10].

2.3.2. Skull—In 8 out of 14 individuals with MPS IVA, subtle abnormal brain MRI findings such as prominent perivascular space, enlarged lateral ventricles, and prominent frontal cerebrospinal fluid (CSF) were reported [74].

3.3.3. Spine—Children with MPS IVA have instability of the neck, odontoid hypoplasia, ligamentous laxity, incomplete ossification of the anterior and posterior rings of the atlas, and spinal cord compression [12,16,75,76] (Fig. 3). Spinal cord compression may occur in any spinal segment; however, cervical spinal compression is the most common site [9]. Spinal cord compression may be due to several factors such as cervical instability, ossified fibrocartilage associated with an abnormal odontoid process, ligamentous laxity, cartilaginous and ligamentous hypertrophy at the atlantoaxial joint, GAG deposition in the extradural space, disc protrusion, kyphoscoliosis, and acquired central canal stenosis [18,77–80].

If MPS IVA is suspected or diagnosed in a patient, frontal and lateral radiographs of the spine should be evaluated [80]. Spinal involvement in MPS IVA occurs at 2 distinct sites; cervical and thoracic [80]. Cervical spinal involvement, particularly instability and compression at the C1-C2 level, is a nearly universal finding and predisposes patients to myelopathy, paralysis, and sudden death [18]. Knowledge of the unique anatomy and pathology of the atlantoaxial (C1-C2) system facilitates radiological detection of upper cervical spine anomalies [80]. Spinal cord compression at the cervicothoracic or the thoracolumbar level due to kyphotic deformity can lead to paraplegia with gradual onset and all of its devastating consequences, although it is not common [81,82]. A lateral cervical spine x-ray of a 6-year-old female patient showed hypoplastic odontoid, platyspondyly, and anterior subluxation on C7 on T1 [9]. If cervical spine instability is suspected on plain film or with inconclusive radiographic findings, then flexion-extension cervical spine MRI can be used to evaluate cord compression [9]. Flexion-extension CT with sagittal reformation and soft-tissue filtration showed cone-shaped dens, a thickened cruciate ligament, and small thick cartilaginous posterior arch of C1. With flexion, there is a narrowing of the canal between the body of C2 and the cartilaginous posterior arch of C1.

2.3.4. Upper Extremities—Characteristic radiographic findings in hand and distal forearms of individuals with MPS IVA include a short ulna, ulnar deviation of the radial epiphysis, and delayed maturation of the carpal bones; the scaphoid, however, may not be radiographically present [20,83]. Metacarpals may be short and the proximal ends of the second through fifth metacarpals are typically rounded or pointed [20,83]. The upper extremities involvement is progressive and affects the wrist strength in some activities of daily living [9].

2.3.5. Lower Extremities—The lower extremity involvement is universal and progressive if untreated [84,85]. The most common lower extremity deformities are knee and ankle valgus. Genu valgum results from distal femoral and proximal tibial involvement and joint laxity [9]. Children with MPS IVA have unique waddling gait, a slower walking speed, reduced cadence, and reduced stride length [86]. The hips are either normal or slightly subluxated to start and may progressively dislocate over time [12]. The capital femoral epiphyses are smaller and progressively flattened, and many become fragmented over time [12]. The articular cartilage is abnormal and will degenerate promptly and build up early arthrosis, especially in the lower extremities [12].

2.3.6. Hips—Early in the disease course, the capital femoral epiphyses are small, and the acetabuli are shallow [9]. Affected individuals can become wheel-chair bound due to the following gradual and destructive changes in the femoral head and acetabuli resulting in hip dislocation, arthritis, and severe joint restriction [18] (Fig. 4). A hip x-ray of an 8-year-old female showed a bilateral irregular flattening of the capital femoral epiphyses and irregular dysplastic acetabuli with lateral joint subluxation [9].

2.3.7. Knee—The knee is the most commonly affected lower extremity joint in MPS IVA. Laxity of the collateral ligaments aggravates the deformity [87]. The proximal tibia contributes to more knee deformity than the distal femur, and there may also be procurvatum of the distal femur with recurvatum of the proximal tibia [87]. Arthrograms or magnetic resonance imaging (MRI) of the knees in MPS IVA patients shows that the proximal lateral portion of the tibia is unossified and the fibula is short; these results offer clarity of the bony and cartilaginous nature of the deformity [18]. Knee valgus causes the ground force to be shifted laterally, which forces the knee to go into further valgus [87] (Fig. 5). Correction of knee valgus using guided growth, such as the 8-plate hemiepiphysiodesis, is proven to be effective as the child is growing [84]. Multiplanar and more severe deformities may be corrected with osteotomies around the knee [88].

2.3.8. Ankle—The ankles of MPS IVA patients are typically in valgus with wedging of the distal tibial epiphysis and shortening of the fibula [87]. The patients might have hindfoot valgus, some degree of equinus in the hindfoot, and adductus in the forefoot [87] (Fig. 6). Ankle valgus can be managed by orthotics but sometimes may require surgical correction such as guided growth or an osteotomy [84]. On lateral images, tarsal bones are irregular, and the talus appears to be plantarflexed [87]. Recurrence of the knee and/or ankle valgus is not uncommon in MPS IVA patients [89].

Imaging of x-rays, computed tomography (CT), and MRI is important for the diagnosis of MPS IVA because of the evaluation of cervical spine instability, stenosis, and cord compression [80]. Radiographs are the mainstay for assessing and monitoring lower extremity bone involvement; two dimensional CT provides detailed information on the bone structure and also allows for precise determination of the bony dimensions [87,90]. However, progressive fragmentation and collapse of the osseous structures can lead to false assumptions regarding the anatomy around joints [87]. To get a more accurate picture of the non-ossified structures and the articular surfaces, arthrography or MRI will be needed [87]. The cartilaginous part of the epiphysis is often not as deformed as could be predicted by the plain radiographs [87]. CT does not offer the ability to assess the health of the spinal cord itself [80]. The detection of canal stenosis, cord compression, and myelomalacia is critical to check for the disease progression [80]. MRI is the most useful method for evaluating the neural axis in MPS IVA and is also currently considered the imaging method of choice for evaluating the spinal cord [80]. No other imaging method provides superior information about the soft tissues, including the cartilage, ligaments, dura, spinal cord, and nerve roots [80].

2.3.9. Imbalance of Growth—MPS IVA is characterized by accumulation of GAGs in chondrocytes, the incomplete ossification, and the successive imbalance of growth, which cause unique clinical features of disproportionate short trunk, hypermobile joints in hands and fingers, a prominent forehead, an abnormal face with a large mandible, short neck, cervical spinal cord compression, tracheal obstruction with crowd thoracic inlet, pectus carinatum, flaring of the rib cage, coxa valga, genu valgum, and pes planus [5,8,18,20,57,91–93].

The frontal bone, parietal bone, occipital bone, and the mandible keep growing, causing MPS IVA patients to have an enlarged head, a prominent forehead, and a large mandible. The cervical spine in the region C1-C7 halts growing earlier in patients with MPS IVA, causing the patients to have a short neck. Cervical spine shows platyspondyly and typical beaking of the anterior margin of the vertebral bodies, causing kyphosis as well as instability of the atlantoaxial joint and spinal cord compression (Fig. 7). Tracheal abnormalities which include stenosis, tortuosity ultimately resulting in obstruction is due to several factors, including the imbalance of growth in patients with MPS IVA. The thoracic spine from T1 to T12, as well as the lumbar region of the spine from L1 to L5, stop growing early causing patients with MPS IVA to have a short trunk. Pectus carinatum is marked deformity of the anterior chest wall because the ribs (costal cartilage) overgrow compared with other parts of the body, causing restrictive lung [94]. The wrist joints show marked hyperlaxity because the ulna stops growing earlier and the radius continues to grow, resulting in an ulnar deviation of the wrist. The metacarpals and carpals grow slowly in patients affected by MPS IVA. The growth plates are wide with mild generalized brachydactyly and hypoplastic carpal centers [95] (Fig. 9). Hip deformities are caused by a combination of the bilateral flattening and fragmentation of the capital femoral epiphyses and acetabular dysplasia with lateral joint subluxation [9]. The pelvis shows wide flared iliac bones laterally [96]. Genu valgum is caused by the mechanical axis shift laterally, where pathologic stress is placed on the lateral femur and tibia which inhibits growth [97]. The lower limbs malalignment is evaluated with

the measurements of the mechanical axis deviation (MAD) [98]. The patellofemoral joint may become shallow, incongruous, or unstable, causing activity-related knee pain in patients [97]. Patients will not only have knee pain and laxity, but they can develop a circumduction gait, in which each leg is swung outward to avoid knocking their knees together due to genu valgum [97].

2.4. Non-Skeletal Manifestations

2.4.1. Ophthalmology—The most common ophthalmologic findings are related with slowly progressive corneal clouding (Fig. 10). Generally, in patients with MPS, corneal opacification of varying severity is frequently seen, as well as retinopathy, optic nerve swelling and atrophy, ocular hypertension and glaucoma [99]. Other ophthalmologic findings that are less common are astigmatism, cataracts, punctate lens opacities, open-angle glaucoma, optic disc swelling, optic atrophy and retinopathy [89,100]. Ocular manifestations are common in MPS and may result in significant visual impairment [99]. Corneal opacification often causes reduced vision in the early childhood of MPS IVA patients, necessitating penetrating keratoplasty for which the outcome can vary [9]. In a study with 20 patients aged 1-65 years, with MPS IV, in which the subtype A or B was not specified, 10 eyes had no corneal clouding, 17 eyes had mild corneal clouding, 4 eyes had moderate corneal clouding, and 4 eyes had severe corneal clouding (corneal clouding was not graded in 5 eyes) [101]. The severity of corneal clouding was related to the increasing age of the patient and results in the reduction in visual acuity [101]. The corneal deposits can also interfere with examination of the other ocular structures, such as the trabecular meshwork, the retina, and the optic nerve [100].

While visual acuity is better in MPS IVA patients compared to other MPS patients, the corneal clouding, refractive errors, glaucoma, and cataracts can affect the visual acuity as the patient ages [100]. Glaucoma or ocular hypertension seems to be unusual in MPS IVA [102]. Electron microscopy shows distended trabecular endothelial cells with a thickened basement membrane in MPS IVA [100]. The inclusions in the trabecular meshwork are primarily multi membranous, whereas other types of MPS inclusions are more fibrillogranular [103,104]. This most probably explains the reduced prevalence of ocular hypertension and glaucoma in individuals with MPS IVA [103,104].

Annual eye examinations should be performed in MPS IVA patients and should include the following: slit-lamp biomicroscopy of the cornea, measurement of intraocular pressure, assessment of refractive error, and examination of the posterior segment [100]. If the vision reduces, evaluation with low-vision aids should be considered [100].

2.4.2. Auditory system—Hearing impairment is common among patients with MPS IVA [9,11,16,100,105–107]. Conductive hearing loss caused by serous otitis media due to frequent upper respiratory tract infections may be present anytime from birth and onwards [9, 94]. Many patients with MPS IVA have one or more sets of ear pressure equalization tubes to treat conductive hearing loss due to recurrent ear infections [16,105]. Some undergo an ear tube insertion after childhood. Hearing loss in MPS IVA is progressive [108–110] and bilateral [9, 93] in general, and its severity ranges from mild to moderate [9,18,94] but can

be severe [105,109,110]. Permanent hearing loss in MPS IVA is not usually identified until adolescence [100] but has been found in children younger than eight years old [108]. Younger patients exhibited conductive hearing loss and the sensorineural hearing loss element is added to the conductive component as the disease progressed [100,105,108]. A recent study reported that some MPS IVA patients who had normal audiometric results exhibited abnormal auditory neurophysiological responses based on otoacoustic emissions and/or abnormal auditory brainstem responses [105]. Their study suggests that the sensorineural hearing impairment may be in progress before patients notice [93].

Conductive hearing loss can be secondary to recurrent serous otitis media [100] or deformity of the ossicles due to the GAG accumulation in the middle ear [94]. The cause of sensorineural hearing loss is unknown, but it is likely due to the GAG accumulation in the cochlea and retrocochlear auditory nerves [100,111,112].

A recent study [105] on hearing function in patients with MPS IVA showed a strong correlation between height and hearing sensitivity and a strong correlation between height and the cochlear outer hair cell function. The strong relationship between short height and hearing loss suggests that patients with severe skeletal dysplasia may be at higher risk for developing severe hearing loss [105].

In addition to annual behavioral audiometric testing appropriate for the age of patients [100,107,113], regardless of age or skeletal severity, neurophysiological hearing testing such as otoacoustic emissions and ABR should be tested annually to monitor hearing disorders due to the progressive nature of the hearing impairment and the increased risk of developing a sensorineural hearing loss with age [88, 93].

2.4.3. Dental—Deciduous teeth erupt normally and are widely spaced and discolored with thin irregular (stippled) enamel and small pointed cusps which flatten over time with normal wear [9] (Fig. 11). Permanent teeth also have hypoplastic enamel [114]. Some common features have been reported with thin tooth enamel as well as multiple cavities.

Levin et al. described the classic oral abnormalities found among 12 patients with MPS IVA [115]. Tooth morphology is highly specific for MPS IVA [116]. The maxillary anterior teeth are widely spaced and flared, and the posterior teeth are tapered with pointed cusp tips. The enamel can be of normal hardness, but some patients have pitted enamel with decreased thickness [115]. In roentgenograms, the enamel was less than one-fourth of normal thickness but was of normal radio density [115]. The dental abnormalities in the MPS IVA are of a type that is unique among the group of genetic MPS [115]. The teeth of patients with MPS IVA are typically small, and the enamel is thin with a greyish color. The cusps of the permanent teeth are sharpened [18]. Due to both dental and upper extremity abnormalities, maintaining oral health can be particularly challenging [110].

3.4.4. Cardiology—Cardiac complications include ventricular hypertrophy and early onset, severe valvular involvement as well as coronary intimal sclerosis [100]. Cases of cardiac valve thickening, regurgitation, and/or stenosis have been reported in patients [117–121]. In a case study in 1990, 10 patients with MPS IVA underwent echocardiographic

assessment, and abnormalities were detected in 6 cases with mitral valve involvement in 5 patients and aortic valve disease in 4 [118]. One patient had severe mitral leaflet thickening to the point of mitral stenosis [118]. Two patients had evidence of myocardial involvement by way of echocardiographic ventricular hypertrophy [118]. Overall, there is a high prevalence of silent cardiac abnormalities in patients with MPS IVA with predominantly left-sided valve involvement [118]. Valve thickening that can be seen on cardiac ultrasound has been found to be nearly as common in patients who do not accumulate dermatan sulfate as in those who do [122]. All MPS IVA cardiac valves may show GAG deposition, although the left-sided cardiac valves are more severely affected [100].

The single cardiac ultrasound study that specifically addresses MPS IVA lacks the color flow Doppler technology which improves the detection of valve stenosis and insufficiency [118]. Despite the absence of color Doppler, valvular heart disease was found to be quite common in the single study devoted to MPS IVA [118]. 5 of the 10 (50%) patients studied had mitral valve regurgitation (1 of whom had mitral valve stenosis as well), 30% had aortic valve regurgitation, and 20% had both mitral and aortic regurgitation in conjunction with left ventricular hypertrophy [100]. Aortic and/or mitral valve thickening was present in 40% of patients tested [100].

Electrocardiography (ECG) examinations were carried out in 20 out of 37 patients [123], and measurements were compared with normal data [124]. All 20 patients had low R wave voltage in V6 [123]. Among the 37 patients who had echocardiography, cardiovascular abnormalities progressed with age although most had mild clinical signs and symptoms [123].

2.4.5. Respiratory—Respiratory complications are a major cause of morbidity and mortality in MPS IVA. This includes airway obstruction, sleep-disordered breathing, and restrictive lung [9]. The GAG accumulation in the following locations: adenoids, tonsils, pharynx, larynx, trachea, and bronchial tree leads to adenotonsillar hypertrophy, tracheal distortion, trachea- and bronchomalacia and obstructive sleep apnea [125,126]. Restrictive lung results from a small thorax, chest wall abnormalities, spine deformities, and neuromuscular compromise from cervical myelopathy and hepatomegaly causes an upward displacement of the diaphragm [100,126].

Patients with MPS IVA often prefer to sleep prone on a flat surface without a pillow to keep the neck extended and to minimize the tortuosity of the airway [9]. Due to the short stature and skeletal dysplasia, alteration in growth and development provides an additional mechanism for respiratory compromise which is frequently noted in patients [18]. Patients with MPS IVA are at increased risk for complications that include recurrent infections, progressive loss of respiratory function, sleep-disordered breathing, and ultimately respiratory failure [16,18,127].

The cause of restrictive lung in patients with MPS IVA is likely multifactorial; however, thoracic deformity (pectus carinatum, rib deformity) appears to be a primary cause [20]. Pulmonary function tests (PFT) such as forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) should be performed regularly to assess changes in lung volume

and obstruction [20]. Pulmonary hypertension, which may be caused by obstructive sleep apnea, is observed in patients with MPS IVA as commonly as observed in other MPS [20]. Patients may complain of nocturnal dyspnea, in which case polysomnography can be used to assess sleep disturbances [20]. 22 MPS IV patients (7 male, 15 females) ranged from 3 to 40 years of age, underwent noninvasive PFTs with vital signs [128].

For lung function studies, the age, size, and fitness are all important considerations [100]. As patients with MPS IVA exhibit a restrictive and obstructive element of respiratory compromise, both aspects need to be assessed [100]. To assess airflow limitation, the most common test utilized is the spirometry [100]. It is also a readily available technique utilized to measure the vital capacity (VC; the maximum amount of air that can be inhaled/ exhaled from full inflation to maximum deflation) which indicates the size of the lungs [100]. Airway resistance is assessed through a measurement known as impulse oscillation (IOS), where it utilizes a speaker to impose external oscillating pressure and airflow impulses over these subject's tidal breathing [100]. The "gold standard" assessment of lung restriction is by measurement of total lung capacity (TLC) [100]. This can be assessed by a variety of techniques such as physiological, which includes whole body plethysmography, gas (typically helium) dilution, and nitrogen washout, or by the radiographic means [conventional chest radiographs or (CT)] [100].

2.4.6. Tracheal Obstruction—Unlike other MPS patients, MPS IVA patients develop severe tracheal stenosis with a characteristic appearance on imaging studies and on direct bronchoscopic examination. Thus it is important to remember that MPS IVA patients have obstruction of large airways in addition to the upper airway obstruction reported in the earlier literature. Characteristics of the tracheal abnormality include right ward deviation of the trachea, twisting and buckling of the trachea which may at a younger age appear simply tortuous. Factors that contribute to this unusual pathological features are both external and internal to the trachea itself. External factors consist of the compression of the trachea due to the crossing of the brachiocephalic artery across and anterior to the trachea, proximity of the cervicothoracic spine which moves forward, the sternum (the manubrium) with the clavicular heads, and the pectus carinatum all competing for space in a crowded thoracic inlet, each contributing varying degrees of compression and narrowing of the trachea [8]. Internal factors contributing to the tracheal pathology include deposits of GAG increasing the thickness of the tracheal walls; unbalanced longitudinal growth of the trachea (in comparison to the growth of the thoracic cavity) resulting in trachea having to 'fold upon itself' which is now known as 'buckling' of the trachea [20] [13]. Patients with MPS IVA can develop respiratory failure secondary to reduced chest wall compliance and airway collapse due to the irregularly shaped vocal cords and trachea [127]. Tracheal obstruction also leads to life-threating complications during anesthesia because of the difficulty in managing both upper and the lower airways in MPS IVA primarily manifested by the difficulty in intubating the trachea [13] (Fig. 12). Tracheal narrowing increases with age as does anesthetic risk from both upper airway and tracheal pathology[13].

Sagittal MRI images of the cervical spine of 28 MPS IVA patients (12 ± 8.14 years) showed that 19 out of the 28 (67.9%) patients had at least 25% tracheal narrowing. 8 out of 28 (28.6%) patients were categorized as severe (>75%) tracheal narrowing when images were

evaluated in neutral head and neck position. The tortuous brachiocephalic artery was the most common cause in the 19 patients with tracheal narrowing (n = 15). Evidence of such tracheal narrowing was evident as early as 2 years of age. Tracheal narrowing increased with age, with all 8 patients over 15 years of age having greater than 50% narrowing. The severity score of the subjects over 15 years of age was nearly twice higher than the score of the 10–15 years old [13]. Greater attention to the trachea is needed when evaluating cervical spine MRIs as well as other imaging and clinical investigations, with the main goal of establishing a timely treatment protocol to reduce the mortality rate in the MPS IVA population.

3. Clinical tests

Since MPS is a progressive disorder that affects many organ systems simultaneously, it is very challenging to identify signs and symptoms that can be applied as suitable parameters for clinical trials. Some clinical endpoint tests are performed by measuring the general endurance since the impairment of stamina is common in all forms of MPS. The longitudinal, prospective MPS IVA clinical assessment program reviewed a decline of endurance tests, 6-minute walk test (6-MWT) and 3-minute stair climb test (3-MSCT) suggesting decreased functional ability over time [129]. Other tests can be used as clinical endpoints in studies that are aimed to demonstrate the efficacy of a new drug for MPS patients such as the stair climb test, lung function, joint range of motion, pain, and quality of life.

3.1. 6 Minute Walk Test (6-MWT)

The 6-minute walk test (6-MWT) is a supervised test that measures the distance a patient can walk on a hard flat surface over a 6-minute period [130]. According to the American Thoracic Society (ATS) guidelines, the 6-MWT is a simple test that requires a 30 meters hallway with no exercise equipment of advanced training for technicians. This test evaluates the global and integrated responses of all body system such as the pulmonary and cardiovascular systems, systemic circulation, peripheral circulation, blood, neuromuscular units and muscle metabolism. It is important to note that most patients do not achieve maximal exercise capacity during the 6-MWT, as the patients choose their own intensity of exercise and are allowed to stop and rest during their test. The strongest indication for the 6-MWT is for measuring the response to medical interventions in patients with moderate to severe heart or lung disease [131].

The advantage of 6-MWT is that it is the easiest to perform compared with other endurance tests and has a good correlation with the functions of the heart and lungs. In contrast, the 6-MWT has several limitations as this test has been studied mostly in adult patients and rarely in children. Nixon et al. used the 6-MWT in severely ill children before they received a lung or a heart transplantation. According to their study, there was a strong correlation of oxyhemoglobin saturation on the bike test compared to the walk test. In general, the results of the various studies of the 6-MWT including MPS patients have to be interpreted with caution as several factors have to be taken in consideration such as the length of the corridor used, the learning effects, and/or encouragement [132]. It is impossible to apply the 6-MWT

in young MPS patients. Therefore, the 6-MWT may not be reliable due to its lack of effectiveness in MPS IVA patients.

Treatment with 2 mg/kg elosulfase alfa weekly resulted in a modest improvement in the 6-MWT in the first clinical trial of 6 months; however, there was no improvement in the extension clinical trial (weekly infusion group) at week 72 [3]. After 120 weeks, results showed mild improvement in 6-MWT [133]. For patients treated with elosulfase alfa at 2.0 mg/kg/week throughout the study, mean 6-MWT improvements from baseline were 32.0 and 39.9 m from the intent to treat and modified per protocol populations, respectively, in relation to the 22.5 m improvement reported in the pivotal study [134]. The effectiveness of 6-MWT as a clinical endpoint remains ambiguous especially in a short term.

3.2. 3 Minute Stair Climb Test (3-MSCT)

The 6-MWT is a submaximal exercise test widely used to measure endurance and flexibility a range of patients [49,135,136], whereas the 3-minute stair climb test evaluates the effort required by the cardiovascular, pulmonary and/or musculoskeletal systems to perform an activity [136,137]. The risk with 3-MSCT is that patients with MPS IVA may get injured with falling down, as well as that patients who are handicapped can not perform this test. There was no significant improvement for patients treated in neither the 2 mg/kg WT nor 2 mg/kg QOW treatment group, compared to the placebo group at week 24. The two treatments groups and the placebo group mean difference in the stair climb rate was only 1.1 stairs per minute [134]. On week 72, both groups maintained the change in 3 MSCT without worsening below baseline. After 120 weeks, the results were higher than those at 24 weeks [139].

3.3. Pulmonary Function Test

Respiratory function tests are difficult to perform in MPS IVA patients due to their characteristic skeletal dysplasia, small body size and lack of cooperation of young patients, causing conventional spirometry for pulmonary function to be very challenging in some cases [128]. The non-invasive pulmonary tests: impulse oscillometry system (IOS), pneumotachography (PNT), and respiratory inductance plethysmography (RIP) in conjunction with conventional spirometry were evaluated in MPS IVA patients, all subjects had normal vital signs at rest including and age-appropriate heart rate [128]. All patients also preserved normal values in IOS, PNT, RIP, and forced expiratory volume in 1 second/forced expiratory volume total which were normal and not significantly impacted by age; however, the predicted forced expiratory total decreased with age and was below normal [128]. The proposed non-invasive pulmonary function tests can cover a greater number of patients (young patients and/or wheel-chair bound), which provides a new diagnostic approach for the assessment of lung function in MPS IVA that in many cases may be difficult to evaluate [128]. In a natural history study, changes in the FVC and maximum voluntary ventilation (MVV) were observed. For patients less than 14 years, the values increased, as would be expected for growth; however, the values decreased in older patients, which raised concerns about disease progression [129]. The compromised respiratory function and decreased FVC and MVV are related to multiple factors, including the progression of bone abnormalities and airway obstruction [138].

3.4. Range of Motion

Patients typically show significant differences in the active and passive range of motion (ROM) at the wrist joint, which shows the loss of stability at the joint [139]. Patients typically show a pronounced decrease in grip and pinch strength and have difficulties performing day-to-day tasks that require strength [139]. This regular assessment of ROM and strength provides inside into the degree and progression of functional impairment of the hands [87]. A goniometer can show both active and passive ROM of the wrists and digits [87].

3.5. Sleep Study

Sleep-disordered breathing (SDB) is common in all MPS diseases and may precede the development of overt respiratory failure during wakefulness [100,125]. Ventilatory abnormalities during sleep include obstructive sleep apnea due to several factors such as GAG accumulation in the upper airway, sustained hypoventilation due to the chest wall deformity and/or respiratory muscle weakness [100]. Sleep studies should also be performed in addition to lung function assessments [100]. Symptoms suggestive of SDB, such as apneas, gasping respirations, snoring, difficult wakening, daytime somnolence, and restless sleep should be assessed annually as part of the clinical evaluation of all patients [100]. Overnight sleep studies can be used to both diagnose the type and severity of SDB and also to evaluate nocturnal ventilatory treatments for the underlying respiratory disorder [100].

3.6. Bone Mineral Density

In the last few years, MPS IVA has been reported to be related with an early-onset osteoporotic phenotype, which can affect the clinical course of the condition [19]. The accumulation of KS disturbing bone mass acquisition and perturbing the regular microarchitecture of bone tissue has been reported to reflect on the bone mass density (BMD) [140]. Bone growth and mineralization have been reported to be affected by GAGs accumulation in animal models of MPS I, II, III, IVA, VI, and VII; there are, however, limited publications on the assessment of bone mineral density in patients with MPS [46,141–144].

In a study with 18 patients (16 unrelated) with MPS IVA with an average age of 21.4 years (3.3 to 40.8 years). In this prospective cross-sectional study, BMD of the whole body (WB), lumbar spine (LS), and lateral distal femur (LDF) was acquired by dual-energy X-ray absorptiometry (DXA) on patients with MPS IVA (Fig. 13). WB DXA could be obtained on only 6 patients (5 full-time ambulators) because of the respiratory compromise caused by the position, presence of hardware, or positioning difficulties. Mean WB Z-score was −2.0 (range − 0.3 to −4.1). Technical issues invalidating LS DXA in 8 patients included kyphosis at the thoracolumbar junction results in overlap of vertebrae in the posterior-anterior view. Mean LS BMD Z-score in full-time ambulators was −3.4 (range − 1.6 to −5.0) and in the non-/partial ambulator was −4.0 (−3.7 to −4.2). Lateral distal femur BMD was acquired on every patient, and average Z-scores were −2 or less at all the sites; fulltime ambulators exhibited higher BMD. LDF proved to be the most feasible site to measure in patients with MPS IV A [145]. Low BMD of the lower extremities as measured by the LDF, DXA is directly associated with lack of ambulation or weight bearing [146–150].

3.7. Dexterity Test

The Functional Dexterity Test (FDT) is validated and timed pegboard test that is not only easy to administer, but also it assesses the ability of the patients to perform functional daily tasks that require a 3-jaw chuck pretension pattern (also referred to as the lamar pinch, pencil pinch or tripod grip) such as writing and buttoning [151,152]. Each patient with MPS IVA syndrome requires regular assessment of upper limb function (fine motor skills) [89]. To obtain consistent measurements, it is important to record the position of the wrist and also to record whether the wrist was supported or not during testing [89]. Passive and active assessments of the range of motion of elbows and shoulders can be useful but do not have therapeutic consequences [89].

The FDT was developed as a measure of dexterity that will take a minimum amount of time to administer, yet still provides information regarding the patient's ability to use the hand for daily tasks requiring a 3-jaw pretension between the fingers and the thumb [152]. The overall, recommended pediatric modifications to the FDT are to use speed (pegs per second) instead of time (seconds) to report the results, and also to not assess penalties [151].

3.8. Gait pattern

Tests on gait and mobility can easily be done by a simple physical exam and an interrogation of the patients [89]. Instrumented gait analysis proves information about the dynamic alignment of the lower extremities and is also helpful in decision making in various conditions [153]. In a study of 9 MPS IV children (who had no previous lower extremity surgery), underwent a 3D gait analysis to describe the gait kinetics and kinematics in children with MPS IV. The mean age at gait analysis for the study was 10.6±4 years, mean height was 105.2±15.6 cm ($z = -4.5$), and mean weight was 22.3±7.2 kg ($z = -1.434$). The measurements obtained from gait analysis in the patients were compared with data from 10 healthy young individuals with age ranging from 9.5 to 11.5 years; the mean height was of 138±6.6 cm, and the mean weight was of 32.5±7.1 kg [86]. There were significant differences in the temporal-spatial characteristics, kinetics, and kinematics in children with MPS IV in comparison with the normal population on instrumented gait analysis. There was a decreased forward velocity, cadence, and stride length that was compared with the normal population ($p<0.05$). The height-adjusted, normalized forward velocity and stride length were also reduced in comparison with the normal population ($p<0.01$). The forward tilt of the trunk and pelvis, hip flexion, hip adduction, and external hip rotation were increased in comparison with the normal population ($p<0.05$). There was increased knee flexion, genu valgus (abduction), and external tibial torsion compared with normal during stance ($p<0.05$). Dynamic knee varus–valgus joint laxity showed a mean difference of 9.5° between the minimum and maximum genu valgus (abduction) that was recorded during stance, which is compared with a difference of 0.9° in the normal population ($p<0.05$). While there was a strong correlation between genu valgus measured on gait analysis and standing radiographs ($r = 0.89$), there was a moderate correlation between genu valgus measured on gait analysis and clinical examination ($r = 0.69$) [86].

3.9. Activity of daily living

The current options for treating MPS IVA in a multisystem manner to address overall quality of life are limited [100]. Currently, due to the absence of an effective and safe systemic treatment option, patients require extensive management and regular intervention to maximize their quality of life [100]. To track and manage the quality of life, patients with MPS IVA should see both physiotherapist and experts on MPS annually to evaluate the degree of impairment, including determination of the range of motion, muscle strength, daily activity, and participation limitations [100]. As MPS IVA disorder process progresses, the quality of life for the patient declines. Patients increasingly become more dependent on caregivers as deteriorating vision, hearing, oral health, respiratory and cardiac function, muscular strength, and endurance make routine daily activities increasingly difficult to complete tasks [100].

The activity of daily living (ADL) questionnaire is made up of three sections: “Movement,” “Movement with Cognition,” and “Cognition.” Each section has four subcategories rated on a 5-point scale based on the level of assistance. The questionnaire was then collected from 145 healthy controls and 82 patients with MPS IVA. Of the 82 patients questioned, 63 patients were severe and 17 patients had attenuated phenotypes (2 were undefined); 4 patients treated with hematopoietic stem cell transplantation (HSCT), 33 patients with enzyme replacement therapy (ERT) for more than one year and 45 untreated patients. MPS IVA patients showed a decline in ADL scored after 10 years of age. Patients with a severe phenotype had a lower ADL score than healthy control subjects, and lower scores than patients with an attenuated phenotype in domains of “Movement” and “Movement with cognition.” Patients who underwent HSCT were followed up for over 10 years, had higher ADL scores and fewer surgical interventions than untreated patients [154]. Further investigation of large study on HSCT is required since it is limited number.

3.10. Growth

Growth impairment is commonly observed in patients with MPS [155]. Patients with MPS IVA are most severely affected in growth and final height, which are used as an indicator of disease severity [16,156]. Short stature is the main evident symptom, and the male and female patients have the growth impairment to approximately an equal degree [16,156,157]. Growth in patients with MPS IVA stops around 7 to 8 years age [156,158].

In 2007, Montano et al. described that the phenotypic classification for severe MPS IVA by height was below 120 cm while the classification for the attenuated type was above 120 cm [158]. Some patients with attenuated MPS IVA continue growing even into their teens and reach over 140 cm [16]. In 2008, Montano et al. proposed that a standard growth chart for each gender of MPS IVA patients should be made for better results of phenotypic classification [158]. Height and weight measurements from MPS IVA patients were collected in the International MPS IVA Registry, and the growth charts for male and female patients were established, compared to reference growth curves of healthy children provided by the CDC [16,20]. In 2012, more height and weight measurements from 193 girls and 195 boys with MPS IVA were collected to revise the growth charts [147]. The mean birth length of boys was 52.4 ± 3.9 cm, and the mean height for males at 18 years of age was 119.3

± 22.6. The mean birth length of girls was 52.1 ± 2.9 cm, and the mean height for girls at 18 years of age was 113.5 ± 23.1 cm. These values correspond to −8.0 SD and −7.7 SD of the mean height for normal males and females. The mean birth weights for boys were 3.56 ± 0.5 and for girls were 3.5 ± 0.7 kg. The growth patterns in MPS IVA patients were characterized by impaired growth velocity after 1 and 2 years of age [156]. According to the isopleth upon which the patient falls, patients above the 90th centile on the growth chart for each gender of MPS IVA are more likely to be defined as mild attenuated while patients between the 75th centile and 90th centile on the growth chart are more likely to be defined as intermediate attenuated. Patients less than the 75th centile are classified as classic severe.

In another study with MPS IVA from Taiwan, 92% of the patients had short stature [159]. Patients treated with ERT showed no statistical significance in height/growth rate [134,160]. Overall, the height and growth velocity are the simplest and objective tests to define the clinical severity and to monitor therapeutic efficacy.

4. Molecular Diagnosis

Molecular analysis is used to confirm the diagnosis and to provide genetic counseling for the family and prenatal analysis [17]. The *GALNS* gene is located on chromosome 16q24.3, contains 14 exons, and generates a 1566 nucleotide mRNA [161–164]. Multiple MPS IVA mutations are believed to be exclusive and found in only one individual or family [70].

As of February of 2018, 334 mutations in the *GALNS* gene have been reported missense/nonsense mutations account for a total of 203, 35 deletions, 22 splicing site mutations, 7 insertions and 3 complex rearrangements [165]. Several mutations are common; the most prevalent recurrent mutations in the *GALNS* gene are c.1156C>T (p.R386C), c.901G>T (p.G301C), c.337A>T (p.I113F), c.1A>G (p.M1V), c.757C>T (p.R253W), c.871G>A (p.A291 T), c.935C>G (p.T312S), and c.1171A>G (p.M391V), accounting for 8.9%, 6.8%, 5.7%, 2.3%, 2.1%, 1.8%, 1.8%, 1.8%, and 1.8%, respectively [166–172].

In a study with 37 MPS IVA patients that were based on clinical data, biochemical assays, molecular analyses, and in silico structural analyses of associated mutations, the results displayed that standard sequencing procedures, albeit identifying novel *GALNS* genetic lesions, and failed to characterize the 2nd disease-causing mutation in the 16% of the patients' cohort [173]. To address this drawback and uncover potential gross *GALNS* rearrangements, the study developed molecular procedures assays, quantitative fluorescent-PCRs (QF-PCRs), endorsed by comparative genome hybridization (CGH) arrays [173]. Using this approach, the study was able to characterize two new large deletions and their corresponding breakpoints [173].

5. Challenges of Diagnosing MPS IVA

The signs and symptoms of MPS IVA overlap with those of other MPS, all of which have a broad spectrum of clinical manifestations [9] (Table 1). In comparison to the other MPS, patients with MPS IVA have normal intellectual abilities as well as less coarsening of the facial features [9]. Laxity of joints (atlanto-axial, fingers, hands, knee) is a major condition for MPS IVA. Atlanto-axial instability, weakness of wrist, and knock-knee are more

common in patients with MPS IVA in comparison to other MPS types [9]. Patients with a severe phenotype accounted for nearly 75% of the 399 MPS IVA patients registered in International MPS IV Registry [20]. With the skeletal involvement, significant morbidity of patients can also result from obstructive sleep apnea, corneal clouding, hearing impairment, respiratory compromise, valvular heart disease and spinal cord compression.

MPS IVA can be diagnosed with the above unique characters although this disorder relates closely to other disorders in some characteristics. The disorder that most commonly resembles MPS IVA is MPS IVB. MPS IVB differs from MPS IVA in that there is an accumulation of only KS due to the deficiency in the enzyme β-galactosidase, and several disease characteristics overlap although MPS IVA is usually more severe than MPS IVB.

Mucopolysaccharidosis type VI known as Maroteaux-Lamy syndrome is an autosomal recessive disorder, caused by mutations in the arylsulfatase B (*ARSB*) gene and leads to a deficiency in the N-acetylgalactosamine 4-sulfatase enzyme [168]. The clinical presentation of MPS VI like MPS IVA varies depending on the age of onset and rate of disease progression [175]. Unlike MPS VI, MPS IVA patients have hypermobile joints, platyspondyly, loud breathing and short trunk [95,176,177].

Mucopolysaccharidosis type VII known as Sly syndrome is an extremely rare recessive lysosomal storage disease caused by the mutations in the GUSB gene leading to a deficiency in the β-glucuronidase enzyme causing accumulation in the DS, HS, and C6S. Unlike MPS VI, MPS IVA patients have hypermobile joints and a large mandible [178–181].

GM1 gangliosidosis is an autosomal recessive storage disorder and is caused by the deficiency of β-galactosidase which is the same as MPS IVB [182]. GM1 gangliosidosis like MPS IVA, have anterior breaking of the vertebral bodies, joint pain, muscle weakness, short stature, coarse face, corneal clouding, visual impairment, hearing loss, cardiac valve abnormalities, hepatosplenomegaly, kyphosis/gibbus, scoliosis, and waddling gait. Unlike MPS IVA, GM1 gangliosidosis patients have CNS impairment, developmental delay, craniofacial dysmorphia and fetal hydrops. GM1 gangliosidosis patients however lack sleep disturbance, disproportionate short stature, hypermobile joints, large head, coarse hair, hypertrophic adenoid and tonsil, large tongue, dental abnormalities, recurrent otitis media, recurrent respiratory infections, large mandibular, short neck, cervical instability, odontoid hypoplasia, chest abnormalities, pectus carinatum, hip deformity, short trunk, platyspondyly, genu valgum, and inguinal hernia.[183,184].

Spondyloepiphyseal dysplasia congenita (SEDc) has very similar radiographic findings to MPS IVA. SEDc is caused by the autosomal dominant mutations in the *TRPV4* gene. SEDc like MPS IVA, have anterior breaking of the vertebral bodies, short stature, normal intelligence, joint pain, hearing loss, chest abnormalities, kyphosis/gibbus, scoliosis, hip deformity, short trunk and genu valgum. While MPS IVA patients have hypermobile joints, SEDc patients have joint stiffness [185–188].

Legg-Calve-Perthes disease (LCPD) is an autosomal dominant disorder of the *COL2A1* gene mutations, in which mild MPS IVA with only hip pain at the early stages can lead to an initial misdiagnosis of Legg-Calve-Perthes disease. Perthes disease, unlike MPS IVA, is a

rare childhood condition that only affects the hip Signs and symptoms for LCPD correlate to MPS IVA because symptoms include muscular weakness, normal intelligence, short stature, hip deformity, genu valgum, and waddling gait. Usually, LCPD only involves one hip. However, both hips can be affected in some children [189–191].

Dyggve-Melchior-Clausen syndrome (DMC), originally reported as Morquio-Ullrich's disease, is caused by mutations in the *DYM* gene and is autosomal recessive. Mutations in the same *DYM* gene can also cause Smith-McCourt syndrome (SMC), which is a condition that is radiographically identical to DMC in which intelligence and psychomotor developments are normal in the patients [192]. DMC can be clinically differentiated from MPS IVA because DMC patients are intellectually disabled, whereas MPS IVA patients are not [10,193,194]. A patient with DMC or SMC will have a lace-like appearance of iliac crests, concavity of the end of the scapula because of defective ossification, a horizontal acetabular roof and a double-humped end-plates of vertebrae, which lacks in MPS IVA patients [195–197].

Although clinical findings and radiographs can provide great insight, laboratory testing is required to reach a diagnosis of MPS IVA [10]. When alternative skeletal dysplasia is suspected, and MPS IVA is considered enough of a possibility that the clinician chooses to perform a laboratory test to rule out the MPS disorders, then urinary screening is not an acceptable method to use by itself because of the high false negative rates for MPS IVA [10].

6. Conclusion

Variable clinical presentation and laboratory testing caveats make MPS IVA particularly challenging to diagnose [10]. Both skeletal and non-skeletal symptoms need to be tested and assessed for clinical suspicion. Especially, imbalance of growth causes major clinical signs and symptoms leading to serious morbidity and mortality. Radiographic, biochemical, and molecular tests are critical for precise diagnosis and prognosis for MPS IVA. The age of diagnosis, the natural progression of the disease, and prognosis of the disease play a role in determining the precise management of MPS IVA.

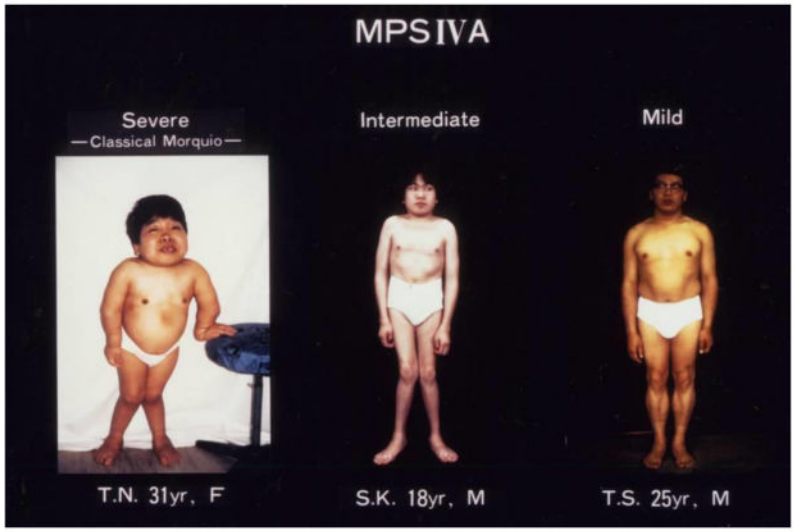
Highlights

- Mucopolysaccharidosis IVA is an autosomal recessive disorder caused by the deficiency of GALNS.
- This enzyme deficiency leads to a progressive accumulation of excessive C6S and KS.
- Spinal cord compression, airway compromise, and valvular heart disease are the leading causes of high morbidity and mortality.
- The attenuated form may not become evident until late childhood or adolescence, and often first manifests hip problems as the primary symptom.
- Imbalance of growth in bones, organs, and tissues causes the hallmark of clinical manifestations.

A



B

Figure 1.

Patients with mild to severe form of MPS IVA. A. Images of patients with distinct differences in clinical features from mild form, immediate form, and severe form of MPS IVA (adapted from Educational CD for Morquio and permitted by Carol Ann Foundation). B. Images of a patient with severe form of MPS IVA. From left to right: patient age is 7, 8, 11, 16, and 16 years (adapted from Educational CD for Morquio and permitted by Carol Ann Foundation) [33].

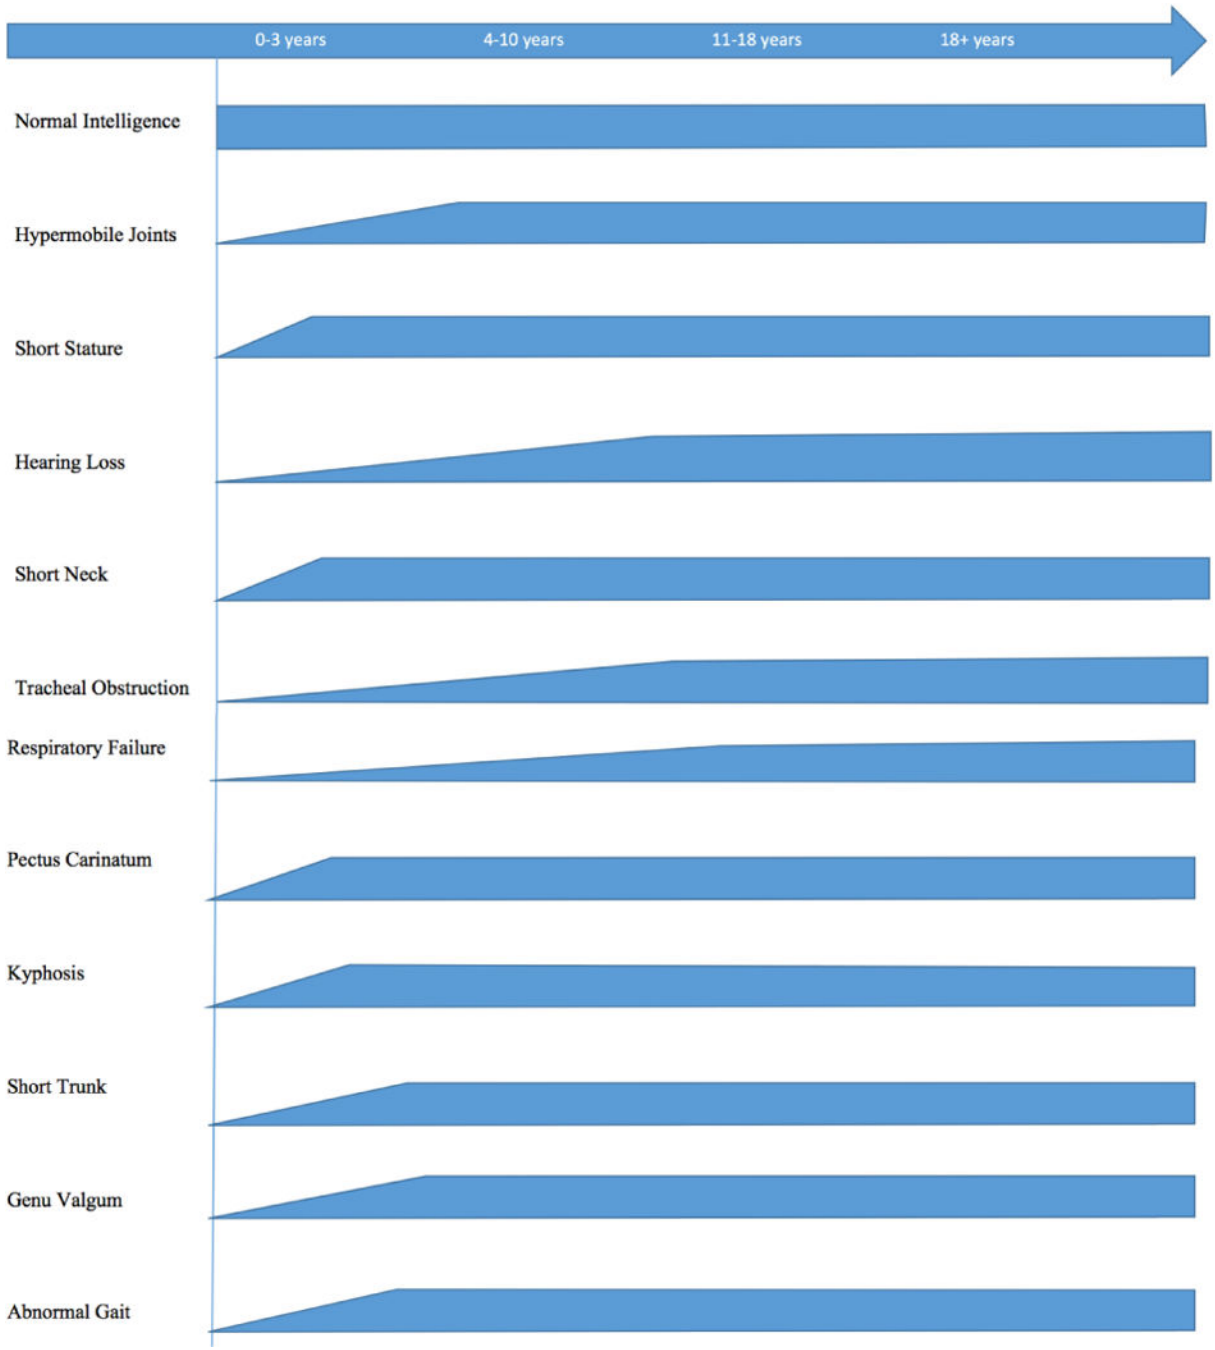


Figure 2.
Time course of clinical symptoms in MPS IVA

Figure 3.

Lateral radiographs of the cervical spine in flexion (a) and extension (B) show atlantoaxial instablity in an 8-year-old female patient with MPS IVA. The anterior arch of C1 moves anteriorly in flexion (arrow) in relation to C2. There is hypoplasia of the dens (dashed arrow) and generalized platyspondyly.

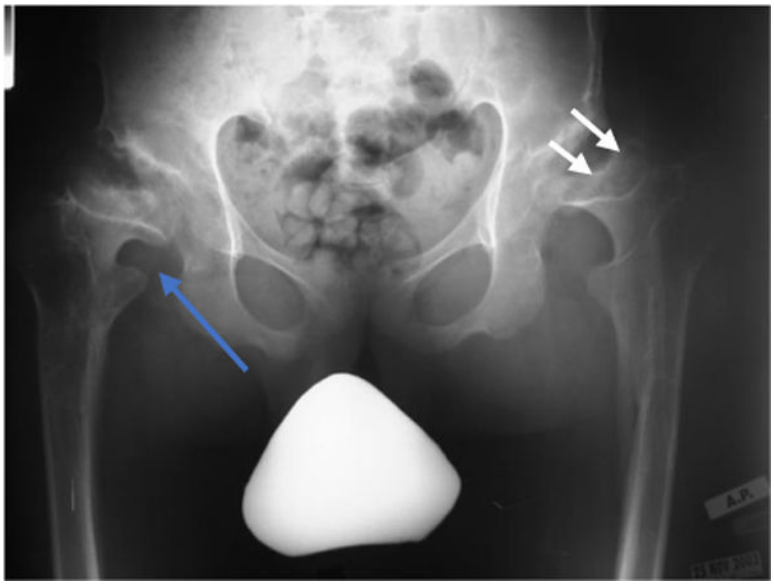

Figure 4.

Erect frontal radiograph of the hips from a patient with MPS IVA. Shown here is progressive proximal and lateral migration (blue arrow) as well as the flattening and eventual disappearance of the proximal femoral epiphysis (white arrows).

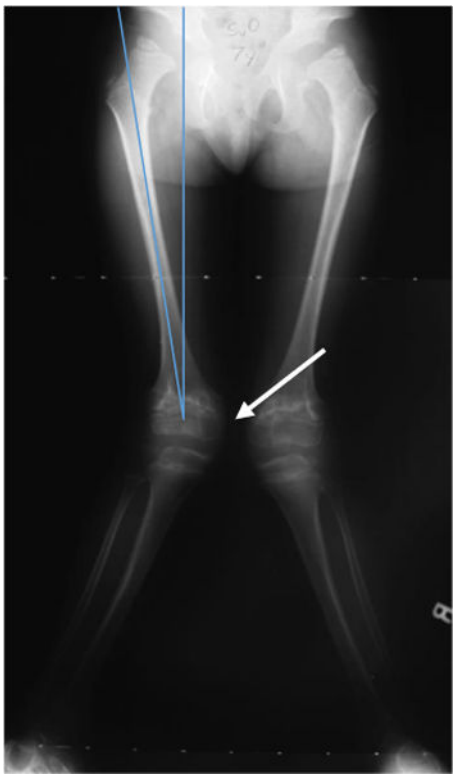

Figure 5.
Erect frontal radiographs of the lower extremities of a patient with genu valgum.

Figure 6.

Feet of a patient with MPS IVA. Photograph of the feet (a) and lateral radiograph of the left foot (b) of this MPS IVA patient show skew foot posture in both feet (white arrows), pronated pes planus (orange arrow), and increased sandal gap between the first and second toes (black arrow).

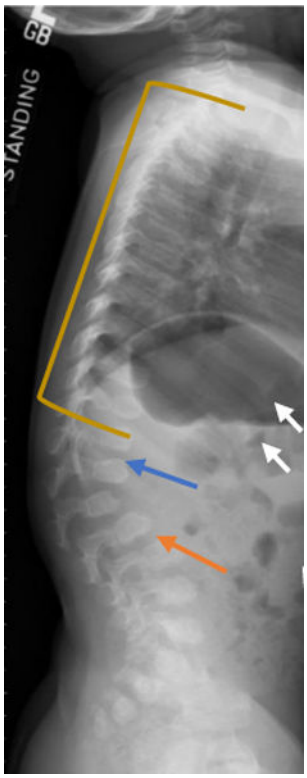

Figure 7.
Lateral radiograph of the spine of a two-year-old MPS IVA patient with vertebral wedging (blue arrow). Platyspondyly (yellow line), anterior inferior beaking (orange arrow), rib flaring (white arrows) are seen in this X-ray radiograph of a patient with MPS IVA.

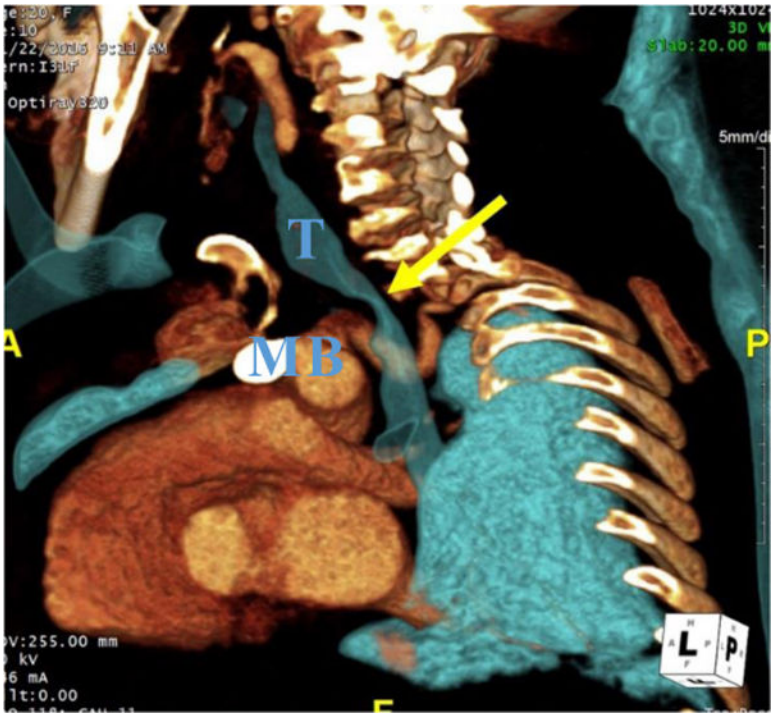

Figure 8.

CT angiography (CTA) of a 20-year-old woman with MPS IVA. 3D oblique reconstruction of CTA demonstrates marked narrowing of the trachea at the thoracic inlet (yellow arrow). T– Trachea, B- Brachiocephalic artery, M- Manubrium.

Figure 9.
X-ray radiograph of an MPS IVA patient hand. Clearly seen are the tapering of the proximal portion for the metacarpals (orange arrows), small irregular carpal bones (white arrow), and the distal portion of the radius being tilted toward the ulna (blue arrow).

Figure 10.

Eyes of a patient with MPS IVA. Image of a 24-year-old patient with MPS IVA shows fine stromal corneal clouding (adapted from Educational CD for Morquio and permitted by Carol Ann Foundation).

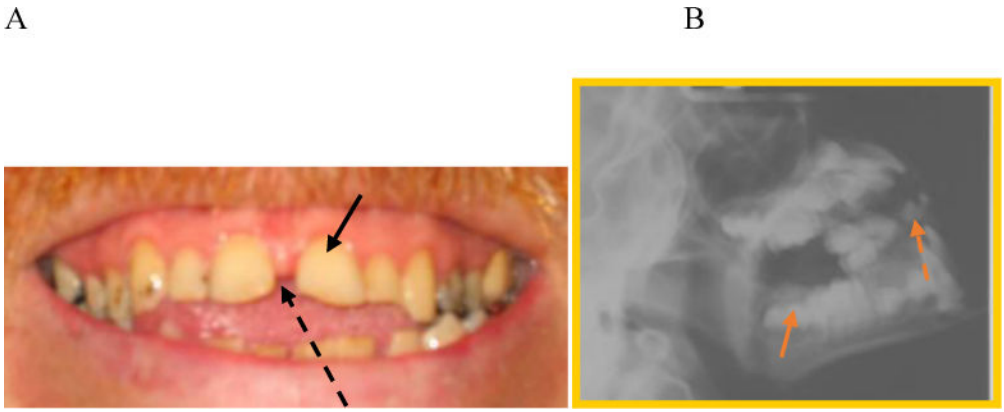

Figure 11.

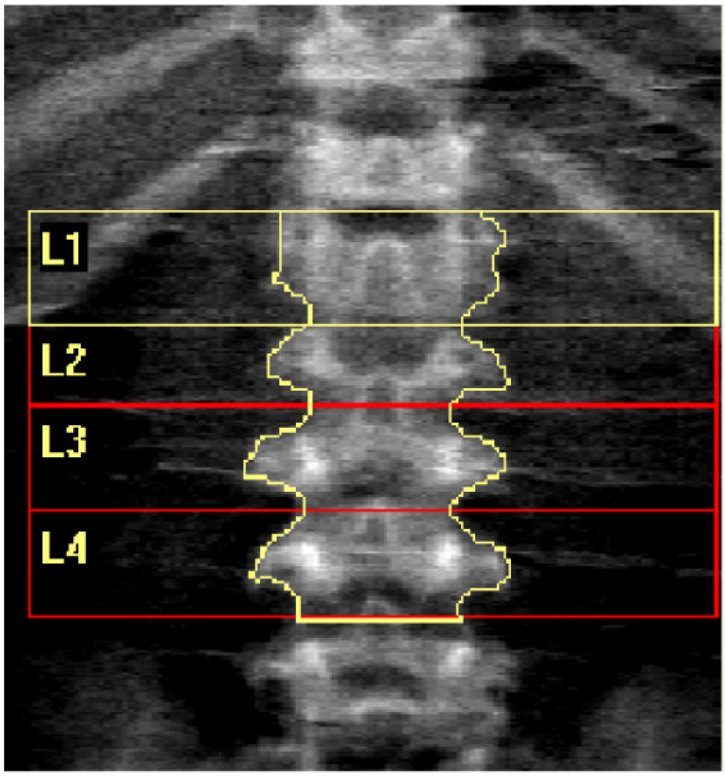
Teeth of a patient with MPS IVA. A. Image of a 24-year-old patient with widely spaced teeth (black arrow) and spade shaped incisors (black dotted arrow) (adapted from Educational CD for Morquio and permitted by Carol Ann Foundation). B. X-ray of a MPS IVA patient with concave occlulsal sufraces (orange arrow) and spade-shaped incisors (orange dotted arrow).

Figure 12.

Sagittal (a) and axial (b) CT images of a 16-year-old boy with MPS IVA focal severe tracheal narrowing at the thoracic inlet (arrows). Tracheal cross-sectional area measures 10 mm^2 at the thoracic inlet and 110 mm^2 intrathoracic below the area of narrowing.



DXA Results Summary:

Region	Area (cm^2)	BMC (g)	BMD (g/cm^2)	T - score	Z - score
L1	6.34	2.00	0.315		
L2	4.49	1.76	0.392		
L3	5.81	2.67	0.459		
L4	6.22	3.27	0.525		
Total	**22.87**	**9.69**	**0.424**		**-1.6**

Total BMD CV 1.0%

Figure 13.

DXA image of the spine of a MPS IVA patient. Lumbar spine DXA requires careful and precise measurement of vertebral body levels and margins (Adapted from Kecskemethy et al. Mol Genet Metab; 2017, 144-149) [145].
