Abstract: The pathophysiology of schizophrenia may involve increased production of inflammatory cytokines by activated microglia. Minocycline can inhibit activated microglia and may improve secondary negative symptoms and/or cognitive functions when used as adjuvant to antipsychotics. Effects on minocycline on primary and enduring negative symptoms in deficit schizophrenia (DS) are unknown. We present a male patient with a 3-year history of DS. He was treated for 12 weeks with risperidone at a maximal dose of 6 mg per day, then for 10 weeks with olanzapine at 20 mg per day. Symptoms did not improve, and body mass index increased from 20.41 to 22.84 kg/m². Serum levels of several inflammatory cytokines were elevated, so we prescribed minocycline as adjunct to aripiprazole for 12 weeks. Negative symptoms and cognitive impairment improved, and serum levels of inflammatory cytokines decreased. Our case suggests that clinicians may consider minocycline as adjunct therapy to antipsychotics in patients with DS with elevated serum levels of inflammatory cytokines. This highlights the need for further research into possible relationships of minocycline with negative symptoms and cognitive function in patients with DS.

Keywords: minocycline, adjunct therapy, deficit schizophrenia

Introduction

Schizophrenia is a devastating mental disorder. Patients with schizophrenia show a variety of symptoms, including hallucination, delusion, blunted affect and emotion, asociality, avolition, cognition impairment, and social withdrawal. Although the etiology of schizophrenia remains unclear, production of various inflammatory cytokines and free radicals by activated microglia may contribute to neuronal degeneration and neurotoxic effects in the disease.¹⁻¹¹

Minocycline, a semisynthetic, second-generation tetracycline antibiotic, shows obvious anti-inflammatory and neuroprotective effects that appear to be independent of its antimicrobial action.^{6,11,12} The drug penetrates brain tissue well, is tolerated well, and is nearly completely absorbed when taken orally.^{13,14} It effectively inhibits activated microglia and protects neurons from degeneration in animal models of schizophrenia.¹⁵⁻¹⁷

Typical and atypical antipsychotics can improve positive symptoms, but show limited efficacy for negative symptoms and cognitive impairments in patients with schizophrenia.^{2,18} Several clinical studies have shown that minocycline can improve negative symptoms and/or cognitive functions of patients with schizophrenia.^{8,18-22}

The concept of deficit schizophrenia (DS) has been used to define a subgroup of patients with schizophrenia who show primary and enduring negative symptoms during the clinically stable stage of the disease. The negative symptoms of DS are not

secondary to anxiety, depression, hallucination, delusion, thought disorder, or medication. Patients who do not meet the criteria of DS are classified as suffering from nondeficit schizophrenia.^{23,24} Their secondary negative symptoms can be treated effectively using second-generation antipsychotics, whereas primary and enduring symptoms often persist despite treatment with conventional or second-generation antipsychotics.²⁴ Concentrations of the inflammatory markers IL-6 and C-reactive protein (CRP) are significantly higher in DS patients than in non-DS patients and may be associated with their negative symptoms.²⁵ To our knowledge, no study has been reported using minocycline as adjunct therapy to antipsychotics in DS patients.

Case presentation

Three years before his admission to our hospital, a 26-year-old Chinese man began to manifest, for no apparent reason, restricted affect, poor speech, diminished sense of purpose, and diminished social drive. His affect was diminished no matter what his parents told him. He lacked interest in doing anything, and did not talk to others. When his parents asked him questions, he answered only “I don’t know”. Sometimes his speech was disorganized and incoherent. He also lost desire to work at his job as a bank clerk, although he previously performed well. He preferred to stay at home and did not want to participate in activities or have contact with friends. His sleep and appetite were poor. He showed no disturbance of consciousness. After these symptoms continued for about 6 months, he was taken by his parents and hospitalized in a local psychiatric ward. General physical and neurologic examinations and routine laboratory investigations at that time showed no notable abnormalities. He was, therefore, diagnosed with schizophrenia and treated with risperidone at a maximal dosage of 6 mg per day for 12 weeks. The patient did not respond, and he was discharged with a weight of 59 kg and body mass index (BMI) of 20.41 kg/m².

After discharge, the patient presented with the same symptoms and he was taken by his parents to our outpatient department 1 year before he was admitted to our hospital. The outpatient physicians diagnosed him with schizophrenia and treated him for 10 weeks with a maximal dose of olanzapine of 20 mg per day. He responded poorly, so he was admitted to our hospital at the request of his parents. The patient reported never smoking and occasionally drinking small amounts of wine. He had no family history of mental disorders. His vital signs were stable, and no abnormal physical or neurologic signs were detected at admission. Blood and urine tests were routine, blood glucose and liver and renal functions were

normal, and no evidence of infection was found. His thyroid function was normal. Cerebrospinal fluid (pressure, appearance, cells, proteins, glucose, chloride, and immunoglobulin) and brain magnetic resonance imaging were also normal. The following serum levels were measured: IL-1 β , 8 pg/mL (reference range, 0–5 pg/mL); soluble interleukin-2 receptor (sIL-2R), 812 U/mL (223–710 U/mL); IL-6, 10 pg/mL (0–7 pg/mL); IL-8, 51 pg/mL (0–62 pg/mL); IL-10, 8.8 pg/mL (0–9.1 pg/mL); tumor necrosis factor- α (TNF- α), 8.7 pg/mL (<8.1 pg/mL); and CRP, 5.5 mg/L (<5 mg/L). Electroencephalography, electrocardiography, and transcranial Doppler ultrasound results were normal. The patient and his family members denied any abuse of illicit substances. The patient’s weight was 66 kg and BMI was 22.84 kg/m².

The patient was diagnosed with schizophrenia based on the Structured Clinical Interview for the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders, Patient Version. The patient was followed up for 6 months after diagnosis to confirm the presence of schizophrenia. The patient was diagnosed with DS using the Schedule for Deficit Syndrome (SDS).²⁶ We dynamically classified the patient and reassessed this classification at 6 and 12 months later using the SDS. The patient scored 82 on the Scale for Assessment of Negative Symptoms (SANS).²⁷ Cognitive function was assessed using the Cambridge Neuropsychological Test Automated Battery (CANTAB) (cambridgecognition.com) at admission as well as 10 weeks later (Table 1).

Table 1 Performance on cognitive tests

Test	Admission	12 weeks	Reference values
DMS, percent correct ¹	61	89	100 (best)
DMS, percent correct (simultaneous) ¹	79	91	100 (best)
DMS, percent correct (all delays) ¹	50	78	100 (best)
IED, stages completed ¹	5	5	9 (best)
IED, total errors (adjusted) ²	14	6	–
PRM, percent correct, immediate ¹	79	95	100 (best)
PRM, percent correct, delayed ¹	59	88	100 (best)
RVP, total false alarms ²	2	0	0 (best)
RVP, probability of hit ¹	0.56	0.97	1 (best)
SOC, problems solved in minimum moves ¹	4	9	12 (best)
SWM, between errors ²	8	1	0 (best)
SWM, strategy ²	32	20	8 (best)–56 (worst)

Notes: ¹Higher is better; ²Lower is better.

Abbreviations: DMS, delayed matching to sample; IED, intra-/extradimensional shift; PRM, pattern-recognition memory; RVP, rapid visual information processing; SOC, stockings of Cambridge; SWM, spatial working memory.

The patient was treated with aripiprazole at a maximal dose of 20 mg per day, and treated with minocycline as adjunct therapy, which was gradually titrated to 100 mg twice daily. After 12 weeks of adjunct treatment, persistent and enduring negative symptoms improved. The patient reported no complaints or side effects from the minocycline, he was able to care for himself during daily activities, and his social engagement improved. His communication with parents and contact with friends notably improved. When his parents told him a joke, he laughed. He was willing to exercise and agreed to join a skills training group. The SANS score was 47, and serum levels of IL-1 β were 5 pg/mL; sIL-2R, 670 U/mL; IL-6, 6 pg/mL; IL-8, 48 pg/mL; IL-10, 9.1 pg/mL; TNF- α , 7.1 pg/mL; and CRP, 3.6 mg/L. At 12 months follow-up after discharge from our center, he reported no signs of negative symptoms and reported that he was functioning well in the community.

Discussion

To our knowledge, this is the first successful report of minocycline adjunct treatment for DS. Minocycline effectively reduced primary and enduring negative symptoms in our patient. These antipsychotic effects are likely to be due exclusively to minocycline, because our patient did not suffer any infectious or immune disease.

Our success with minocycline as adjunct therapy to aripiprazole in a patient with DS is consistent with case reports and with randomized, double-blind, placebo-controlled trials indicating that minocycline adjunct therapy can improve negative symptoms in patients with early-phase or chronic schizophrenia.^{8,18–20,22,28–30} These findings are consistent with the notion that during schizophrenia, activated microglia produce various inflammatory cytokines that contribute to neuropathology.^{6–11}

Cognitive evaluation of our patient using the CANTAB showed that minocycline led to improvement on several dimensions of attention, memory, and executive function. The Rapid Visual Information Processing Test assesses sustained attention, which is highly sensitive to brain damage or dysfunction. The Pattern-recognition Memory Test assesses visuospatial memory domains. The Delayed Matching to Sample Test assesses simultaneous visual matching ability and short-term visual recognition memory for nonverbalizable patterns. Improvement was also seen on the Battery's three tests of executive function: the Spatial Working Memory Test assesses ability to retain and manipulate information in spatial working memory, the Intra/extradimensional Shift Test assesses cognitive shifting and flexibility, and

the Stockings of Cambridge Test assesses planning and organizing a goal-oriented sequence of actions.³¹ Our results suggest that minocycline as adjunct therapy to atypical antipsychotics may decrease damage to different domains of cognitive function, which is consistent with previous studies.^{19,20} In contrast, one study found no significant cognitive difference between patients treated with minocycline or placebo, except in attention.¹⁸ This discrepancy may reflect the heterogeneity of schizophrenia and differences among cognitive testing tools.

Schizophrenia features diverse symptoms and clinical heterogeneity. These different clinical symptoms may result in different response to antipsychotic treatment.²⁴ In our previous work, we found that patients with DS are a relatively homogeneous subgroup of schizophrenia,^{32–34} but the impact of second-generation antipsychotics on DS patients remains controversial.²⁴ Several studies have compared the efficacy of amisulpride, clozapine, and olanzapine in treating primary negative symptoms, but without conclusive findings.^{35–37} Our case indicates that minocycline adjunct therapy may be a therapeutic strategy for treating primary and persistent negative symptoms in patients with schizophrenia.

Serum levels of most inflammatory cytokines in our patient decreased after treatment. Conversely, the serum level of IL-10 increased, although it remained within the normal range. Certain atypical antipsychotics may decrease serum levels of cytokines.^{6,38} Meta-analysis of available evidence suggests that IL-1 β and IL-6 are state markers, because they normalize with antipsychotic treatment. In contrast, sIL-2R and TNF- α may be trait markers, because they remain elevated following antipsychotic treatment.⁴ Aripiprazole has been shown to inhibit only levels of inflammatory cytokine TNF- α ,³⁹ implying that minocycline reduced serum levels of other inflammatory cytokines in our patient, presumably by inhibiting microglial activation.

When treating patients with DS, it may be useful to consider the possibility of neuroinflammation and monitor serum levels of inflammatory cytokines. Large, randomized studies should follow up patients for longer periods after minocycline adjunct therapy in order to assess long-term outcomes and confirm its efficacy against primary and persistent negative symptoms and cognitive function in DS.

Conclusion

We conclude that minocycline may be considered by clinicians as adjunct therapy in schizophrenia patients with primary and persistent negative symptoms and elevated serum levels of inflammatory cytokines. This highlights the need

for further research into potential association of minocycline with negative symptoms and cognitive function in patients with DS.

Ethics statement

Written informed consent for the publication was obtained from the patient and his parents for the case report. This study was approved by the Ethics Committee of West China Hospital, Sichuan University.

Acknowledgments

The authors would like to thank all of their coworkers of West China Hospital, School of Nursing, Chengdu Medical College and The Mental Rehabilitation Center, Karamay Municipal People's Hospital on this case for their skillful contributions. The authors would like to thank the patient and his parents for their written informed consent to publish this case. This work was partly funded by Science and Technology Department of Sichuan Province of China (2017SZ0049, Zhe Li; 2018ZR0216, Zhenzhen Xiong), Health and Family Planning Commission of Sichuan Province of China (17PJ080, Zhe Li), and The Fundamental Research Funds for The Central Universities of China (2017SCU11072, Zhe Li).
