INTRODUCTION. Pulmonary aspiration syndrome is the principal cause of ARDS and nosocomial pneumonia, which increase hospital morbidity, mortality and healthcare costs. Previous attempts to identify the risk factors for overt nosocomial aspiration were not systematic.

OBJECTIVES. To derive and validate comprehensive prediction model for overt nosocomial pulmonary aspiration. We hypothesized that such prediction model will show adequate discrimination and calibration in historical patient cohorts.

METHODS. A retrospective case-control study of consecutive adults admitted to Mayo Clinic hospital in Rochester, MN from 2006 through 2015. Nosocomial aspiration was defined using a novel electronic medical record-based diagnostic algorithm (termed "aspiration sniffer") based on natural language processing of clinical notes[1]. The patients who screened positive for aspiration and who were either in the ICU within 48 hours before aspiration or required ICU care within 48 hours after aspiration, were enrolled and split into the derivation and the validation cohorts. An equal number of controls were selected from among those who screened negative for aspiration, matching for age, sex, and year of hospitalization. A blinded manual chart review was performed on a random sample to assess the sniffer's accuracy for aspiration/non-aspiration. Predictor variables included a comprehensive list of demographic characteristics, comorbidities, prognostic scores (Charlson, SOFA, APACHE), and clinical variables (all present or have occurred before aspiration). We performed LASSO regression analysis to select the variables for the model. All variables with P< 0.15 contributed to the final multivariable conditional logistic regression model. The model's discrimination was assessed with the receiver operating characteristic curve.

RESULTS. Out of 45,115 patients, 917 fulfilled the aspiration enrollment criteria and after adding matched controls were split into the derivation (458 pairs) and validation (459 pairs) datasets. The random-sample manual chart review showed 100% accuracy of the sniffer-based aspiration/non-aspiration assignment. Variables selected for the final model are presented in Table 1. This aspiration prediction model showed very good discrimination. The concordance statistic using the point score for the derivation and validation models were 0.777 (95% CI 0.74, 0.82) and 0.78 (95% CI 0.74, 0.82). Using the best discrimination cutoff of 4.5, sensitivity and specificity were 71.2/72.3 and 72.5/69.9 in the derivation/validation models, respectively.

CONCLUSIONS. We derived and validated electronic prediction model for overt nosocomial pulmonary aspiration, programmable for automated identification of hospitalized patients' at risk, in whom potential prevention strategies can be developed and tested.

INTRODUCTION. Acute respiratory distress syndrome (ARDS) remains under-recognized, under-treated and is associated with a high mortality. There is a potential for improvement in the management of these patients.

OBJECTIVES. To study the impact of an evidence based ARDS management on outcomes (28 and 90-day mortality, Ventilator Free days, use of adjunctive).

METHODS. A prospective before-after study for patients with ARDS admitted to 5 intensive care units (ICU´s) from 2012-2017 at Cleveland Clinic. An ARDS management protocol addressing multiple domains (adherence to lung protective strategy: tidal volume< 8; Plateau Pressure< 30; PEEP titrated to ARDSnet PEEP: FiO2 ; volume conservative strategies; sedation, analgesia and neuromuscular blocker protocol; prone position ventilation protocol) was developed and launched in 2016 in all the participating ICU´s.

RESULTS. 546 patients with ARDS were admitted during the study period. After the implementation of the protocol clinician recognition of ARDS improved significantly (23% vs 9%; P< 0.0001 of mechanically ventilated patients). There was no difference in the demographics, causes of ARDS, co-morbidities, severity of illness score (APACHE III and SOFA) in the before and after group. After the implementation of the protocol there was no difference in the median tidal volume over the first 72 hours (7.4 vs 7.6; p 0.11), but the Plateau Pressure (25 vs 29; p < 0.001) and driving pressure (14 vs 15, P0.004) were significantly lower. Similarly, after the implementation of the protocol PEEP discrepancy from the ARDSnet protocol was lower (-6 vs -7.2; P0.03), minute ventilation was lower (10.7 vs 11.3; p 0.002). Use of adjunctive therapies decreased significantly after the implementation of the protocol (40% vs 46%; p0.01). After the implementation of the Protocol the ventilator free days increased (4.5 vs 0 p< 0.001) and both 28-day (42% vs 54% p0.009) and 90-day (52% vs 66% p 0.002) mortality decreased significantly. We also developed a sub-group analysis for patients with moderate-severe ARDS (PF< 150), and there was significantly higher adherence with lung protective ventilation (p0.001), and PEEP based on ARDSnet recommendations (p0.02). The cumulative fluid balance was significantly lower (4 vs 6.5 liter p0.04) after the implementation of the protocol. Use of adjunctive therapies, and 28 and 90-day mortality remained significantly lower after the implementation of the protocol. A cox proportional hazard model was developed and after adjustment for Charlson index, APACHE III, PF ratio, PEEP and volume status on day 7, the mortality remained significantly lower after the implementation of the ARDS protocol (HR 0.54 (0.38-0.78), P< 0.001).

CONCLUSIONS. Implementation of an evidence based protocol improves clinician recognition of ARDS, and is associated with a significant decrease in 28 and 90-day mortality. This approach also decreases the use of adjunctive therapy.

INTRODUCTION. Airway Driving Pressure (DP),Plateau Pressure (Pplat) and Respiratory System Compliance (Crs) are known to correlate with patients' outcome during Controlled Mechanical Ventilation (CMV)[1].Monitoring patient respiratory mechanics during Assisted Mechanical Ventilation is more challenging but could help avoiding lung injury.The measurement of DP, Pplat and Crs during Pressure Support Ventilation (PSV) is feasible[2] and routinely performed in our clinical practice but correlation with clinical outcomes has not been investigated yet.

OBJECTIVES. We aimed to understand the reliability of respiratory system mechanical properties (DP, Pplat and Crs) measured during PSV and their association with clinical outcomes.

METHODS. We conducted a retrospective study on patients undergoing invasive mechanical ventilation for at least 5 days. We included all subjects who spent >24 hours in CMV followed by >24 hours in PSV. We collected from the Electronic Medical record data of the first and last CMV day and averaged the first three days of PSV.We analyzed a) the correlation between measurements taken during CMV and PSV and b) the association between DP, Pplat and Crs values during PSV and clinical outcomes (mortality in ICU and weaning duration in survivors). Data are expressed as mean±SD.

RESULTS. We screened 373 patients, 193 of which met the inclusion criteria. Crs measured during the last day of CMV and during the first three days of PSV were correlated (R^2=0.63). Crs and DP collected during PSV were significantly different between survivors and non survivors (Crs 54
±17 vs 42±16 ml/cmH$_2$O, DP 9.9±2.2 vs 11.5±3 cmH$_2$O during PSV in survivors vs non survivors, p< 0.05 for all comparisons). When DP and Crs were partitioned into quartiles, increasing DP and decreasing Crs were correlated with increasing mortality (Fig.1). No correlation with mortality was found for Peak Pressure and Pplat values. We further stratified survivors into two groups according to the weaning duration; higher PEEP (9.5±3 vs 11.6±3.6 cmH$_2$O), Pplat (19.4±3.8 vs 21.6±4.4 cmH$_2$O), Ppeak (Ppeak 17.4 ±4.5 vs 21±4.7 cmH$_2$O) and PS level (7.9±2.5 vs 9.4±2.6 cmH$_2$O) and lower Crs (58±17 vs 52±16 ml/cmH$_2$O) were associated with weaning longer than 7 days (p< 0,05 for all comparisons).

CONCLUSIONS. The measurement of DP, Crs and Pplat during PSV is feasible and clinically meaningful. Both DP and Compliance of the respiratory system are strongly associated with mortality in patients undergoing spontaneous assisted breathing.

INTRODUCTION. APRV is a relatively new mode of mechanical ventilation which can be used in treatment of patients with impaired oxygenation, but this mode is not widely used by clinicians. Physiological dead space (VDphys.) is an important parameter to assess respiratory function which is equal to the the volume of airway plus ventilated non- perfused alveoli. We conducted this study to compare APRV and BiPAP modes regarding VDphys. and other respiratory variables (pressures and blood gases). Our hypothesis is that the long inspiratory phase in APRV may increase VDphys. (by impairing perfusion) and may affect other respiratory variables.

OBJECTIVES. To compare APRV and BiPAP modes regarding VDphys., respiratory pressures and blood gases parameters.

METHODS. Mechanically ventilated patients with PO2/FiO2 ratio< 300 were randomized into two groups: Group A (APRV group) :APRV mode was used with high pressure (Phi) 20 cmH2O , low pressure (Plo) 5 cmH2O with I:E ratio (Phi phase: Plo phase ratio) 4:1 for 3 hours. Group B(BiPAP group) : BiPAP mode was used with high pressure (Phi) 20 cmH2O, low pressure (Plo) 5 cmH2O with I: E ratio (Phi phase: Plo phase ratio) 1:1 for 3 hours. Then all patients were left for ventilation according to the preference of the physician in charge. VDphys. was measured using the metabolic module of GE

ventilators. Respiratory variables were also recorded. All measurements were done at 30 minutes and at the end of the intervention period (3 hours).

RESULTS. Sixty patients were available for final analysis (30 in each group). There was no statistically significant difference in age (51.7±15.2 vs 54.3 ±16.1, p=0.52) and weight (75.80±13.28 vs 76.57±15.93, p=0.840) between the two groups. VDphys/tidal volume (VT) at 30 minutes was (0.47 ±0.09 vs 0.46 ± 0.08, P=0.61) and at 3 hours was (0.44 ± 0.10 vs 0.43 ± 0.11 , p=0.67) in the two groups respectively. there was a reduction in VDphys/VT within each group at 3 hours but it was not statistically significant (p=0.11 for group A and 0.13 for group B). There was improvement of dynamic compliance within each group (36.17 ± 9.1 vs 39.7±8.33, p=0.002 for group A) and (37.87 ± 7.84 vs 42.37 ± 7.84, p=0.001 for group B). PCO$_2$ was increased in group B (39.17 ± 8.72 vs 42.67 ± 7.73, p=0.013) but it was not clinically significant.

CONCLUSIONS. APRV mode didn't increase physiological dead space compared to BiPAP mode. Both modes improved dynamic compliance.

INTRODUCTION. *In vitro* and animal studies of nebulisation via nasal high flow (NHF) therapy circuits showed theoretical delivery of drug amounts to patients compatible with a significant bronchodilatatory effect.

OBJECTIVES. To compare bronchodilatory effect observed after beta-2-adrenergic agonist nebulisation via a NHF circuit and standard facemask nebulisation in adult patients.

METHODS. Patients with recently (< 3 weeks) documented reversible airflow obstruction received 2.5 mg albuterol nebulised via 3 methods. 1. NHF circuit (vibrating mesh nebuliser placed upstream of the humidification chamber of a Fisher & Paykel Airvo®2 device, 30 L/min gas flow); 2. a standard facemask jet nebuliser and 3. sham nebulisation via NHF (no drug nebulised), in a blinded random order. Pulmonary function tests were performed before and after each session.

RESULTS. Twenty four patients were included. No side effects were observed, and tolerance was good in both active and sham nebulisation delivery. 15 patients (62%) showed significant reversibility after nebulisation via the NHF circuit (forced expiratory volume in one second (FEV$_1$) increase > 12% and/or > 200 mL): median increase 340 mL (110; 380), 18% (7; 23). Of the remaining 9 patients; two patients showed significant reversibility to standard facemask nebulisation only and 7 did not show reversibility to either active nebulisation. Seventeen patients (70%) showed no reversibility after sham nebulization via the NHF circuit. FEV$_1$ improvement after active nebulization via the NHF circuit and after standard facemask nebulisation were well correlated (rho 0.73, *p*=.0005).

CONCLUSIONS. Nebulisation of 2.5 mg albuterol via NHF is feasible and may produce clinically significant bronchodilation among patients with reversible airflow obstruction similar to the effects observed after standard facemask nebulisation.

Comparison of global enddiastolic volume index (GEDVI), extravascular lung water index (EVLWI) and cardiac index (CI) derived from transpulmonary thermodiltion (TPTD) during high flow vs. low/no flow ECMO: the HEUREKA-III animal study

W. Huber, M. Konrad, S. Kammerzell, R. Schmid, A. Herner
Klinikum rechts der Isar; Technical University of Munich, Medizinische Klinik und Poliklinik II, Munich, Germany
Correspondence: W. Huber
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0006

INTRODUCTION. Accurate measurement of CI to optimize the choice of cannulas and ECMO-flow might increase the effectiveness of ECMO. Furthermore, markers of preload (GEDVI) and pulmonary oedema (EVLWI) might help to improve patient selection for ECMO and fluid management. However, there are concerns regarding a potential loss of indicator (LOI) into the ECMO-circuit during indicator injection into right atrium for TPTD and pulmonary arterial thermodilution.

OBJECTIVES. We hypothesized that in particular the derivation of GEDVI and EVLWI might be prone to loss of indicator (LOI). We expected the highest risk of LOI during *high* ECMO-flows, whereas previous data suggest that there is little risk of LOI at low flow (≤0.5L/min). Therefore, the HEUREKA-III-study compared (primary endpoint) GEDVI, EVLWI and CI during maximum ECMO-flow vs. low or no ECMO-flow (GEDVI_max, GEDVI_base etc.).

METHODS. 8 pigs (49.4±4.2kg) with a jugular CVC and femoral artery PiCCO catheter (Pulsion, Germany). Veno-venous ECMO with CARDIOHELP (Maquet/Getinge; Rastatt, Germany) via a femoral drainage and a jugular return cannula. In each animal several sessions with increasing and decreasing ECMO-flow (0-3.5L/min) were performed.

Due to different endpoints, several modifications were performed for the HEUREKA-studies I-IV including variations in the catheter positions, injectate sites and pharmacological modulations of CI by ß-blockers or dobutamine. For the HEUREKA-III study only the first session with increasing ECMO-flow up to the maximum and only sessions with constant conditions except the ECMO-flow were included.

Finally, a total of 13 sessions could be analyzed.

All indicator injections for TPTD were performed via a jugular CVC. Triplicate TPTDs with 15mL of ice cold saline 0.9mL were performed during no/low-flow and during maximum ECMO-flow.

Wilcoxon-test for paired samples. Spearman correlation. SPSS 4

RESULTS. ECMO-flow was significantly (p=0.001) increased from 0.12 ±0.15 (0-0.5) L/min to a maximum flow of 3,0±0.56 (2.0-3.5) L/min. GEDVI_max and GEDVI_base were not significantly different (411±76 vs. 423±49mL/m²; p=0.507). Changes in GEDVI ranged from -111 to +65mL/m². Similarly, EVLWI did not change during maximum ECMO-flow (8.6±1.4 vs. 8.5±1.5mL/kg; p=0.589) with differences of ±2mL/kg. Finally, there were no changes in CI (3.69±1.25 vs. 3.58±1.44L/min/m²; p=0.638) with differences between -1.68 and +1,80L/min/m². Changes in GEDVI, EVLWI and CI were neither associated with baseline values of GEDVI, EVLWI and CI nor with the maximum ECMO-flow.

CONCLUSIONS.

1.) Our data suggest that in pigs equipped with a femoral drainage and a jugular vein return cannula for ECMO with a maximum flow of 3.5L/min does not result in LOI, if a jugular CVC and a femoral arterial catheter are used for TPTD.

2.) Further studies and techniques are required to detect and quantify a potential LOI in case of other catheter settings and higher ECMO flow-rates.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0007

INTRODUCTION. The relationship between arterial pressure and stroke volume changes during a respiratory cycle (pulse pressure variation, PPV; and stroke volume variation, SVV; respectively) has been termed dynamic arterial elastance (Ea$_{dyn}$)[1]. Since, Ea$_{dyn}$ describes the interaction between the flow generated by the heart and the properties of the arterial system, it has been postulated that this parameter could represent an index of the coupling between the heart and the arterial circulation[1].

OBJECTIVES. We aimed to confirm that Ea$_{dyn}$ is a ventriculo-arterial coupling (VAC) index, affected by contractility and the arterial system properties. For this purpose, we use the gold-standard as reference for defining the contractility and afterload, and for investigating VAC.

METHODS. Experimental study in 11 pigs. LV pressure-volume data was obtained with a conductance catheter and peripheral arterial pressures were measured via a fluid-filled catheter in the aorta and radial artery. The slope of the end-systolic pressure volume relationship or Ees (a load independent-indicator of myocardial contractility), was calculated during a transient occlusion of the inferior vena cava. Effective arterial elastance (Ea, a global index of afterload) was calculated as the ratio LV end-systolic pressure / stroke volume. VAC was defined as the ratio Ea/Ees. LV efficiency was defined as the ratio between stroke work (SW) and the pressure-volume area (PVA). Ea$_{dyn}$ was calculated as the ratio between the aortic PPV and conductance-derived SVV, and radial Ea$_{dyn}$ as the ratio between arterial pressure waveform analysis-derived SVV and radial PPV. The experimental protocol consisted in three consecutive phases with two opposite interventions each: changes in afterload (phenylephrine and nitroprusside), preload (bleeding and fluid bolus), and contractility (esmolol and dobutamine). Measurements were obtained before and after each hemodynamic intervention. The impact of different components of VAC (Ees, Ea, Ea/Ees) and LV efficiency on central Ea$_{dyn}$ and radial Ea$_{dyn}$ was assessed using a mixed-effect regression analysis and reported as their estimated fixed effect.

RESULTS. VAC, LV efficiency, and Ea$_{dyn}$ variations and throughout the study are shown in Figure 1. The estimated fixed effects for all components of VAC and LV efficiency on central and radial Ea$_{dyn}$ are detailed in Table 1. Dynamic arterial elastance was inversely related with VAC and directly related with LV efficiency. The higher the Eadyn, the higher the LV efficiency and the lower the VAC.

CONCLUSIONS. Eadyn is a ventriculo-arterial coupling parameter that is directly related to LV efficiency and inversely related to VAC.

INTRODUCTION. Acute heart failure (AHF) due to acute myocardial infarction (AMI) is likely to involve cardiogenic shock (CS), with neurohormonal activation, when early revascularization is not efficient. An increase in circulating vasopressin (VP) has been associated with poor prognosis in AHF (1). Thus, in CS, vasopressin system may be involved in microcirculation alteration leading to inadequate tissue oxygenation.
OBJECTIVES. The aim of the experimental study was to investigate the implication of vasopressin in the alterations of circulation and tissue oxygenation observed in AMI with suspected cardiogenic shock.
METHODS. This animal study was approved by the local ethics committee (CEEA-LR). Surgical left coronary artery ligation was performed (AMI, n=39) or not (Sham, n=21) on male Wistar rats treated (AMI-SR, n=6 and Sham-SR, n=6) or not with the VP antagonist SR-49059. Animals were sacrificed one day after surgery. Echocardiography was performed to determine ejection fraction (EF) and to validate AHF. Mesenteric oxygenation (MO) was measured by percutaneous abdominal near infrared spectroscopy to estimate tissue oxygenation (INVOS™ 5100C, Medtronic) and was expressed as absolute values or normalized to the basal MO measured before surgery. Plasma lactate and copeptin levels were determined on the day of sacrifice. The contractile responses to VP were evaluated *ex vivo* on aortic rings by measuring variations of isometric tensions. Results expressed as mean ±SEM were compared between AMI with EF< 40% and Sham; 14 AMI animals had an EF< 40%.
RESULTS. In Sham and AMI groups, mortality rates were respectively 4 and 36%. The treatment with SR-49059 prevented mortality in AMI as no death was noticed in this group (AMI-SR). We observed that MO dropped immediately after surgery in all groups and fully or partially recovered except in AMI as illustrated in Fig1. MO absolute values increased from 31 ±1.1 to 38±2.4% in Sham (p=0.02), from 30±0.5 to 38±2.2% in Sham-SR (p=0.01) and from 30±1.4 to 38±2.0% in AMI-SR (p=0.01) while in AMI MO remained low (29±0.9 to 32±1.4%, p=0.16). Lactate and copeptin levels were respectively higher in AMI group when compared to Sham (2.9±0.3 vs 2.0±0.2 mmol/l, p=0.01; 637±94 vs 384±47 pmol/l, p=0.01). Furthermore, the contractile response of aorta to VP was impaired in AMI (p=0.04) with a decreased sensitivity consistent with a reduced availability of receptors (Fig2).
CONCLUSIONS. CS after AMI, associated with an increase in plasma lactate level, was characterized by a high mortality rate and a prolonged decrease in mesenteric oxygenation which were prevented by treatment with a vasopressin antagonist (SR-49059). A higher level of copeptin reflected an acute increase in VP secretion in severe AMI that may explain the alteration of arterial contractile response to vasopressin and indicate a critical role of vasopressin system in CS.

Acute heart failure and renal resistive index assessed by Doppler: application to a murine model

A. Blet[1], B. Deniau[1], P.-R. Koundé[2], P. Bonnin[1], J.-L. Samuel[1], A. Mebazaa[1]

[1]U942 INSERM, Paris, France; [2]Paris Diderot University, Paris, France

Correspondence: A. Blet

INTRODUCTION. Heart failure (HF) is a common condition that affects more than 10% of people over the age of 65[1]. Whatever the form, acute or chronic, kidney injury is common during HF[1]. An increase in the renal resistance index (RRI) is correlated with the evolution, severity and mortality of HF[2].

OBJECTIVES. The objective of this study is to describe, for the first time, the change of RRI in an acute heart failure (AHF) model in mice.

METHODS. The study was approved by the local ethics committee (S84/CNREEA#9). AHF was induced by 4 injections of subcutaneous isoproterenol for 2 consecutive days[3] and was defined by a decrease in the shortening fraction of $\geq$ 10% compared to the baseline value. The RRI was defined by the formula: RRI=(systolic peak - diastolic peak)/ systolic peak. The RRI was measured on the right renal artery 3 times and averaged. A first RRI assessment was performed before the induction of the AHF, then a second 24 hours after the last isoproterenol injection. RRI assessments were compared by a paired Wilcoxon test (GraphPad Prism 5.0). A p value < 0.05 was considered significant.

RESULTS. 17 C57Bl6 mice were included. 24 hours after the last isoproterenol injection, all mice had AHF with systolic failure. The RRI was unchanged after AHF induction (0.73 ± 0.12 vs 0.70 ± 0.16, p=0.89) as well as mean velocity (16.68 ± 5.98 vs 17.56 ± 2.51 cm/s, p=0.84). The systolic and diastolic peaks of the right renal artery were unchanged (67.82 ± 26.55 vs 53.90 ± 18.33 cm/s, p=0.34 and 16.42 ± 6.18 vs 13.73 ± 4.76 cm/s, p=0.10). Cardiac output was significantly increased (17.73 ± 13.61 vs 26.61 ± 14.97 ml/min, p< 0.05). Heart rate was significantly decreased after induction of AHF (560 ± 73 vs 445 ± 78 bpm, p< 0.05). Table 1 summarizes the change of these parameters after induction of AHF by isoproterenol in mice.

In our study, the RRI was not altered after induction of AHF by isoproterenol injection in mice. The RRI assessed by Doppler during the experimental AHF could be an additional tool to study renal injury in mice. The initial objective of our study was to describe the feasibility of this technique in this model.

CONCLUSIONS. Kidney injury is one of the most common organ dysfunctions during AHF. The RRI could be an additional tool in small animals. Our study shows that this technique is feasible in mice with acute heart failure. Further studies are needed to demonstrate the validity of this marker during acute AHF after isoproterenol injection.

INTRODUCTION. Arterial hyperoxia may induce vasoconstriction and reduce cardiac output, which is particularly undesirable in patients with already compromised perfusion of vital organs. Due to the inaccessibility of vital organs in humans, vasoconstrictive effects of hyperoxia have primarily been studied in animal models. However, the results of these studies vary substantially. Here, we investigate the variation in magnitude of the hyperoxia effect among studies and explore possible sources of heterogeneity, such as vascular region and animal species.

OBJECTIVES. The objective of this systematic review and meta-analysis is to provide an overview of the characteristics, quality and outcomes of all animal studies on the effect of hyperoxia on arteriolar tone, both *in vivo* and *ex vivo*. In addition, we investigate the variation in magnitude of the hyperoxia effect among studies and explore sources of heterogeneity.

METHODS. Pubmed and Embase were searched for studies up to November 2017. *In vivo* and *ex vivo* animal studies investigating changes in vascular tone induced by local or systemic normobaric hyperoxia were included. Data of lung, brain or fetal vasculature or the ductus arteriosus were not included. We extracted the following data: species, vascular region, blood vessel characteristics and method of hyperoxia induction. Overall effect sizes were estimated with a standardized mean difference (SMD) random effects model.

RESULTS. We identified a total of 60 studies, which reported data of 67 *in vivo* and 18 *ex vivo* experiments. In *in vivo* studies, hyperoxia caused vasoconstriction with an SMD of -1.42 (95%CI -1.65 to -1.19). *Ex vivo*, the overall effect size was SMD -0.56 (95%CI -1.09 to -0.03). Between-study heterogeneity (I^2) was high for *in vivo* (72%, 95%CI 62% to 85%) and *ex vivo* studies (86%, 95%CI 78% to 98%). *In vivo*, in comparison to the overall effect size, hyperoxic vasoconstriction was less pronounced in the intestines and skin (P=0.03) but enhanced in the cremaster muscle region (P< 0.001). Increased constriction was seen in vessels 15-25μm in diameter. Hyperoxic constriction appeared to be directly proportional to oxygen concentration. For *ex vivo* studies, heterogeneity could not be explained with subgroup analysis.

CONCLUSIONS. The effect of hyperoxia on vascular tone is substantially higher *in vivo* than *ex vivo*, suggesting that extravascular mechanisms play a role in hyperoxic vasoconstriction. The magnitude of the constriction is most pronounced in vessels ~15-25μm in diameter and is proportional to the level of hyperoxia. Relatively increased

constriction was seen in muscle vasculature, while reduced constriction was seen in the skin and intestines. *Ex vivo*, the response of the coronary vasculature to hyperoxia is highly variable.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0011

INTRODUCTION. Cervical spine injury (SCI) can result in catastrophic respiratory failure requiring invasive mechanical ventilation (MV) which is a leading cause of mortality and cost. Diaphragm Pacing (DP) was developed to replace/decrease mechanical ventilation.
OBJECTIVE. Report the largest long term analysis of DP in a subgroup of traumatic SCI.
METHODS. A retrospective review of prospective IRB approved protocols. All patients underwent laparoscopic diaphragm mapping and implantation of electrodes. DP electrodes were characterized and diaphragm strengthening with mechanical ventilator weaning was initiated immediately post op.
RESULTS. March 2000 through June 2017 there have been a total of 486 DP implants at this single site. Within this group, 155 had spinal cord damage and 92 of those patients had SCI secondary to trauma. The manner of injury: MVA 44, Sports 22, Falls 12, GSW 7, Crush 3, Forceps Delivery 2, Assault 1, and electrocution 1. The age at time of injury ranged from birth to 74 years old with the average of 27.3 years and median age of 23 years. Time on mechanical ventilation prior to DP was an average of 47.5 months (6 days to 25 years with median of 1.58 years). Patients' highest level of injury: 27 C1, 36 C2, 14 C3, 7 C4, 5 C5 and 3 C6. Twelve patients had internal permanent cardiac pacemakers. There was no device to device interactions between DP and cardiac pacemakers. A total of 83% of patients achieved 4 consecutive hours of pacing with fifty-six patients (60.8%) being full time and an additional 13% using DP >12 hours. DP decreased the need and risk of cuffed tracheostomy with 60% of patients going to cuffless tracheostomy and 7 decannulations. One patient with early DP implant avoided tracheostomy. Five patients were not successful in weaning off MV. Five patients had full recovery of automatic breathing with subsequent DP removal. Two pediatric patients have had growth spurts of 10 inches or greater without need of electrode replacement. There have been 23 deaths with no primary respiratory origin. Subgroup analysis showed that earlier DP implantation leads to greater 24 hour use of DP and no need for any MV. This group also had the greater proportionate recovery of breathing.
CONCLUSIONS. DP can successfully decrease need for mechanical ventilation for a significant number of SCI patients. There is a correlation of early implantation to greater weaning success, recovery of independent breathing and has the potential to obviate need for tracheostomy. Liberation from MV can substantially improve SCI rehabilitation. To minimize MV days and complications, DP should be considered early after injury even in those who may re-gain independent breathing.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0012

BACKGROUND. Existing prognostic models for trauma patients are limited. Copeptin is a sensitive surrogate marker for AVP release indicating the individual stress response. The prognostic value of copeptin in trauma patients has not been evaluated.
OBJECTIVE. The aim of the current study is twofold. First, we seek to evaluate the prognostic significance of copeptin in patients with trauma. Second, we aim to investigate whether the addition of copetin to the existing trauma triage score, specifically TRISS (Trauma and Injury Severity Score) and MGAP (Mechanism Glasgow scale and Arterial Pressure) score, could improve their predictive power.
METHODS. Trauma patients presented to the emergency department of a level 1 trauma center between 2016 June to 2016 December were prospectively enrolled. Copeptin levels were measured at admission with the commercial assay (Kryptor, Thermo Fisher Scientific) and trauma triage scores including TRISS and MGAP scores were calculated for each patient. The association of admission copeptin level with mortality or composite outcome of death and ICU admission was tested using receiver operating characteristics curve. Incremental value of copeptin toTRISS or MGAP score was evaluated by logistic regression and reclassification analysis.
RESULTS. One hundred and thirty one trauma patients were enrolled with a median injury severity score of 9 (Interquartile range 4-26) and 30-day mortality of 16%. After exclusion of patients presenting with out-of-hospital cardiac arrest, copeptin showed a significant correlation with 30-day in-hospital mortality. Median copeptin admission levels were significantly higher in non-survivors as compared with survivors (495 IQR 75-761 pmol/L versus 35.7 IQR 16.5-73.0 pmol/L; $p < 0.0001$). The area under the ROC curve in predicting in hospital mortality was 0.901 for MGAP score, 0.892 for copeptin, and 0.734 for TRISS. Adjusted for TRISS or MGAP in the regression model, copeptin remains significantly associated with the death outcome, indication an incremental value of copetin to the two trauma triage scores. The risk prediction improvement was also reflected by a net reclassification improvement of 37% ($p = .006$) for TRISS and 16% (P< 0.001) for MGAP score. Copetin-augmented MGAP score could achieved the best discrimination (AUC 0.96, 95% CI 0.87-1.00) with a sensitivity of 94.4% (95%CI: 72.7%-99.9%) and a specificity of 99.1% (95%CI: 95.0%-100.0%). Copeptin alone could reach a sensitivity of 92.6 % (85.3%- 97.0%) and a specificity of 92.55 % (85.3%-97.0%) to predict death among trauma patients at a cutoff of 125 pmol/L.
CONCLUSION. Copeptin is a highly accurate biomarker that can be used for rapid risk stratification of polytrauma patients. Combining the information of copeptin and MGAP score will further increase the mortality prediction accuracy. Prospective multicenter studies are needed to validate our findings.

Serial analysis of the immune cells in severe trauma patients

D.W. Kim, I.S. Jeong
Chonnam National University Hospital, Thoracic and Cardiovascular Surgery, Gwangju, Korea, Republic of
Correspondence: D.W. Kim
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0013

INTRODUCTION. Trauma-induced injury actives innate immune responses to produce pro- and antiinflammatory cytokines.These

immune cells are thought to have a significant impact on the prognosis of the patient. Therefore, we tried to analyze the effect of serial measurement of immune cells in severe trauma patients.

OBJECTIVES. Immune function is very important in the severe trauma patients, but it is usually overlooked. We examined the progression of immune function in trauma patients.

METHODS. From January to December 2017, we studied 21 patients who were admitted to Chonnam National University Hospital, Regional Trauma Center with chest trauma.

Blood sample tests were performed on the day of admission, day1, day3, day7, and day30 of admission. Granulocyte (CD66b), helper T-cell (CD4), cytotoxic T cell (CD8), Gamma delta T cell (CD3+TCRrd+), regulatory T cell (CD25+Foxp3+), B-cell (CD19), NK cell subtypes (CD56brightCD16±, CD56dimCD16+, CD56-CD16+), Monocyte subtypes (CD14+CD16-, CD14CD16+, CD14+CD16+) level were measured in the peripheral blood by flow cytometry.

RESULTS. Mean age was 55.3±16.3 yearls old and male were 16 patients (76.2%), The mean ISS was 17.3±6.9, SOFA score 1.6±2.3. The CD56+CD16+ NK cell wea significantly decreased in severe trauma patients (ISS>15, N=6), compared to patietns with ISS < 15 (p=0.04). and CD4/CD8 was also decreased in severe trauma patients (p< 0.01). Most of the immune cells in severe trauma patients were not recovered within 1 month.

CONCLUSIONS. This study confirmed that the immune function of patients with severe trauma was not recovered within one month. Further studies are needed to confirm the association of immune function with clinical outcomes.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0014

INTRODUCTION. Over the last decade, the incidence of gunshot wound trauma (GWT) globally increased in France (1,2). Few studies have characterized the infectious complications in this setting (3), and no international guidelines are available for the antibiotic prophylaxis (ABX) in these cases.

OBJECTIVES. The goal of this present study is to assess the risk factors of infection after GWT.

METHODS. Retrospective study(2011-2017) of all GWT admitted in our ICU. Results are presented in median (IQR) and proportions. The associated factors of infections were analysed in univariate analysis followed by an exact logistic regression (variables with a p-value< 0.15).

RESULTS. 50 patients were analysed; 98% male, median age 26 (22-34) years, ISS score 9 (5-12), SAPSII score 15 (8-20). The entry anatomical region of the projectile was chest (n=29), abdomen (n=22), lower extremity (n=23), upper extremity (n=17) and head (n=1). At the time of admission, 25% of the patients were in haemorragic shock and

18% had a vascular effraction with active bleeding. 44 (88%) were admitted in operative room during the first 24h. 46 (92%) of the patients were treated by an ABX for a duration of 2 (2-5) days by amoxicilline-clavulanate (100%). 9 (18%) of the patients developed a wound infection in a delay of 5 (3-8) days : 2 chest wall abscesses (*E. faecalis*), 1 pulmonary abscess (*E. coli, Bacteroides fragilis, Clostridium spp, Pediococcus spp*), 2 abdominal abscesses (*S. aureus*, and one negative culture), 1 lower limb infection (*E. coli*) and 3 homolateral pneumonia (2 *Enterobacter spp, P. aeruginosa*). One patient died after a *P. aeruginosa* pneumonia. Table represents the risk factors of GWT infections (univariate analysis). In multivariate analysis, mechanical ventilation (MV) was the only risk factor identified for GWT infection (OR = 10.7, p=0.013).

CONCLUSIONS. In this cohort of GWT, 18% of the patients developed an infection. Except MV, no associated factors were identified. A prolonged duration of ABX≥48h was not associated with a decreased incidence of these infections (OR 5.7 (0.8-37), p=0.07).

INTRODUCTION. Trauma can induce hypocoagulability, emanating from imbalances between procoagulant factors, anticoagulant factors and fibrinolysis. Early hypocoagulability may convert into a hypercoagulable state(1), possibly as an endogenous response to trauma or due to therapeutic intervention. Whether late hypercoagulability predisposes patients to organ failure is unknown.

OBJECTIVES. We aimed to study the incidence, risk factors and outcome of late hypercoagulability in trauma patients, as assessed by viscoelastic hemostatic assays (VHA).

METHODS. A substudy of the prospective multicenter study 'Activation of Coagulation and Inflammation in Trauma II' (ACIT II) was performed in patients recruited between January 2008 and January 2015 in 6 level-1 trauma centers in Europe. Clot strength, as measured by the G-value on thromboelastometry (ROTEM) or thromboelastography (TEG), was used to define hypercoagulability (TEG>12400 dynes/cm^2, ROTEM>11700 dynes/cm^2). Blood samples were taken immediately in the emergency department and 72 hours after injury. Multiple Organ Failure (MOF) was defined as failure of at least two organ systems (SOFA score ≥6). Logistic regression models were used to determine the drivers of hypercoagulable VHA tracings and the association with organ failure.

RESULTS. A total of 819 patients were included with a median ISS of 21 (IQR: 10-29). At baseline, hypercoagulability was present in 8% of all patients. Hypercoagulable patients were less likely to have traumatic brain injury (AIS head score ≥3, 29.1% vs 36.1, p=0.039) and were less shocked, (Base Deficit, -2.6±4.6 vs -3.5±5.7 mmol/L, p=0.022). After 72 hours, 41% of patients were hypercoagulable. Multivariable modeling showed that tranexamic acid (TXA) was the only risk factor for the development of late hypercoagulability (OR 1.9, 95%CI 1.3-2.6, p< 0.001). TXA also was an independent risk factor for the development of MOF (OR 1.9, 95%CI 1.3-2.8, p=0.001). However, late hypercoagulability itself showed no association with the development of MOF (OR 1.3, 95%CI 0.9-2.0, p=0.146).

CONCLUSIONS. Late hypercoagulability is present in nearly half of this severely injured cohort 3 days after trauma. This was associated with early TXA administration, but not with the development of MOF.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0016

INTRODUCTION. Seasonal as well as pandemic influenza are a major cause of serious illness and deaths worldwide each year. Early antiviral treatment of the disease might improve outcomes.

OBJECTIVES. To study the effect on ICU-mortality of early treatment with oseltamivir in patients with severe pneumonia due to influenza.

METHODS. Secondary analysis of a prospective study in critically ill patients with severe pneumonia due to confirmed influenza, admitted to 148 Spanish ICUs between June 2009 and April 2014. Demographic, clinical and treatment data were collected. All patients who required mechanical ventilation were analysed. Patients who received early oseltamivir (EO) therapy (within ≤ 48h of onset of symptoms) were compared with those who received late oseltamivir (LO) therapy (> 48h). To evaluate the effect of oseltamivir on mortality, a multivariate analysis and a Propensity score (PS) analysis were performed.

RESULTS. The total population comprises 1814 ventilated patients. The median APACHE II and SOFA scores were 17.2 (SD ± 6.9) and 7.5 (± 3.5) respectively. The EO group (412 patients, 22.7%) was

compared with LO group (1402 patients, 77.3%). Patients in EO group were older (median, 54.3 vs 52.3 years, p=0.03), had higher APACHE II score (18.2 vs 17.0, p=0.03) and they were more asthmatic than patients in the LO group (14.6% vs 7.9%, p=0.001). In contrast, patients with LO were more obese (36.2% vs. 29.6%, p=0.01), had a longer hospitalization delay (5 vs. 3.2 days, p=0.001) and had more bacterial coinfection rate (22.1% vs. 17.7%, p=0.05). The overall mortality was 28.2% (511 patients) and ICU-mortality rate was higher in the LO group (29.6% vs 23.3%, p = 0.012). The multivariate analysis showed that early therapy with oseltamivir was associated with better survival rates (OR=0.70, 95% CI 0.51-0.95, p=0.025). Furthermore, these results were confirmed after performing the PS analysis (OR=0.75, 95% CI 0.56-1.00, p=0.05) (Figure). Finally, we also found that the number needed to treat (NNT) was only 15 to prevent one additional bad outcome, even greater impact was observed (NNT = 8) in patients who did not have comorbidities (OR=0.5, 95% CI 0.2-0.9, p=0.03).

CONCLUSIONS. Our results suggest that the early administration of oseltamivir in ventilated patients with severe influenza pneumonia is associated with better outcomes.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0017

INTRODUCTION. Critical illness may profoundly alter the pharmacokinetics (PK) of antimicrobial drugs[1]. Dosing regimens based on PK data from healthy volunteers may therefore not be accurate. Several population PK models have been constructed based on data from critically ill patients. The population PK model with the lowest bias and imprecision should be implemented in dosing software designed for dose-optimisation[2].

OBJECTIVES. To compare the accuracy of seven piperacillin population PK models to predict concentrations in an independent validation cohort of critically ill patients receiving continuous infusion piperacillin.

METHODS. All population PK models included were constructed with data from critically ill patients receiving either intermittent, extended or continuous infusion. A statistical evaluation was undertaken to compare imprecision (root mean square error, RMSE and ΔRMSE) and bias (mean error, ME and ΔME) of predictions by these seven PK models for an independent dataset containing piperacillin concentrations of 45 critically ill patients receiving continuous infusion piperacillin. The application used to predict serum piperacillin concentrations was ID - ODSTM (Individually Designed Optimum Dosing Strategies) (http://www.optimum-dosing-strategies.org).

RESULTS. Absolute imprecision (RMSE) ranged from 20.82 mg/L to 135.70 mg/L and absolute bias (ME) ranged from -76.85 mg/L to 93.13 mg/L. The approached that ranked best with regards to absolute bias showed an ME of 7.04 mg/L (95% CI -3.68; 17.77) and the model that ranked best with regards to absolute impression showed an RMSE of 20.82 mg/L (95% CI 54.79; 75.29)

CONCLUSIONS. All evaluated PK models demonstrated a low to moderate prediction accuracy of the independent dataset of critically ill patients receiving continuous infusion piperacillin. Whilst software-guided dosing is likely better than product information dosing, we recommend supplementing dosing software with TDM using an adaptive feedback approach to maximize accuracy.

INTRODUCTION. Pneumonia due to Methicillin-resistant *Staphylococcus aureus* (MRSA) in the intensive care unit treated with intravenous vancomycin or linezolid still showed lower clinical response rate. However, there were few studies evaluating the efficacy of aerosolized vancomycin in MRSA pneumonia.

OBJECTIVES. This study was prospective, non-comparative, two-staged trial to investigate the efficacy and pharmacokinetics of aerosolized vancomycin in mechanically ventilated patients with MRSA pneumonia. (ClinicalTrials.gov Identifier NCT01925066).

METHODS. More than 48 hours mechanically ventilated patients on intravenous vancomycin treatment of MRSA pneumonia were screened. Enrolled patients received aerosolized vancomycin (250 mg every 12 hours) via a nebulizing device for five days. The primary outcome was the clinical response at the end day of treatment. Secondary outcomes included microbiological response, bronchoscopic response, ICU and hospital mortality. Pharmacokinetics of aerosolized vancomycin and were monitored in selected patients. Treatment-related adverse events such as bronchospasm, desaturation, systemic toxic effect, and the emergence of vancomycin-resistant microbe were also evaluated.

RESULTS. Total 20 patients (nosocomial pneumonia, n=18; community-acquired pneumonia, n=2) were included. 13 patients (65.0%) showed clinical cure or improvement at the end day of treatment, which was satisfied with the completion of the first stage. Microbiologic eradication of MRSA also identified in 14 patients (70.0%). ICU and hospital mortality were 30.0% and 35.0%, respectively. Some patients with tracheobronchitis showed an improvement in airway inflammation. The peak concentration of aerosolized vancomycin was 105.31 mcg/mL at 4-5 hour after nebulization. No significant treatment-related adverse events were reported except asynchrony to the ventilator.

CONCLUSIONS. In conclusion, additional aerosolized vancomycin showed acceptable clinical and microbiological outcomes in mechanically ventilated MRSA pneumonia patients. This strategy might be safety and alternative treatment option.

INTRODUCTION. Randomized Clinical Trials (RCTs) on Hospital-Acquired (HABP) and Ventilator-Associated Bacterial Pneumonia (VABP) are common methods to investigate antimicrobials seeking new drug approval. However, the heterogeneity in endpoints used in these RCTs is striking (1).

OBJECTIVES. To reach a consensus on possible clinical endpoints for future clinical trials evaluating the efficacy of antimicrobial treatment for HABP/VABP.

METHODS. Twenty-six international experts with intensive care (n=15) and infectious disease (n=7) departments background and from the pharmaceutical industry (n=4) were polled using the Delphi method (four successive rounds) from January 2016 to January 2017. To achieve consensus, a similarity greater than 70% of the answers to a question was required.

RESULTS. The panel recommended a hierarchical composite endpoint (Figure 1) including, by priority order, for VABP (i) all-cause mortality, (ii) mechanical ventilation (MV)-free-days and (iii) clinical cure; and for HABP (i) all-cause mortality and (ii) clinical cure. Clinical cure was defined by consensus as the association of 3 criteria: resolution at end of therapy of signs and symptoms present at enrolment, no further antimicrobial treatment requirement, and improvement or lack of progression of radiological signs. No consensus timepoint was achieved for clinical cure and MV-free days assessment, due to the variability in expert answers. However, more than 70% of them finally agreed to assess mortality, MV-free days at Day 28 and clinical cure within the first seven days following end of treatment. Hierarchy between endpoint components (especially clinical cure and MV-free days) was also difficult to obtain, requiring 3 Delphi rounds to achieve an agreement of only 72% of the experts. Indeed, expert opinions varied according to their specialty and their nationality: all-cause mortality was more frequently chosen as most desirable among non-European experts (55% vs. 7%, p=0.02) and from industry (75% vs. 18%, p=0.04).

CONCLUSIONS. Based on a Delphi process, we provide separate hierarchical composite endpoints for VABP and for HABP, and a consensus definition of clinical cure that could be considered as a component of the efficacy measurements of antimicrobial agents used in future HABP/VABP clinical trials.

Does dosing of piperacillin-tazobactam in critically ill patients on ECMO need to change? A pharmacokinetics study

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0020

INTRODUCTION. The growing adoption of extracorporeal membrane oxygenation (ECMO) into adult intensive care units (ICUs) has lead clinicians to re-evaluate the use of conventional dosing regimens in this patient population. Neonatal studies have suggested modified antimicrobial dosing regimens are necessary in the presence of ECMO to attain PK/PD targets for optimised bacterial kill and clinical cure. However, due to significant differences in physiology, these findings cannot be safely transferred to the adult population. Empirical antibiotics such as piperacillin-tazobactam have no defined titratable end-point, leading to possible sub- or supra- therapeutic management in this group of critically ill patients.

OBJECTIVES. The aim of this study is to describe the pharmacokinetics (PK) of piperacillin in critically ill patients receiving ECMO. Through the improved understanding of ECMO-induced PK effects, propose dosing strategies that are more likely to attain the PK/PD targets of 50% $fT>_{MIC}$ to optimise therapeutic outcomes.

METHODS. This study was a multi-national, open-label study designed to describe the PK of piperacillin over one dosing interval. Critically ill adults with severe cardiac and/or pulmonary dysfunction from six intensive care units in Australia, New Zealand and

Switzerland were eligible for recruitment. Serial blood samplings were taken over pre-defined time-points. Centralised bioanalysis occurred to determine plasma piperacillin concentration through validated chromatographic methods. The concentration-time data were then used to generate pharmacokinetic parameters through non-compartmental methods.

RESULTS. Eight patients were recruited to the study [Table 1]. One patient was excluded from analysis due to incorrect labelling. Non-compartmental analysis yielded a median (IQR) of 12.76 (3.28-22.37) L/h for total clearance and 32.76 (22.82-68.70) L for volume of distribution at steady state. Refer to Figure 2 for the total plasma concentration time graph.

CONCLUSIONS. The PK parameters generated by this study were generally consistent with published parameters of critically ill patients not receiving ECMO. It appears that conventional dosing of piperacillin in the critically ill population may provide the target attainment of 50% $fT>_{MIC}$. It is important to acknowledge the heterogeneity within the results and that further analysis and recruitment is required to produce robust recommendations in dosing antibiotics in adults on ECMO.

INTRODUCTION. Clinical judgment is insufficient to an early identification of outcomes in septic children and studies of biomarkers in this scenario are relatively scarce.

OBJECTIVES. We aimed to describe the plasma cytokine profile at the admission at Pediatric Intensive Care Unit (PICU) and its association with outcomes.

METHODS. We prospectively included children with community-acquired sepsis, from 3 PICUs in tertiary hospitals in Rio de Janeiro, Brazil. Patients' plasma samples were analyzed, using a multiplex system simultaneously measuring 17 cytokines (IL-1 beta, IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12, IL-13, IL-17, interferon-gamma, granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor, monocyte chemoattractant protein [MCP]-1, macrophage inflammatory protein-1 and tumour necrosis factor-alpha).Outcomes of interest were PICU mortality, use of vasopressors and invasive mechanical ventilation (IMV).

RESULTS. We studied 93 septic children (median age: 2 years, 55% male; infectious focus 65% respiratory, 13% central nervous system). Overall PICU mortality rate was 13%.We considered for analysis in this study cytokines whose detection percentage was at least 50% (G-CSF, IL-7, IL-8, MCP-1, MP-1 and TNFα). The cytokine profile at admission was comparable in survivors and non-survivors. When we considered organ failures and the use of invasive support, MIP-1 and TNFa levels were higher in children with shock requiring vasopressors and use of IMV, respectively. These results were even more evident when we analysed a more homogeneous subgroup with pulmonary infections.

CONCLUSIONS. In this exploratory analysis, plasma cytokine values on admission were not able to discriminate survivors and non-survivors. However, we observed higher levels of of MIP-1 in

patients with shock and higher levels of TNFα in those requiring IMV. With the current preliminary results, we conclude that single-point evaluation of cytokines at ICU admission are not useful prognostic tools and can't be used in the decision-making process.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0022

INTRODUCTION. Spontaneous hypothermia in sepsis is associated with increased mortality compared to patients presenting with fever. Studies have failed to illicit a biological mechanism for the hypothermic response. Thereby, it is unknown whether hypothermia merely reflects disease severity or that specific pathophysiologic pathways are involved.
OBJECTIVES. In this prospective cohort study we aimed to characterize the blood genomic response and associated cellular biological pathways in patients presenting with hypothermic sepsis compared to patients with febrile sepsis.
METHODS. This study prospectively included septic patients in two tertiary intensive care units from January 2011 to June 2012. Blood was collected in PAXgene tubes within 24 hours of ICU admission. Total RNA was isolated and genome-wide blood gene expression profiles of sepsis patients with hypothermia (defined as a body temperature $< 36°C$ in the first 24 hours of admission) were compared to febrile patients (body temperature $>38,3°C$ in the first 24 hours of admission). Analysis was performed between unmatched patient groups as well as between groups matched for Acute Physiology And Chronic Health Evaluation (APACHE)-IV score and/or the presence of shock (hypotension requiring treatment with vasopressors).
RESULTS. In total, 67 patients with hypothermic sepsis and 101 patients with febrile sepsis were included in this study. Patients with hypothermic sepsis had significantly increased 30-day mortality compared to febrile septic patients (43% vs 11%, p=0.001). Blood microarray analysis of unmatched patients revealed 6 elevated and 12 reduced gene expression indices (adjusted p< 0.05). The matched analysis for APACHE-IV included 60 patients in both groups and the APACHE-IV + shock analysis included 55 patients in both groups. In the comparison matched for APACHE-IV score, 6 gene pathways were over-expressed in the hypothermia group, including genes involved in dopamine, noradrenaline and adrenaline degradation pathways. These cellular biological pathways appeared to be related to shock as these were no longer significant in the analysis corrected for shock. The analysis matched for APACHE-IV + shock revealed 3 over-expressed gene pathways in hypothermic patients, including; tryptophan degradation X, putrescine degradation III and phenylaline degradation IV (adjusted p< 0.05).
CONCLUSIONS. Hypothermic septic patients show marked differences in blood genomic response compared to febrile septic patients. Several pathways remain upregulated after correcting for disease severity and shock. Given the high mortality associated with hypothermia during sepsis, these pathways warrant further investigation.

Composition of alveolar myeloid cells is altered and their phagocytic capacity is decreased in septic shock patients

INTRODUCTION. Sepsis evokes multiple maladaptive changes in the immune system but most of them are investigated in the peripheral blood (PB). However, local tissue milieu can specifically influence the activity of immune cells. Despite systemic immunosuppression, sepsis often generates an inflammatory response in the lungs. Therefore, we hypothesized that lung myeloid cells can be differently affected during sepsis, then their circulating counterparts.
OBJECTIVES. To analyze the composition of myeloid cells in the bronchoalveolar lavage fluid (BAL) of septic patients and compare the phagocytic activity of these cells to the circulating cells.
METHODS. BAL and PB were collected from 10 patients with peritonitis derived septic shock on the 1st day. Flow cytometry was applied to analyze the phenotype of the myeloid cells populations and the FITC-labeled *E. coli* assay (Phagotest, BD) was used to evaluate the phagocytic capacity of monocytes and macrophages. Median values are presented.
RESULTS. BAL analysis revealed that CD206+CD169+CD14- alveolar macrophages constituted 48.8% of CD45+ cells, CD16+CD24+ neutrophils constituted 21.9% of CD45+ cells and frequency of CD14 +CD206-CD24- monocytes was 1.1%. The main subpopulation of monocytes were the CD14+CD16+ cells (57.6%) followed by CD14 +CD16- (34.1%) and CD14-CD16+ (1.2%). Phagocytosis of *E. coli* was executed by almost 100% of monocytes and granulocytes from the PB. However, among BAL cells, only 5% of CD14+ monocytes and 5% of all myeloid cells were able to engulf bacteria. Incubation of BAL cells in the plasma from the same patient increased the phagocytosis rate almost 10-fold.
CONCLUSIONS. BAL from septic shock patients contains an increased proportion of neutrophils and reduced frequency of macrophages. Interestingly, alveolar monocytes and macrophages showed reduced phagocytic activity in comparison to PB cells. Furthermore, this discrepancy seems to be partially an intrinsic feature of the alveolar cells. Activation status of the alveolar cells differs from their circulating counterparts and its monitoring should be considered in the trials with immunomodulatory agents.

Metabolic profiles in sepsis evolve over time

D.B. Antcliffe, F. Al-Beidh, A.C. Gordon
Imperial College London, Section of Anaesthetics, Pain Medicine and Intensive Care, Department of Surgery and Cancer, London, United Kingdom
Correspondence: D.B. Antcliffe
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0024

INTRODUCTION. Despite hundreds of trials investigating novel treatments for sepsis, there are no new therapies in routine clinical use. In part this reflects the huge heterogeneity of this syndrome and that some therapies may benefit some, but not all, patients. New methods to stratify patients and track response to treatment are needed to identify subgroups who may benefit from specific therapies.

OBJECTIVES. To analyse metabolic profiles in serum samples collected from patients with septic shock to identify clinically useful groups and to track metabolic changes over time.

METHODS. Serum was collected from 162 patients enrolled into the VANISH (1) clinical trial at enrolment and up to three subsequent time points. Metabolic profiles were measured using ultra performance liquid chromatography -mass spectroscopy (UPLC-MS) and analysed using a combination of unsupervised and supervised multivariate statistics.

RESULTS. Multivariate analysis was able to successfully distinguish abdominal from respiratory infection (R^2 0.73, Q^2 0.29, p< 0.001, AUROC 0.86) and those who had surgical intervention for abdominal sepsis from those who did not (R^2 0.94, Q^2 0.58, p< 0.001, AUROC 0.97). Metabolic trajectories over time were different between those with uneventful recovery from sepsis and those with liver failure (R^2 0.41, Q^2 0.31, p< 0.001).

CONCLUSIONS. Metabolic profiling shows promise both to detect meaningful subgroups of patients with septic shock at the point of admission and to track clinical trajectories over time. This has promise to determine subgroups who may respond to specific sepsis therapies and to track response to treatment over time.

INTRODUCTION AND OBJECTIVES. Septic cardiomyopathy is a severe complication of sepsis and leads to poor prognosis (1). Recently, septic cardiomyopathy is thought to be associated with mitochondrial dysfunction and impaired metabolism in myocardium. The beta-3 adrenergic receptor (β3AR) has a lipolysis effect and the expression is enhanced in failing heart (2). Several studies have reported β3AR stimulation has a beneficial effect for heart failure, however the role of β3AR in septic heart is unknown.

METHODS AND RESULTS. We made a sepsis model by intraperitoneal injection of lipopolysaccharide (LPS) of 10 mg/kg into C57Bl/6 mice. We divided these subjects into 3 groups as 1mg/kg of the β3AR agonist CL316243 (CL), 1mg/kg of the β3AR selective antagonist SR59230A (SR) and 200μl of normal saline (NS). Kaplan-Meier analysis showed that 24 hour-survival rate was significantly improved in the SR as compared to the CL and the NS (the survival rate was 100% of the SR, 60% of the NS and 20% of the CL, n=10 of each). Echocardiography revealed decreased LVEF was observed at 6 hours after LPS and gradually restored within 24 hours. LVEF did not reduce in the SR (62.3±9.7%), whereas it got worse in the CL(32.5 ±6.4%) than that in the NS (47.1±6.2%). Myocardial ATP was preserved in the SR, on the other hand it was significantly decreased in the NS and the CL. Quantitative PCR analysis revealed that gene expressions associated with fatty acid oxidation (FAO) and mitochondrial function was improved in the SR; *Cpt-1*, an enzyme for free fatty acid intake to mitochondria, and *Pparα*, a nucleus transcriptional factor to promote FAO, were upregulated in the SR. In addition, *Pgc1a* and *Erra*, which are transcriptional factors associated with mitochondrial biogenesis, were also improved in the SR. In contrast, those expressions were downregulated in the NS and the CL. Interestingly, *Il-6*, a major inflammatory cytokine, was significantly decreased in the SR, whereas it was significantly increased in the CL. Oil red O staining of the septic heart showed that the deposition of lipid droplets which had not been utilized for energy in mitochondria was markedly increased in the CL, but significantly reduced in the SR. These results suggested the β3AR antagonist improved metabolic pathway of FAO.

CONCLUSIONS. Blockade of the β3AR spared cardiac energy by improving FAO in a septic heart. The β3 AR is a novel metabolic target for septic cardiomyopathy.

INTRODUCTION. Optimal transfusion practice in VV-ECMO patients is still under debate. Traditionally, the threshold for transfusions of packed red blood cells (PRBC) in ECMO aims to keep hemoglobin (Hb) in the near-normal range (12-14 g/dL). Since blood management practices in critically ill patients have changed over the years, we hypothesize that practice may vary also in the treatment of the ECMO patients

OBJECTIVES. To assess Hb triggers worldwide, and parameters considered, in addition to Hb, for transfusion during VV-ECMO.

METHODS. Web-based (SurveyMonkey) descriptive, semi-structured and voluntary, anonymous, non-funded, self-administered cross-sectional survey, approved and endorsed by the European Society of Intensive Care Medicine (ESICM) Research Committee. Organized into four domains:

1) participant experience and ECMO program characteristics;
2) institution-specific blood product transfusion trigger;
3) transfusion trigger in VV-ECMO;
4) other parameters taken into account in case of uncertainty.

RESULTS. In total, 447 respondents worldwide answered the questionnaire: Europe 277 (61.9%), North America 99 (22.1), Asia-Oceania 36 (8.2%), Central and South America 35 (7.8), working mainly in teaching hospitals (79.4%). According to volume of the center, 59.2% manage < 12 VV-ECMO run/year, 19.4% between 12 and 24 run/year, and 21.4% > 24 run/year. The circuit adopted is more frequently "tip-to-tip" heparin coated (75.6%).

In terms of transfusion policy, most centers do not have a fixed Hb trigger for critically ill patients (56.4%) or for ECMO patients (54.4%), and hematocrit is not considered a trigger in critically ill (80.6%) and in ECMO (79.9%) patients. For centers that do have a defined trigger, it was higher in ECMO patients (9.1 g/dl) than in critically ill patients (8.3 g/dl) (p value < 0.01). The adoption of a definite Hb trigger was higher among respondents from higher volume centers: < 12 run/year 37.6%, 12-24 run/year 48.5%, >24 run/year 63.6% (p value: < 0.01). Moreover the mean Hb value was inversely associated with the center´s volume: < 12 run/year 9.6 g/dl, 12-24 run/year 8.9 g/dl, >24 run/year 8.4 g/dl (p value < 0.01).

The main parameters considered when there is uncertainty about a transfusion are SvO2, lactates, peripheral perfusion, hemodynamic stability, and bleeding.

CONCLUSIONS. The survey evidenced that there is no consensus on the Hb trigger among ECMO practitioners, but a higher Hb target is considered plausible, and higher-volume centers seem more frequently to adopt a protocol of transfusion practice, and tolerate lower Hb levels during VV-ECMO. Prospective observational studies are needed to define current triggers for transfusion during VV-ECMO. Transfusion practice may be one of the reasons that centralization of ECMO patients in high volume centers carries benefits, as recent position papers have highlighted.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0027

INTRODUCTION. Prone position (PP) is a life-saving therapy for severe ARDS[1] although widely underused in the largest recent observational study[2]. Veno venous extracorporeal membrane oxygenation (vvECMO) is proposed for severe hypoxemia unresponsive to PP. The combination of both therapies has been investigate in only small cohorts for feasibility and safety issues[3].

OBJECTIVES. We report herein a large retrospective cohort study of consecutive severe ARDS patients treated with vvECMO and compared patients exposed to at least one PP session during ECMO run with patients in the supine position during all their ECMO run.

METHODS. Retrospective analysis of medical charts of patients > 18 years supported by vvECMO in two ICU in Marseille, France, between January 2012 and April 2017. Patients supported by vvECMO after lung transplantation were not included. The decision to perform or not PP during ECMO belonged to the intensivist staff in charge of the patient.

RESULTS. During the studying period 235 consecutive patients were supported with vvECMO. Among them, 66 were lung transplant recipients and therefore not studied. We compared 77 patients in the supine

position during their ECMO run (supine ECMO group) to 92 patients with at least one PP session during their ECMO run (prone ECMO group). Among the 169 patients, 103 (61%) were weaned alive from vvECMO and 80 (47%) were discharged from the ICU. Median ECMO duration was 12 IQR (6;18) days and ICU length of stay 25 IQR (12;35) days. In the prone ECMO group, a median of two sessions of PP was performed IQR (1;4) totalizing 269 sessions. Patients from the prone ECMO group were more frequently weaned alive from vvECMO than patients in the supine ECMO group 70% vs 51 %, p=0.017. ICU survival rate was greater in the prone ECMO group as compared with the supine ECMO group 55% vs 38 %, p=0.03. Concerning potential confounding factors, patients in the prone ECMO group were more frequently postured on PP before cannulation as compared with the supine ECMO group, 76% vs 49 %, p< 0.01, were hospitalized more frequently during years 2015 to 2017, 64 % vs 38%, p< 0.01 and were less critically ill, SAPS II score of 46 (39;54) vs 52 (41;64) in the supine ECMO group, p=0.045.

CONCLUSIONS. Combination of PP during vvECMO for severe ARDS is potentially associated with a higher rate of ECMO weaning and ICU survival. However, confounding factors need to be analyzed in a competing risks approach model.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0028

INTRODUCTION. Among the attempts to improve the effectiveness of extracorporeal membrane oxygenation (ECMO) are less invasive devices as well as optimization of patient selection, anticoagulation and treatment set-up. Since the extra-corporeal flow should exceed 40-60% of cardiac output (CO), accurate measurement of CO is important before the onset of ECMO (choice of cannulas) and during the extracorporeal procedure to adjust the ECMO-flow and to optimize haemodynamics. Indicator dilution techniques such as the pulmonary arterial catheter (PAC) and transpulmonary thermodilution (TPTD) are considered as gold standard to measure CO. However, due to a potential loss of indicator into the extra-corporeal circuit there are concerns regarding both PAC and TPTD during ECMO. One option to avoid a loss of indicator could be a combination of PAC and TPTD with an injection of the indicator into the distal lumen of the PAC and detection of the signal with a TPTD catheter in the femoral artery (CI_PATPTD). A similar option has been suggested two decades ago using trans-pulmonary *dye* dilution. To the best of our knowledge it has not been validated combined with single indicator transpulmonary *thermo*dilution.

OBJECTIVES.

1.) To validate CI_PATPTD vs. CI_TPTD in a subset with ECMO-flow ≤0.5L/min (no risk for loss of indicator).

2.) Comparison of CI_TPTD vs. CI_PATPTD during higher ECMO-flows up to 3.5L/min which might result in loss of indicator for CI_TPTD, but not for CI_PATPTD.

METHODS. 8 pigs (49.4±4.2kg) instrumented with a PAC and a CVC (both via jugular vein) and a PiCCO catheter (Pulsion, Germany) in the femoral artery. Veno-venous ECMO with CARDIO-HELP (Maquet/Getinge; Rastatt, Germany) via a femoral drainage and a jugular return cannula.
Haemodynamic measurements were recored before and during ECMO with increasing and decreasing extracorporeal flow (0.5, 1.0, 2.0 and maximum flow of 3.5L/min). Each dataset consisted of triplicate measurements of CI_TPTD and CI_PATPTD.

RESULTS. In 18 datasets with an ECMO-flow ≤0.5 (mean 0.21 ±0.22) L/min CI_TPTD and CI_PATPTD (3.36±1.06 vs. 3.46±1.07L/min/m²; n.s.) were comparable and showed an excellent bias (-0.01±0.17L/min/m²) and percentage error PE (9.6%). Therefore, we considered CI_PATPTD as gold-standard for all measurements. In all 64 datasets (ECMO-flow of 1.66±1.17 L/min), CI_TPTD correlated with CI_PATPTD (r=0.982; p< 0.001). CI_TPTD and CI_PATPTD were slightly different (3.45±1.13 vs. 3.55±1.23L/min/m²; p=0.042). This resulted in a low bias of -0.08±0.26L/min/m² and an acceptable PE of 14.7%. In multivariate regression analysis the bias (CI_TPTD - CI_PATPTD) was neither associated with high ECMO-flow nor with low CI_PATPTD.

CONCLUSIONS.

1.) Measurement of CI_PATPTD combining PAC with TPTD is feasible, accurate and precise.
2.) Measurement of CI using conventional TPTD (CI_TPTD) did not result in a substantial bias and PE compared to CI_PATPTD even during high ECMO flows.

A systematic review of the effectiveness of extracorporeal membrane oxygenation (ECMO) to treat severe acute respiratory failure in adults

E.C. Camacho, A.A. da Silva, G.F.J.d. Matos
Hospital Albert Einstein, Critical Care Unit, São Paulo, Brazil
Correspondence: E.C. Camacho
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0029

INTRODUCTION. Acute respiratory failure (ARF) has been associated with poor outcomes in intensive care unit (ICU). Extracorporeal membrane oxygenation (ECMO) has been introduced to increase survival in patients with ARF.
The ECMO in many western countries is one of the main issues regarding the different modes and types of cannula. This is because of its strong impact on the organisation of the ICU in terms of the number of personnel, their expertise, the infrastructure and costs.

OBJECTIVES. To provide an up-to-date assessment of the effectiveness of ECMO on mortality, length of stay (LOS) in intensive care unit (ICU) and hospital and adverse events in ICU patients with ARF.

METHODS. We have combined highly sensitive searches utilizing text words with hand searching and acquisition and review of cited references searched the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library 2017), PUBMED (1966 to November 2017), LILACS (2005 to January 2018), Scopus (2004 to January 2018). In an effort to identify further published, unpublished and ongoing trials we searched trials registers (November 2012) and reference lists.
We included any study that examined ECMO versus NON-ECMO treatment for ARF conducted in adults ICU.
Data from the studies were independently selected and extracted by two reviewers utilizing the online tool COVIDENCE. The disagreement was resolved with a third reviewer consensus.

RESULTS. See the attached figures

CONCLUSIONS. The mortality in ICU has not shown big differences between ECMO and mechanical ventilation in this SR. The high heterogeneity between studies can influence the results.

ECMO could be effective for ARDS but some design changes must be required. A development ECMO program brings all staff in the ICU to a higher level so they all have similar skills and knowledge.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0030

INTRODUCTION. A lung rest strategy has been recommended during ECMO for severe ARDS. This strategy is based on the rationale of preventing ventilator-induced lung injury by minimizing dynamic strain. However, the optimal approach to PEEP in this context is unclear.
OBJECTIVES. To compare the effects of low, intermediate and high airway pressures on lung injury, while applying a near-apneic ventilation, in a severe ARDS model supported with ECMO.
METHODS. Domestic pigs (27-35 kg) were anesthetized, mechanically ventilated (Vt 10 ml/kg, PEEP 5, O2 1.0) and invasively monitored. Lung injury was induced by repeated lavages with 30 ml/kg of warm saline until PaO2/FiO2 dropped below 250, followed by a 2-hour injurious ventilation with PEEP = 0, Pinsp = 40 cmH2O, RR = 10/min, I:E = 1:1. After completing lung injury (time 0, T0) animals were connected to ECMO through an AVALON 23F double-lumen cannula at a blood flow of 60-70 ml/kg/min (1). Animals were randomized into one of three groups (n=6 each):

i) Low:PEEP: 0, Pinsp 10 cmH2O, RR 5/min, I:E 1:1,
ii) Intermediate:PEEP 10, Pinsp 20 cmH2O, RR 5/min, I:E 1:1,
iii) High:PEEP 20, Pinsp 30 cmH2O, RR 5/min, I:E 1:1, and ventilated according to randomization for the following 24 hours. Respiratory and hemodynamic data were collected during the 24h study period. After euthanizing animals tissue samples were extracted from the lungs and histological injury evaluated by microscopy. Total lung water content was estimated by the wet-dry weight ratio.

RESULTS. All animals developed severe respiratory failure at T0 with profound hypoxemia and low compliance, without differences between groups. Oxygenation improved throughout the 24-hour study period in the Intermediate and High groups, but not in the Low group (Figure 1). During the study period most animals required hemodynamic support with Noradrenaline but this effect was more marked in the High group. Lung wet-dry weight ratio was 9.9±1.0 in the Low group, versus 7.4±1.0 and 7.5±0.5, in the Intermediate and High groups, respectively (p< 0.05). Histological lung injury was lower in the Intermediate group compared to the other 2 groups (Figure 2).
**CONCLUSIONS.** Applying low airway pressures, associated to near-apneic ventilation, favors more lung edema and impedes recovery of gas exchange during ECMO. On the other hand, high airway pressures favor more hemodynamic compromise. An intermediate level of airway pressure is associated to less lung injury while allowing the best balance between gas exchange, lung edema and hemodynamic tolerance.

INTRODUCTION. The development of postoperative delirium (POD) is associated with major postoperative complications, cognitive decline, longer hospital stay, higher medical costs and mortality (1). Preoperative identification of predisposing factors has a major role in POD prevention.

OBJECTIVES. We aimed to investigate the incidence of preoperative cognitive dysfunction and its relation with POD in elderly patients submitted to oncologic surgery.

METHODS. After approval by the ethics committee, an observational prospective study was performed in consecutive oncologic patients aged 65 and older, scheduled for elective surgery. For the evaluation of pre-existing cognitive impairment, Mini-Cog test was applied during the preoperative assessment. Nursing Delirium Screening Scale (NU-DESC) was used for the detection of delirium during the postoperative period. We collected data on education, ASA score, preoperative medications, substance use, comorbidities, sensorial deficits, surgery type and duration, type of anaesthesia, anaesthetic drugs, Mini-Cog score, postoperative pain, NU-DESC score. Statistical analysis was performed using Student's t test for continuous data and Chi-square test for nonparametric data. A probability value < 0.05 was considered statistically significant.

RESULTS. Of 131 patients enrolled, 68 (51.9%) were diagnosed with preoperative cognitive dysfunction, defined as a Mini-cog score between 0 and 3. 113 patients received general anaesthesia and 26 patients (23%) developed delirium in the 48 hours after surgery as assessed using the NU-DESC. In bivariate analysis, predictive factors for delirium were Mini-Cog score (p< 0.01), clock draw (p< 0.001), word recall (p< 0.001), surgery type (p< 0.009) and duration (p< 0.001) and postoperative pain score (p< 0.001). The probability of developing POD was 50% in patients with a preoperative Mini-Cog score of 0 to 1 and 13.4% in patients with a score of 4 to 5.

CONCLUSIONS. In this sample of elderly surgical oncologic patients, preoperative cognitive dysfunction had a high incidence and predicted the emergence of postoperative delirium. Incorporating Mini-Cog as a screening tool for the cognitive assessment, into the preoperative evaluation of elderly patients seems valuable and feasible.

INTRODUCTION. Flexible adult ICU visiting hours have been suggested as a potential intervention for the prevention of delirium, yet most adult ICUs worldwide adopt restrictive visitation policies. Randomized trials evaluating the impact of flexible family visitation models (FFVMs) on patients, family members and ICU professionals are scarce.

OBJECTIVES. To compare the effectiveness and safety of an FFVM versus a restrictive family visitation model (RFVM) on delirium prevention among ICU patients, as well as to analyze its potential effects on family members and ICU professionals.

METHODS. A cluster-randomized crossover trial, which compares a FFVM (12 h/day) with a RFVM (< 4.5 h/day), has been conducted in 40 mixed adult ICUs in Brazil since March 2017 [1]. Participant ICUs with restrictive visiting policies (< 4.5h/day) are randomly assigned to either a FFVM or a RFVM in a 1:1 ratio. After enrollment and follow-up of 25 patients, each ICU is crossed over the other visitation model, until 25 more patients per site are enrolled and followed. The primary outcome is the cumulative incidence of delirium measured using the Confusion Assessment Method for the ICU. Secondary outcomes include daily hazard of delirium, ventilator-free days, any ICU-acquired infections, ICU length of stay, and hospital mortality among the patients; symptoms of anxiety and depression and satisfaction among the family members; and prevalence of burnout syndrome among the ICU professionals. Tertiary outcomes include need for antipsychotic agents and/or mechanical restraints, coma-free days, unplanned loss of invasive devices, and ICU-acquired pneumonia, urinary tract infection, or bloodstream infection among the patients; self-perception of involvement in patient care among the family members; and satisfaction among the ICU professionals.

RESULTS. The results of the present study will be presented in the 31st ESICM annual congress. Currently, 40 ICUs representative of the Brazilian geopolitical territory were included in the study (figure). Until April 2018, 1620 patients, 1208 family members and 829 ICU professionals were included and followed. We expect that this study will be concluded in May 2018.

CONCLUSIONS. The results of the ICU Visits study will allow health care professionals, researchers, and policymakers to drawn conclusions about the effectiveness and safety of a flexible family visitation model for delirium prevention in adult ICUs.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0033

INTRODUCTION. The development of delirium in patients can be thought of in terms of organ failure. This metaphor has implications as new data has suggested that patients who develop delirium have increased mortality compared to patients who do not 1-3. Thus the screening, diagnosis and treatment of delirium is of paramount importance 4.
Recently, the PRE-DELIRIC score has been developed; a multivariate linear regression model that aims to predict the development of delirium 5.
OBJECTIVES.

1. Calculate the Expected Delirium Rate (EDR) using PRE-DELIRIC and visualise how that has changed overtime in our local ICU.
2. Explore the relationship between Mortality and PRE-DELIRIC.
3. Calculate the Standardised Delirium Index (SDI) to benchmark how 'deliriogenic' our practice is.

METHODS. Our Electronics Health Record (EPR) was interrogated for variables that are required for the calculation of PRE-DELIRIC and Mortality. ICNARC primary admission diagnosis was used for

admission category. Acidosis was defined as a Base Excess < 2. Coma, Morphine and Sedatives use were not available; the minimum coefficients were used instead thus forming a 'lower' bound.
Expected Delirium Rate was calculated as the mean PRE-DELIRIC score multiplied by the number of patients; akin to the calculation of Standardised Mortality Index.
Diagnosis of delirium was not available on our EPR and thus the calculation of the SDI was not performed.
RESULTS. A strong correlation between PRE-DELIRIC and Mortality was found ($p < 0.0001$) despite controlling for severity of disease using APACHE-II.
CONCLUSIONS. Expected Delirium Rate is increasing in recent times with a statistically significant correlation with mortality.
The Standarised Delirium Index was developed; a new index that encompasses both patient and environmental factors that benchmark's the local unit's 'deliriogenic' practices.
We aim to prospectively collect targetted data aimed at calculating the SDI as well as compare our local data with publically available datasets.

Calculating PRE-DELIRIC model with SAPS II for early detection of delirium in ICU Patients

M. Sampaio[1], T. Cardoso[1], M.L. Bastos[2], I. Aragão[1]
[1]Centro Hospitalar do Porto, Porto, Portugal; [2]Faculdade de Farmácia da Universidade do Porto, Porto, Portugal
Correspondence: M. Sampaio
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0034

INTRODUCTION. Delirium is a common and serious disorder, prevalent in Intensive Care Units (ICU) patients, associated with negative clinical outcomes, namely higher morbidity and mortality. Accurate diagnosis is limited. General preventive measures in all ICU patients are time and resources consuming without consensual results. Predicting delirium enables physicians to focus on high-risk patients with non-pharmacological preventive measures and drug interventions resulting in better outcomes. The risk of delirium can be assessed through PRE-DELIRIC model which stratifies patients as having low, moderate, high and very high-risk of developing delirium. It uses APACHE II as one of its parameters. Although most European ICUs use SAPS II instead of APACHE II as physiological severity score to estimate death risk, there are no studies using SAPS II for delirium risk assessment.

OBJECTIVES. The purpose of this study was to validate PRE-DELIRIC model using SAPS II score in sedated patients.

METHODS. Prospective cohort study performed for six months in adult patients admitted at a Tertiary Care Hospital twelve-bed mixed ICU, for a minimum period of 48 hours and sedated for at least 24 hours. Our main outcome measure was to compare PRE-DELIRIC scores calculated with APACHE II and SAPS II. Results generally presented as median (IQR) and Intraclass Correlation Coefficient (ICC).

RESULTS. One-hundred patients (71 male) were included from a total of 219 admissions. Mean age was 59 years old (SD±15). Satisfying PRE-DELIRIC criteria, 52 patients were medical, 25 neurological or neurosurgical, 15 surgical, and eight trauma at ICU admission. ICU length of stay (LOS) was 10.5(6-16) days and patients were sedated for 88.5 hours (19.5-158.8). APACHE II and SAPS II scores were 20.5(15-26) and 48.0(41-58), respectively. APACHE II scored for patient was compared with APACHE II score calculated through a mathematical model from SAPS II and results presented an ICC of 0.93(0.890-0.950, p=0.000). PRE-DELIRIC calculated with APACHE II and PRE-DELIRIC calculated from SAPS II scored a median of 87 and presented an ICC of 0.99(0.986-0.994, p=0.000) between them. Delirium was not evaluated in 31 patients (due to patient´s death or discharge to other unit with deep alterations of conscience before evaluation). Among remaining 69 patients delirium was observed in 23 patients, an incidence of 33%. ICU LOS for patients with delirium was 16(10-23) days vs. 11(8-16) days in patients without delirium (p=0.074).

CONCLUSIONS. APACHE II score correlation with SAPS II score presents a coincident agreement with other studies. Use of SAPS II to calculate PRE-DELIRIC score has an excellent correlation with the one calculated with APACHE II. It is possible to use SAPS II in the calculi of risk of delirium through PRE-DELIRIC score, allowing identification of high-risk patients and early institution of preventive measures.

Fig. 1 (abstract 0034). ICC SAPS II - APACHE II

Fig. 2 (abstract 0034). ICC PRE-DELIRIC SAPS II - PRE-DELIRIC APACHE II

RESULTS. Out of the 297 ICU admissions for AIS, 129 (43,4%) underwent TRB. Systemic thrombolysis previous to TRB was administered to 63 (48,8%). CS was applied in 55 cases and GA in 74. Reasons for GA were: elective (51), GCS< 8 (12), agitation (9) and respiratory impairment (2). In three patients TRB was started with CS but changed to GA due to patient restlessness during the procedure. These patients were analyzed within the GA group.

APACHE II and initial NIHSS scores were significantly higher in the GA group (Table 1). We found no differences in onset to reperfusion times. The GA group had longer arrival to puncture intervals but puncture to reperfusion times were shorter. Angiographic reperfusion was similar for both groups. Although there were no differences regarding neurological improvement (NIHSS≥4), modified Rankin scales scores at six-months were significantly better for the CS group even after adjusting by initial NIHSS [OR for Rankin 3-6 for GA: 2.3 (IC95 1.00-4.34;p=0.048)](Table 2). Median extubation time was 12h (5-28.7). Patients undergoing GA had longer ICU stays [2 days (2-5) vs 1 day (1-2);p< 0.001 but hospital length of stay was similar [13 days (8-28) vs. 12 days (9-27);p>0.05].

In the unadjusted logistic regression analysis for six-month mortality, the OR for the GA group was 2.5 (IC95 0.93-7.03;p=0.068). After adjusting for age, APACHE II and initial NIHSS scores the OR dropped to 1.3 (IC95 0.36-4.89;p=0.66).

CONCLUSION. In our series the use of GA did not lead to an increase in six-month mortality even though this group had higher initial APACHE II and NIHSS scores.

GA was related with a shorter TRB procedure, but onset to reperfusion times were similar. Although no differences in reperfusion rates or neurological improvement (NIHSS≥4) were found, the CS group performed neurogically better at the six-month mark.

According to our results the use of GA or CS should be a customized election based on TRB feasibility and patient's safety.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0035

INTRODUCTION. Thrombectomy (TRB) for acute ischemic stroke (AIS) has become a well-recognized and widely available treatment. Whether it should be performed under conscious sedation (CS) or general anesthesia (GA) remains controversial.
OBJECTIVE. To compare six-month mortalities as well as variations in treatment times and neurological improvement for both strategies.
METHODS. Retrospective study (October 2013-June 2017). We included all AIS patients treated with TRB admitted to our ICU. Data collected are shown in Tables 1 and 2. Complete angiographic reperfusion was defined as a IIb/III punctuation in the Modified Treatment in Cerebral Infarction Score (mTICI) and neurological improvement as a difference ≥4 points between the initial and before discharge NIHSS scores. Duration of mechanical ventilation and ICU and hospital length of stays where also registered. Univariate analysis: Mann-Whitney (numerical) and X^2 or Fishers test (categorical). Multivariate analysis: logistic regression.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0036

INTRODUCTION. Clinical situations in intensive care unit (ICU) change rapidly and may result in alarm activation; however false alarm and alarm fatigue may potentially increase error rates _ and workload in ICU. By introducing information system into daily care for patient can reduce workload and improve quality of care.

OBJECTIVES. This prospective study aims to detect the effect of implantation of information system and care bundle in ICU on length of stay and work load for the ICU team member.

METHODS. Taipei Medical University Hospital is a community based teaching hospital with 736 beds capacity (includes 58 general ICU beds). We build up electronic ICU (e-ICU) dashboard to automatically upload and calculate physiologic information and clinical data within critical care unit to provide real time information to the care team start on 1th Feb, 2017. We use e-ICU software with automatic collect clinical information and calculation of SOFA (Sequential Organ Failure Assessment) score every 48 hours. If SOFA score decrease more than 2 points, e-ICU system will automatic show reminder for transferring patient to ordinary ward. We prospective collected data from intensive care unit (ICU) before and after implantation of e-ICU. Patients who admitted to our ICU from July 2016 through July 2017 were collected for basic information, time-points of intervention and cost for analysis.

RESULTS. There are 1857 patients who admitted to our ICU during this period (915patients before e-ICU and 942 after). There is no significant difference in background and mortality rate between the two group, and length of stay is reduced from 7.2 days to 6.5 days (p=0.01) after automatic reminder for patient with decrease SOFA score.

Additional effect:

1. 187.9 work hours/per month of documentation by simplify the work flow through automatic uploads.
2. 887.4 work hours/per month of nursing handovers by incorporating clinical information and data.
3. Response time to abnormal laboratory and physiologic information alarm of the patient can decrease 0.6 minutes /episode (8.6 minutes to 8 minutes).
4. Actual paper print-out saves 600 USD/ year.
5. Accuracy of vital signs input can improve from 85.9% (manual entry) to 100 %(automatic upload).

The cost for implantation of the e-ICU is 122,000 USD (117,000 USD for hardware set up, and 5,000 for software development).

CONCLUSIONS. Implantation of information system (e-ICU) with incorporated clinical information and automatic care bundle in ICU can help reduce length of stay in ICU and decrease workload of the ICU team members.

INTRODUCTION. During the last decades our society is growing older, and so do the patients admitted to Intensive Care Units (ICU)[1]. Thus, resources management acquires a strategic importance, due to limited means. We need studies to determine which patients will benefit from being admitted to an ICU in order to provide a better care.

OBJECTIVES. To describe the population of patients over 79 years old admitted to our ICU and the applied level of invasiveness in management. To search for mortality related factors in the elderly.
METHODS. Retrospective monocentric study based on data collection and analysis from electronic clinical records in those patients older than 79 years old admitted in our ICU between 2006-2016. We excluded patients admitted only for programmed procedures and had no complications. We collected variables concerning demographic data, comorbidity, clinical course and procedures. We used logistic regression to describe factors associated with in-hospital mortality. Results expressed in mean value and standard deviation (SD) for numerical variables and percentage over total patients for categorical variables.
RESULTS. 1360 elderly patients between 80 and 99 years were admitted to ICU during the studied period, 11.9% of the total ICU patients. After exclusions, 84.0% were analysed. The mean age was 83.2 years old and 61.9% of the patients were male. The most common comorbidities were diabetes mellitus (30.5%), isquemic cardiomyopathy (24.0%) and peripheric vasculopathy (17.4%). The mean Charlson index score was 5.8 points (SD 1.6 points). In 87.0% of the patients the admission cause was medical and only 30.0% of them were due to coronary heart disease. Vasoactive drugs were used in 26.4% of the cases, mechanic ventilation in 9.7% and renal replacement therapy in 2.5%. Delirium in ICU was registered in 12.7% of the patients. Limitation of life-sustaining treatment (LST) occurred in 12.2%. Mortality in ICU was 9.5% and in-hospital mortality 14.0%. In the multivariant analysis, in-hospital mortality was associated with limitation of LST (OR 122.8; CI 95% 47.8-315.4), urgent surgery as ICU admission cause (OR 6.0; CI 95% 2.0-18.5), use of vasoactive drugs (OR 6.0; CI 95% 2.6-13.9), renal replacement therapy (OR 5.5; CI 95% 1.1-27.0) and mechanic ventilation (OR 4.8; CI 95% 1.9-11.7).
CONCLUSIONS. Elderly patients are a very significant population in our ICU. No relation has been found between mortality and previous comorbidity; mortality and ICU admission cause are associated. The outcome is worse when the management is more aggressive.

ABO blood group and short-term and long-term mortality in a large cohort of ICU patients
S.P. Kevenaar, M.W.N. Nijsten
UMCG, Intensive Care, Groningen, Netherlands
Correspondence: M.W.N. Nijsten

INTRODUCTION. With the exception of sex, genetic markers have not been widely used in ICU cohorts. A very common recorded genetic feature in medicine is ABO blood group. It is known that populations with different genetic backgrounds may display different ABO blood group distributions [1]. Recent research showed that a non-O blood group was associated with higher risk of arterial and venous thromboembolic events [2], possibly related to higher circulating levels of von Willebrand factor [3]. Whether a non-O blood group is associated with outcome has not been studied in ICU patients.
OBJECTIVES. The objective of this study was to assess the association of blood group non-O with in-hospital mortality and long-term outcome in ICU patients.
METHODS. This study was a retrospective cohort study. Over a period of 24 years (1992-2015) laboratory findings were recorded in an anonymized database of patients admitted to the ICU as previously described [4]. Amongst these laboratory findings ABO blood group was determined. The presence or absence of blood group O was used as the independent variable. In-hospital mortality and long-term survival after ICU admission were the main

outcomes. The chi-square test and Kaplan-Meier survival analysis with the log-rank test were used for statistical analysis
RESULTS. The database contained more than 48,000 patients with ABO blood group data, of these patients, 63% were male and 37% female with a mean ±SD age 60 ±15years. The prevalence of blood groups O, A, B and AB was 46%, 42%, 8.7% and 3.4% respectively. Rhesus positivity and negativity were 83.6% and 16.4% respectively . Hospital mortality was 12.4%. For blood group O versus non-O, hospital mortality was 12.3% and 12.5% respectively (P= 0.66;chi-square test). Kaplan-Meier curves with a follow up of up to 20 years showed similar survival for blood groups O and non-O (P=0.215; with log-rank test).
CONCLUSIONS. In our large cohort of ICU patients from the northern part of the Netherlands, ABO blood group non-O was not associated with outcome.

INTRODUCTION. The MFI is a composite summary instrument widely used to assess frailty and is associated with outcomes in hospitalized patients. However, studies evaluating MFI use in ICU patients are still scarce.
OBJECTIVES. To evaluate the association of the MFI hospital mortality and resource use in a large cohort of critically ill patients.
METHODS. Retrospective cohort study in 129,680 admitted to 93 Brazilian ICUs during 2014 and 2015. MFI encompasses 11 domains related to frailty (comorbidities, previous acute complications and functional capacity) in a 0-11 scale. Using MFI, we classified patients in no-frail (0), pre-frail (1-2) and frail (≥3). Primary outcome was hospital mortality. Secondary outcomes were use of organ support during ICU stay, ICU and hospital LOS, and hospital discharge needing nursing care. We used multivariable mixed regression modeling to assess the association between MFI and the outcomes adjusting for confouders.
RESULTS. There were 40,779 (32%) no-frail, 64,407 (50%) pre-frail and 24,494 (18%) frail patients. Frail patients were older, more frequently admitted for non-surgical reasons and had higher illness severity. Frail patients had higher hospital mortality (OR 2.41, 95% CI 1.89-3.08); this association was more pronounced in patients with lower illness severity (Figure). Frail patients were more frequently discharged in need of nursing care (OR 1.86, 95% CI 1.26-2.75), required more often mechanical ventilation (OR 1.36, 95% CI 1.05-1.75), dialysis (OR 3.56 , 95% CI 2.76-4.61), vasopressors (OR 1.84, CI 95% 1.45-2.35) and blood transfusion (OR 1.69, CI 95% 1.43-2.01) during the ICU stay. Frail patients had higher ICU and hospital LOS, with lower hazard for discharge (hazard for ICU and hospital discharge of 0.94; 95% CI 0.92-0.96 and 0.79; 95% CI 0.78-0.81).

CONCLUSIONS. The MFI seems an interesting surrogate marker for frailty in large studies in ICU patients. Using this instrument, frailty was independently associated with short term outcomes and resource use in these patients.

INTRODUCTION. ICU mortality can be predicted using the Sequential Organ Failure Assessment (SOFA) score, whose neurologic subscore is based on the Glasgow Coma Scale (GCS). But, GCS is not reliably measured in all ICUs, and many use other neurologic assessments, such as the reliable and validated Richmond Agitation-Sedation Scale (RASS). Single center data suggested a RASS-based SOFA (mSOFA) predicted ICU mortality.
OBJECTIVES. In a prospective, multicenter, international ICU cohort, we aimed to validate a mSOFA using RASS, which we hypothesized would be comparable to the GCS-based SOFA.
METHODS. In our nested cohort within the 2016 Fourth International Study of Mechanical Ventilation, we found ICU subjects with both RASS and GCS assessments. We transformed daily RASS into GCS via a proportional odds logistic regression model adjusting for neurologic injury (stroke, traumatic brain injury) and daily exposure to propofol, dexmedetomidine, benzodiazepines, and/or opiates. ICU mortality logistic regression models and c-statistics were constructed using SOFA (GCS-based) and mSOFA (RASS-transformed), adjusted for age, sex, body-mass index (BMI), region (Europe [reference], North America, South America, Africa, Asia, Australia-New Zealand), and post-operative status (medical/surgical).
RESULTS. In 4,120 patients, representing 20,023 patient-days across 32 countries, the mean SOFA=9.4+/- 2.8 and mean mSOFA=10.0 +/-2.3, with ICU mortality=31%. Mean SOFA and mSOFA similarly predicted ICU mortality (SOFA: AUC=0.784, 95%CI=0.769-0.799; mSOFA: AUC=0.778, 95%CI=0.763-0.793, P=0.139). Across models, other strong independent predictors of mortality included higher age, female sex, medical patient, and African region (all P< 0.001).
CONCLUSIONS. We present the first mSOFA model in an externally generalizable multicenter international clinical cohort. RASS transformed into GCS preserves predictive validity for ICU mortality. ICU mortality may be influenced by sex, post-operative status, and world region. Alternative neurologic measurements can be viably integrated into severity of illness scoring systems.

INTRODUCTION. The relationship among the disruption of metabolic homeostasis in critical illness and the effects of treatment remains obscure.
OBJECTIVES. We conducted an ancillary study on plasma samples from the VITdAL-ICU trial to determine whether vitamin D_3 alters the metabolic landscape of critical illness over time. The VITdAL-ICU trial randomized 475 critically ill adult patients with 25(OH)D< 20 ng/mL to 540,000 IU vitamin D_3 or placebo given orally.
METHODS. 1255 plasma samples from 453 patients at randomization, day 3 and day 7 were analyzed using four ultra high-performance liquid chromatography/tandem accurate mass spectrometry methods identifying 769 metabolites. We removed metabolites with the lowest interquartile range of variability, leaving 576 metabolites. The data was normalized with cube root transformation and Pareto scaling.
Response to vitamin D_3 was defined as an increase of 25(OH)D> 10 ng/mL between baseline and day 3. Correlations between individual

metabolites and response to vitamin D_3 over time were determined via linear mixed models correcting for age, gender, baseline 25(OH)D, SAPS II score, admission diagnosis and plasma day. Mixed effects logistic regression was used to estimate the odds of 28-day mortality of individual metabolites adjusted for response to vitamin D_3, age, gender, baseline 25(OH)D, SAPS II score, admission diagnosis and plasma day. A multiple test-corrected threshold of $P < 8.68 \times 10^{-5}$ was used to identify all significant associations.

RESULTS. 23.8% of the cohort demonstrated a response to vitamin D_3. 28-day mortality was 24.3%. 28-day mortality in responders to vitamin D_3 was 11.7%. In non-responders the 28-day mortality was 28.3%. In responders to vitamin D_3, the odds for 28-day mortality was decreased by 68% [OR 0.32 (95%CI 0.16-0.64) P=0.001] relative to non-responders following adjustment for age, gender, baseline 25(OH)D level, SAPS II score, and admission diagnosis.

44 metabolites had significant positive associations with response to vitamin D_3 dominated by increases in Sphingomyelins, Plasmalogens, Lysoplasmalogens and Lysophospholipids. Increases in 28 of these metabolites were significantly associated with decreases in 28-day mortality. 112 metabolites had significant negative associations with response to vitamin D_3 primarily by decreased Acylcarnitines, Phosphatidylethanolamines and Tryptophan metabolites. Decreases in 96 of these metabolites were significantly associated with decreases in 28-day mortality.

CONCLUSIONS. Our observations have biological plausibility and relevance to the observed improved outcomes in responders to vitamin D_3. The changes in Sphingomyelins, Plasmalogens, Lysophospholipids and Acylcarnitines are reflective of stress response, antioxidants, immunomodulation and mitochondrial dysfunction respectively. Dynamic metabolomics can illuminate complex mechanisms associated with response to interventions in critical illness.

INTRODUCTION. Whether dose or route of nutritional support in patients with different grades of gastrointestinal dysfunction and requiring vasopressors affects the outcomes remains unclear.

OBJECTIVES.

1. To evaluate the prognostic relationship between the Maximum Acute Gastrointestinal Injury Score(AGI_{max}) and the mean Kcal/kg received in patients requiring vasopressors, and the role of supplemental parenteral nutrition.

2. To identify hospital mortality determinants in this same population.

METHODS. Prospective multicenter cohort study carried out in 10-ICUs in Argentina. Consecutive patients admitted to the ICU on mechanical ventilation ≥48 hr, requiring vasopressors (>0.1μ/kg/min) and receiving enteral nutrition (EN) were included. Epidemiological data, APACHE II, $SOFA_{24}$, NUTRIC scores, days on vasopressors, mean kcal/kg/day intake, and use of supplemental parenteral nutrition were collected. Acute gastrointestinal Injury (AGI) score was calculated daily; the maximum AGI (AGI_{max}) was identified, and patients were classified in 5 categories (0 to 4) according to AGI score*. Comparisons of clinical and outcome variables were performed in 3 predetermined groups, according to the mean amount of calories received via EN: < 10 kcal/kg/d, ≥10 to < 20 kcal/kg/d, or ≥20 kcal/kg/d. During episodes of shock, the decision to maintain, decrease or withhold EN was taken by attending physicians. Hospital mortality was the main endpoint. A Kaplan-Meier curve was built to assess hospital mortality according to the 3-different kcal/kg groups. Differing variables from survivors and nonsurvivors (p< 0.20) were entered into a logistic regression model. A p value ≤0.05 was considered significant. STATA 14 software was used for statistical analysis.

RESULTS. Out of 800 patients, 494 (62%) required vasopressor therapy. Hospital mortality was 53%. Tables 1 and 2 show characteristics and outcomes of the 3 subgroups of patients on vasopressors. Figure 1 shows a Box-plot graph of AGI_{max} and the 3 caloric subgroups, as well as the K-M curve of hospital mortality according to the 3 caloric subgroups. Table 3 shows the multiple logistic regression model for hospital mortality.

CONCLUSIONS.

1. Patients who received < 10 kcal/kg were more severely ill, had more organ failures, recorded more AGI_{max} and hospital mortality. However, patients who received ≥10kcal/kg, presented lower AGI_{max} and hospital mortality.

2. Determinats of hospital mortality were age, Charlson score, type of admission, and AGI_{max}.

3. AGI_{max} shows a direct relationship with hospital mortality and an inverse relationship with caloric intake. Therefore, kcal intake cannot be considered a protective factor for hospital mortality in patients receiving vasopressors, but it reflects/evidences this lower mortality.

4. Supplemental Parenteral Nutrition in this population might be beneficial, but its role needs to be evaluated further.

*Intensive Care Medicine Experimental* 2018, **6(Suppl 2):**0043

INTRODUCTION. Steatotic liver grafts reduce the success rates of liver transplantation. Diabetes and obesity have been known as risk factors for liver steatosis (LS). Insulin resistance is frequently associated with critical illness and LS is a common phenomenon in the ICU patients. But there has been no interest the links between acute insulin resistance and LS in the area of intensive care.

OBJECTIVES. We hypothesized that acute insulin resistance in brain-dead donors (BDDs) may promote the development of LS. The purpose of the current study was to evaluate the effect of acute insulin resistance on LS and its progressing pattern in BDDs.

METHODS. A retrospective cohort study was conducted between January 2003 and December 2017. The liver samples were classified into a mild (< 30%) and a moderate-to-severe (≥ 30%) (MTS) steatotic group. Serum glucose level was adopted to reflect insulin resistance. According to the recommendation of the Western Pacific Regional Office of the WHO, BDDs with body mass index (BMI) < 18.5 kg/m^2 and ≥ 30 kg/m^2 were excluded to avoid a bias by extreme values.

RESULTS. A total of 179 BDDs were included in the study. MTS was found in 29 BDDs (15.1%). The length of predonation period was negatively correlated with steatosis (r = -0.379, P < 0.001). BMI (r = 0.176, P = 0.019) and the serum glucose level (r = 0.267, P < 0.001) were also correlated with steatosis significantly. The incidence of MTS was 25.2% in the group of predonation period less than 4 days and 10.9% more or equal than 4 days (P = 0.014). The procurement rate of the liver reached 94.7% in mild steatotic group and 77.8% in MTS group (P = 0.009).

CONCLUSIONS. Liver steatosis can be developed acutely in critically ill condition and is related to blood glucose level, reflecting insulin resistance. Therapeutic intervention that maintains proper glucose level and reduces both severity and duration of systemic inflammation is essential, not only to recovery of critically ill patients but also to improvement of graft quality by reducing liver steatosis.

INTRODUCTION. Frailty has recently been described as an independent predictor of short- and long-term outcomes in critically ill patients. Since nutrition might be associated with frailty, further characterization of nutritional status in critically ill patients with frailty is warranted.
OBJECTIVE. To describe the prevalence, nutrition risk scores and resource use associated with frailty among critically ill patients who required nutrition support therapy in a Brazilian tertiary hospital.
METHODS. We conducted a prospective single-center cohort study of patients admitted to the Intensive Care Unit (ICU) of Hospital Sírio-Libanês (São Paulo, Brazil), between October 2015 and March 2017. Frailty syndrome was classified using the Clinical Frailty Scale (CFS). Patients were considered to be frail if they had a score>4[1].
RESULTS. We studied 449 patients during the study period (mean age was 69.4 years, 64.8% were admitted for non-surgical reasons, 49.9% had cancer, 56.6% were frail and 27.2% died during hospitalization). Frail patients were more severely ill compared to non-frail patients (SAPS 3 of 52 [44 - 60] versus 37 [32 - 47] respectively; p< 0.001), were older, more frequently came from the emergency room due to non-surgical reasons, and had higher mortality (36.6% vs 14.9% respectively, p< 0.001). Frailty was associated with lower body mass index (p=0.045) and higher NUTRIC scores (p< 0.001), but with a lower prevalence of significant weight loss (p=0.04) and lower MUST scores (p=0.012). Frail patients stayed longer in the ICU (p=0.03), and more frequently required enteral nutrition for a longer period (p< 0.001), although invasive organ support during ICU stay was not different comparing frail with non-frail patients.
CONCLUSION. Frailty is very common in our cohort of critically ill patients undergoing nutrition support therapy, and it was associated with higher hospital mortality. Although nutrition risk assessment performed differently, frail patients required enteral nutrition more frequently.

INTRODUCTION. Vitamin D has pleiotropic effects that extend beyond the musculoskeletal system, with a strong association between a poor vitamin D status and excess morbidity and mortality. Vitamin D deficiency is common in patients with chronic liver disease, and has been associated with increased morbidity and mortality, but has not been extensively evaluated in patients undergoing orthotopic liver transplantation (OLT).
OBJECTIVES. Explore the level of Vitamin D before and after OLT in the first 28 days. Explore if vitamin D level is a marker of disease in OLT recipients and a marker of good graft function.
METHODS. Prospective observational study. Explorative analyses of vitamin D levels in 68 consecutive OLT recipients during the first 28 days after OLT in a liver transplantation center in southern Italy from September, 2016 to July, 2018.
RESULTS. Sixty-eight (68) OLT recipients were enrolled: Age 57 years ±7, BMI, 26 ±4, Child-Pugh 8 ±2, clinical MELD 15 ±8, HCC n. 43, Charlson Comorbidity Index 6 ±1.4, creatinine 0.9 mg/dl (0.72-1.27), MDRD 86 ±31, total calcium 8.5 mg/dl ±0.59, phosphate 3.30 mg/dl ±0.75, parathyroid hormone 51 pg/ml (35-80). The baseline vitamin D value was 8.7 ng/ml (6.2-12-7), indicating a severe deficiency. On Spearman correlation analysis, vitamin D was inversely associated with Child-Pugh and MELD (p< 0.01), and was significantly higher in the presence of hepatocarcinoma and when chronic kidney disease was not present.
During the first week after OLT the vitamin D value decreased further, while there was a consistent increase at 28 days (p< 0.01) (Table 2, Figure 1), In a multiple generalized linear model this increase was not influenced by the trend in creatinine or MDRD.
The baseline value of vitamin D was associated with the risk of a diagnosed invasive infection in the first 28 days after OLT: OR 0.87, 95% CI 0.78-0.97, p=0.01, and it was associated with increased ICU length of stay (LOS) (Spearman Correlation Coefficient -0.29; p=0.01). The vitamin D value on day 7 was associated with hospital Lenght Of Stay (Spearman Correlation Coefficient -0.31; p=0.01).
The lower vitamin D levels at POD 28 were associated with an incomplete graft function (defined as INR>1.5 and/or bilirubin >2 mg/dl and/or large volume of ascites): 8.1 ng/mg (6.0 - 10.4) vs. 13.7 (10.9 - 16.4) p< 0.01.
CONCLUSIONS. The baseline vitamin D level was very low in a large population of adult OLT recipients, showed a strong correlation with pre-OLT disease severity, and was highly associated with ICU LOS and with the risk of acquiring invasive infection in the first 28 days after OLT. Moreover, at 28 days after OLT vitamin D showed a relevant association with graft function. Being a possibly modifiable factor, further studies should shed light on the role of vitamin D supplementation in this select population.

INTRODUCTION. ICUs are challenged to retain clinicians and therefore need to understand why they are leaving their career prematurely. Beside organizational issues, the quality of interprofessional collaboration during ethical decision-making (EDM) may further affect the intent to jobleave.
OBJECTIVES. To determine the relationship between the EDM climate and the intent to job leave in the ICU.
METHODS. During April-May 2014, perceptions of EDM climate among clinicians of 68 adult ICUs in 13 European countries and the US were measured, using a self-assessment questionnaire, together with the intent to jobleave (1). The EDM climate questionnaire (EDMCQ) was validated and determined 7 important factors (2): mutual respect within the interdisciplinary team, open interdisciplinary reflection, ethical awareness, self-reflective physician leadership, active decision-making by physicians, more specifically at end-of-life, and involvement of nurses at end-of-life. We used hierarchical mixed effect models to assess associations between these 7 factors and the intent to job leave in clinicians within ICUs, within hospitals and within countries. Results are expressed in odds ratios together with 95% confidence intervals.
RESULTS. Of the 3610 nurses and 1137 physicians providing ICU bedside care, 63.1% and 62.9% participated respectively. Of the 2992 participating clinicians, 782 (26.1%) had the intention to leave their current job, of which 615 (78.6%) were nurses, 74 (9.5%) junior and 93 (11.9%) senior physicians. Factors significantly associated with a higher intent to jobleave were the Big Mac index of the country (OR 1.59 [95% CI 1.006- 2.53]), the numbers of hours working per week (1.01 [1.001-1.02]) and the mortality in the ICU (1.03 [1.003-1.05]). 'Mutual respect within the interdisciplinary team' (0.77 [0.66-0.90]), 'open interdisciplinary reflection' (0.73 [0.62-0.86]) and 'active decision-making by physicians' (0.87 [0.75-1.006]) more specifically at end-of-life (0.87 [0.77-0.98]) were associated with a lower intent to jobleave together with the clinicians' older age (0.98 [0.97-0.99]).
CONCLUSIONS. This is the first large multicenter study showing an independent association between intent to jobleave and the quality of the EDM climate. Interventions to reduce intent to jobleave should mainly focus on improving mutual respect, open interdisciplinary reflection and active decision-making by physicians at end-of-life in the ICU.

Timing is everything: early DNR in the ICU matters for patient outcomes

D. Ouyang[1], D. Russell[2], D. Berlin[1,3], A. Su[1], Z. Cooper[4], P. Maciejewski[1,5,6], H. Prigerson[1,5], L. Lief[1,3]

INTRODUCTION. Do-Not-Resuscitate (DNR) orders are intended to prevent cardiopulmonary resuscitation (CPR) of patients to avoid suffering at the end of life and allow a natural death. Nevertheless, little is known about the timing of DNR orders in patients' final intensive care unit (ICU) stay and its impact on patients' quality of death.
OBJECTIVES. To determine the relationship between the timing of DNR order placement in the ICU and patients' perceived suffering, peacefullness, and quality of death.
METHODS. 200 ICU patients at New York Presbyterian Hospital in New York and Brigham and Women's Hospital in Boston were assessed by the ICU nurses (n=100) who cared for them during their last week of life. Trained research staff interviewed the ICU nurses about their perceptions of the patients' experience using validated measures to assess the patients´ quality of death, extent of peacefulness, and suffering. Data from charts were abstracted in order to assess the timing of DNR orders in the patients´ terminal ICU stay. A

mixed-effects model that adjusted for the nurse as a random effect was used to model DNR timing and length of stay as fixed effects.

RESULTS. 77.5% (155/200) of enrolled patients had a DNR order at the time of death. 18% (36/200) of patients were admitted to the ICU with a pre-existing DNR order and 59.5% (119/200) had a DNR order placed during their ICU stay. 13% (26/200) of patients had a DNR placed within 48 hours of ICU admission (early DNR) and 46.5% (93/200) had DNR orders placed after 48 hours of ICU admission (late DNR). 42.5% (85/119) of patients had a DNR order placed within 24 to 48 hours of their death. Compared to those without a DNR order, patients with an early DNR order were much less likely to have a poor quality of death (27.6% vs. 54.5%; $p<$ 0.05) and more likely to be "at peace" (56.0% vs. 38.8%; $p<$ 0.05). [Table 1] Results from a mixed effects regression model adjusting for length of stay indicated that those with late DNR were significantly more likely than those with early DNR to experience suffering in the last week of life ($p<$ 0.05).

CONCLUSIONS. At the time of death in the ICU, many patients have DNR orders in place, though most of these were placed after admission to the ICU and many in the last 1 to 2 days of life. Placement of a DNR order prior to ICU admission and earlier in the terminal ICU stay is associated with an improved quality of death. Ensuring earlier conversations about DNR among patients dying in the ICU may improve patients' quality of death and reduce suffering at the end of life.

Table 1 (abstract 0047). Patient Quality of Death by DNR Status

	Early DNR	Late DNR (Within 48 Hours)	No DNR (After 48 Hours)	p-value
Poor Overall Death	27.6%	31.5%	54.5%	0.01
Not at Peace	14%	27.1%	38.5%	0.03

A quarter of cardiac arrest survivors admitted to an ICU in Greece should not have been resuscitated. The need for a Do Not Attempt Resuscitation (DNAR) policy

I. Andrianopoulos, A. Papathanasiou, G. Papathanakos, V. Salma, X. Zikou, V. Koulouras
University Hospital of Ioannina, Intensive Care Unit, Ioannina, Greece

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0048

INTRODUCTION. DNAR orders are employed in cases where CPR is considered futile,or it will prolong patients´ suffering.Lack of DNAR policy in Greece probably results in an increased frequency of CPR performance in cardiac arrest cases with a questionable outcome.
OBJECTIVES. The purpose of this study was to identify those patients that survived a cardiac arrest and in whom CPR would have been deemed inappropriate and assess their final outcome.
METHODS. We retrospectively collected all data and recorded the outcome of all consecutive patients that were admitted to our ICU after surviving cardiac arrest during a 4 year-period.We reviewed each case separately and discussed whether CPR was appropriate in terms of patients´comorbodities,QoL and wishes.
RESULTS. 56 patients that survived a cardiac arrest and were admitted to our ICU were identified.26 out of 56(46%) survived to exit ICU.-When we retrospectively assessed each case separately we found that in 14/56(25%)CPR was inappropriate.From these 14 patients 13 passed away in ICU, and one was discharged home in coma receiving mechanical ventilation after a 3 month hospital admission.Inappropriateness was justified for the following reasons.7 patients had advanced dementia requiring assistance with most of their daily needs while 4 of them were bed-bound. 2 had advanced metastatic

cancer not responding to treatment, 2 had end-stage disease(decompensated cirrhosis with hepatorenal syndrome not suitable for transplant, end-stage pulmonary fibrosis), one was elderly(88) with NYHAIV heart failure, one(bed bound for years with ependymomas of the spine) had expressed in the past that did not wish to receive CPR and a bed-bound patient with Duchenne´s muscular dystrophy was the only one to be discharged from hospital.Unfortunately there is neither DNAR regulation nor laws regarding treatment futility in Greece setting doctors in an area of medicolegal vulnerability.Doctors do need to practice medicine with the principle "first do no harm" and discussion among the caring physician, the patient as well as its NOK regarding the patient´s prognosis/outcome should take place well before the patient becomes moribund, allowing time for the patient and its family to decide on further treatment and CPR.This will reduce the cases of inappropriate CPR.
On the other hand medical societies in Greece need to campaign in favor of DNAR policy, demanding improvement in palliative care and to push-on for legislation amendments.It would be of great assistance if European medical societies were also involved in this process by providing counseling and making appeals for EU legislation on these matters.
CONCLUSION. CPR was retrospectively considered inappropriate in a quarter of patients that actually achieved return of spontaneous circulation resulting only in postponing patients´ death by a few hours/days.These findings underline the need for a DNAR policy and improvements in end-of-life care.

INTRODUCTION. The illness and recovery of ICU survivors or the loss of a loved one impacts fundamental aspects of everyday family life. Therefore, high quality ICU care must also meet the needs of family members.
OBJECTIVES. To use free-text responses of family members on a family-experience questionnaire to provide richer context for families' quantitative assessments of the quality of ICU care, describe further quality areas of importance for families, and compare experiences of Danish and Dutch family members.
METHODS. Written comments from a total of 1,077 euroQ2 (euroFS-ICU and euroQODD) questionnaires (1, 2) focusing on family evaluation of the quality of care in the ICU completed in Denmark and The Netherlands were analyzed by content analysis.
RESULTS. More than half of participants provided comments describing a wide range of patient- or relative-related issues and providing a varied description of experiences in the ICU. Four themes emerged as important to families: information, clinician skills, ICU environment, and discharge from the ICU. Families highlighted the importance of receiving information that was accessible, understandable and honest. They indicated that quality care was ensured by having clinicians who were both technically and interpersonally competent. The ICU

environment and the circumstances of the transfer out of the ICU were described as contributing to experiences of quality of care. The comments identified room for improvement within all four themes. These analyses did not reveal differences between Danish and Dutch comments.

A total of 7% of family members (n=77) provided strongly negative comments, and of those 87% (n=67) had scored 7-10 in the quantitative assessment of overall quality of care (on a scale from 0-10) suggesting an important disconnect between the quantitative and qualitative results.

CONCLUSIONS. Family members identified information, clinician skills, ICU environment, and discharge from the ICU as issues that contributed significantly to their perception of the quality of ICU care. The study suggests the important role for incorporating both qualitative and quantitative sources of data to enable a more complete picture of family experiences in the ICU.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0050

INTRODUCTION. Withholding and withdrawing life-sustaining therapy (LST) are complex ethical decisions made in many critically ill patients. End of life decisions (EOL) are part of intensive care daily practice and they may be influenced by many factors beyond patient characteristics and severity.

OBJECTIVES. We aimed to describe EOL decisions in patients with acute respiratory failure and their impact on patients' prognosis.

METHODS. The centers participating in the international observational LUNG SAFE study included all patients with acute hypoxemic respiratory failure over a one-month period. More than 450 ICUs from 50 countries were involved in the project. Demographic, clinical and biological data were compared between patients with and without decisions of LST limitation. We also compared LST decisions according to the model of physician/patient relationships. Countries were classified as directed physician decisions or patient autonomy based on published data. This classification was validated by the countries coordinators.

RESULTS. A total of 4041 hypoxemic patients were included. Overall mortality was 37.2%. A decision of withholding or withdrawing LST was reported in 948 patients (23.4%). Mortality in patients with EOL decisions was 84.4% (N=800).

In bivariate analysis, patients with a decision of LST limitation were older, had a lower body weight, a higher SOFA score, were more frequently hospitalized for a medical condition; they also presented with more frequent active neoplasia/immunosuppressionor chronic liver failure (p< 0.001 for all). Patients admitted for non-cardiogenic shock had more LST limitation decisions (p=0.018). Patients admitted after trauma, drug overdose orpulmonary contusion were less likely to have a LST limitation decision (p< 0.001). EOL decisions were less frequent in lower-middle income countries as compared to high and middle-high income countries (p< 0.001) and less frequent in countries with physician directed relationship model than in countries with patient autonomy model.

Almost half of the 1503 patients who died during their hospital stay did not receive a decision of LST limitation (46.8%, N=703).

CONCLUSIONS. Decisions of LST limitation are frequent in the ICU, concerning almost one quarter of hypoxemic patients. Not only patients' characteristics but also health system (patient-physician relationship, gross domestic product) seem to impact these decisions. Almost half of the patients who eventually died in hospital had not been the subject of a decision of LST limitation.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0051

BACKGROUND. Ventilatory modes that rely on patient spontaneous breathing (SB) activity are increasingly used in patients with acute respiratory distress syndrome (ARDS). The effects of SB during invasive mechanical ventilation on relevant patient outcomes are controversial and largely unknown.

METHODS. Planned secondary analysis of the LUNG SAFE study[1], to describe the characteristics and outcomes of patients with or without SB. Because inspiratory effort was not measured in LUNG SAFE, SB was defined by actual respiratory rate > set respiratory rate during the first 48 hours of mechanical ventilation.

RESULTS. SB was present in 67% (344/515) of patients with mild ARDS, 58% (488/844) of patients with moderate ARDS, and 46% (184/397) of patients with severe ARDS. Patients with SB were older and had significantly lower ARDS severity, SOFA scores, ICU and hospital mortality, and were less likely to be diagnosed with ARDS by clinicians. Mean tidal volumes (VT) were higher in patients with SB (7.9 ±1.7 vs. 7.5±1.5 ml/kg PBW, p< 0.001). In adjusted analysis, SB during the first 2 days was not associated with an effect on ICU or hospital mortality (respectively 33% vs. 37%, OR 1.18 [0.92-1.51], p=0.19, and 37 vs. 41%, OR 1.18 [0.93-1.50], p=0.196). SB was associated with increased ventilator free days (13 [0-22] vs. 8 [0-20], p=0.014) and shorter duration of ICU stay (11 [6-20] vs. 12 [7-22], p=0.04).

CONCLUSIONS. SB is common in patients with ARDS during the first 48 hours of ventilation. SB was not associated with worse outcomes and may hasten liberation from the ventilator and from ICU. Further studies incorporating the magnitude of inspiratory effort are required.

INTRODUCTION. Sedation load is strongly associated with morbidity and mortality in mechanically ventilated, critically ill patients [1]. Neurally adjusted ventilatory assist (NAVA) may help reduce sedation requirement by improving patient-ventilator synchronisation and the ability to monitor and optimise neural respiratory drive [2].
OBJECTIVE. To compare the effect of NAVA versus Pressure Support Ventilation (PSV) on Richmond Agitation Scale (RASS) scores and sedation load.
METHODS. Secondary a priori outcomes including RASS and sedation load, were analysed from a pilot RCT (NCT01826890) in 78 patients at risk of prolonged invasive ventilation conducted in a London hospital between 2012 and 2017. Patients were randomised to NAVA or PSV for weaning. The primary outcome was protocol compliance (time in NAVA mode). Mean hourly RASS, proportion of time at, above and below target RASS (-2 to 0) and mean sedation dose per infusion day were analysed in the following sub-groups:

1. All ventilation modes via endo-tracheal tube or tracheostomy
2. All modes excluding time with tracheostomy
3. NAVA or PSV mode
4. NAVA or PSV in *allocated mode*. Compliant data with no cross-over
5. Mandatory ventilation modes (to assess impact of diaphragmatic monitoring in the acute phase)

RESULTS. At randomisation, groups were well matched with no differences in age, APACHE II, RASS or sedation load (Table 1). A trend towards improved RASS was observed in the NAVA group in all data (p=0.086) and all sub-groups, which reached significance when compliant to allocated mode (p=0.020) (Figure 1). A trend towards greater time at target RASS (Figure 2), and significantly less time below target RASS (p=0.043) (Figure 3) was observed in the NAVA group. Sedation doses, number of bolus doses per infusion day and unplanned extubations were similar between groups (Table 2).
CONCLUSIONS. These results suggest that compared to PSV, NAVA was associated with better RASS and less time in deeper sedation. The differences observed during mandatory mode ventilation suggest a possible additional effect of diaphragmatic monitoring. These data are consistent with a potential benefit from NAVA. Further research is needed to better understand mechanism and establish clinical effectiveness.

INTRODUCTION. Difficulty in weaning from mechanical ventilation is encountered in approximately 20% of patients in the intensive care unit.Recent investigations focusing on lung, diaphragmatic and cardiac ultrasound highlights the potential role of ultrasonography in prediction of outcome following extubation. The present study attempted to assess the ability of a combined lung, diaphragmatic and cardiac ultrasound protocol to predict weaning success and failure following extubation.
OBJECTIVES.

Primary:

1. To assess the ability of an Integrated USG protocol during weaning to predict weaning success or failure.

Secondary:

2. To assess the role of lung, diaphragmatic and cardiovascular dysfunction to failed weaning.
3. To assess the changes in Lung ultrasound Score (LUS) following SBT.

METHODS. All patients scheduled to undergo SBT were evaluated by USG to measure LUS, Diaphragmatic Thickness fraction(DTF) and changes in Velocity Time Integral (VTI) to passive leg raise at the beginning of SBT. Changes in LUS following SBT was recorded. Patients extubated following SBT were classified as weaning success if non invasive or invasive mechanical ventilator support was not required in the next 48 hours.
RESULTS. 60 patients who underwent extubation following a successful SBT were included in the study.27 patients(45%) required either non invasive or invasive mechanical ventilator support during the next 48 hours and were classified as weaning failure (Group F). Rest 33 patients were designated as weaning success (Group S).Patients in Group F had significantly longer ICU length of stay, higher LUS change during SBT(p< 0.001),lower DTF (p< 0.05) and showed lower VTI increment to PLR(p< 0.001).Using a binary logistic regression model,DTF< 26% (odds ratio 6.20,95% CI 1.06-36.04) and VTI change to PLR< 10.2% (odds ratio 6.16,95%CI 1.14-33.13) were found to be significant predictors of weaning failure(p< 0.05).The AUROC for VTI and DTF for predicting weaning failure were 0.79 and 0.64 respectively(Figure 1).
CONCLUSIONS. An integrated Ultrasound protocol using a combination of ultrasonographic parameters of lung, diaphragm and cardiac sonography was a reliable predictor of weaning failure. This study highlights the role of diaphragmatic dysfunction and preload independence of the heart in contributing to failed weaning, earlier detection of which may lead to better tailoring of therapy.

Evaluation of diaphragmatic function using Tissue Doppler Imaging (TDI) - correlation with transdiaphragmatic (Pdi) parameters

E. Soilemezi, A. Vemvetsou, K. Kosmidis, C. Dimitroulakis, M. Tsagourias, D. Matamis

Papageorgiou General Hospital, ICU, Thessaloniki, Greece

Correspondence: E. Soilemezi

INTRODUCTION. Tissue Doppler Imaging (TDI) is an ultrasonographic technique extensively used in cardiology to evaluate cardiac systolic and diastolic function. It uses Doppler to quantify the velocity of tissue rather than blood, and it, therefore, allows direct measurement of the velocity of moving tissue. TDI of the diaphragm has never being used so far to assess the characteristics of diaphragmatic contraction and relaxation.

OBJECTIVES. This study attempts to correlate TDI-derived parameters with transdiaphragmatic (Pdi)-derived parameters, which are already evaluated and used in clinical practice.

METHODS. In twelve patients undergoing a T-piece weaning trial (9 weaning success and 3 weaning failures) a TDI examination of the diaphragm was performed. High quality images of diaphragmatic TDI were very easily obtained in all patients with a cardiac 4 MHz sector transducer. In all patients a nasogastric tube, equipped with two balloons for measuring esophageal and gastric pressures, was previously inserted for feeding purposes allowing for Pdi recording. Simultaneous Pdi and TDI tracings were recorded for 207 breaths in total (approximately 15 breaths/patient). For every breath, the Pdi signal was analyzed to measure the following parameters (fig 1): maximum Pdi (Pdi_{max}), pressure time product (PTP), and the slope of the initial steepest part of the descending part of the Pdi curve, ie the diaphragmatic Maximum Relaxation Rate (Pdi-MRR). These Pdi-derived parameters were respectively correlated with the following TDI-derived parameters (fig.2): TDI peak contraction velocity, the velocity-time integral during inspiration (VTI), and the slope of the initial steepest part of the velocity curve of diaphragmatic motion during relaxation, ie, the TDI-derived maximum relaxation rate. The level of significance and the correlation coefficient were calculated for each comparison.

RESULTS. A highly significant correlation was found between the Pdi-MRR and the TDI-derived maximum relaxation rate (r=0.93, y=1.7x+30, p< 0.001). Furthermore, TDI peak contraction velocity was also highly correlated with PTP and Pdi_{max}, (r=0.91 and r=0.89 respectively, p< 0.001). On the contrary, a weak but significant correlation (r=0,54, y=2x+3.2, p< 0.01) was found between the PTP and the VTI.

CONCLUSIONS. Our results suggest that TDI represents an ultrasonographic technique that can be used to assess features of the contraction and relaxation of the diaphragm, until now thought to be acquired only with Pdi recordings; it bears the additional advantages of all ultrasonographic techniques, ie, it is non-invasively performed on the bedside, compared to the cumbersome method of acquiring and interpreting Pdi tracings. Further studies are needed to demonstrate the potential utilities of this new ultrasonographic examination of the diaphragm in the everyday ICU practice.

Using ultrasound of heart, lungs and diaphragm to predict weaning success: a prospective observational study

BACKGROUND. In ICU patients deciding the optimal timing for extubation is challenging and clinical predictors are not very accurate. Ultrasonographic assessment of the diaphragm function has been used to predict successful extubation.[1] However, cardiorespiratory function also greatly impacts a patient's ability to wean from mechanical ventilation.
OBJECTIVE. To assess if a combination ultrasound measurements of the diaphragm, heart and lungs could predict extubation success more accurately than using single-organ ultrasonography assessment.
METHODS. This prospective observational study in the Intensive Care Unit of a tertiary academic hospital included adult patients who were invasively ventilated for > 72 hrs. Exclusion criteria included paraplegia, tracheostomy or planned non-invasive ventilation (NIV) after extubation. Ultrasound measurements of heart (left ventricular function (LVF)), lungs (number of B-lines) and diaphragm (thickening fraction (TFdi%)) were performed within 6 hours before extubation during spontaneous breathing trial. Patients not needing reintubation or NIV within 48 hrs after extubation were recorded as successful extubation. A logistic regression prediction model using backward selection was made.
RESULTS. In this interim analysis, 39 patients were included of which 77% were male, with a mean age of 61 (±17) years and a median of 126 [95-207] and 96 [84-185] hours on mechanical ventilation in the successful and failed group, respectively. Of these patients, 7 (18%) required reintubation within 48 hours. Patients in need of reintubation compared to patients who were extubated successfully had no significant difference in TFdi% (21.2% vs. 25.5%; p=0.36), left ventricular function (72% good vs. 71% good, p=.94) or B- lines (17 [9-24] vs. 7 [3-15] p=.072), although a trend for more B-lines was observed in the extubation failure group. Multivariable regression analysis showed that addition of B- lines and classic parameters such as PaO_2 and FiO_2 to the thickening fraction has added value in predicting extubation (Table 1). This was not the case for LVF.
CONCLUSION. The results of this study suggest that addition of lung ultrasound to diaphragm ultrasound might have added benefit in predicting extubation success, while for LVF this does not seem to be the case.
Variables included:
Age, Gender, Ventilation Time (VT), FiO2, PaO2, SOFA-score, Thickening fraction, BLUE-Profile, B-lines, Whitebloodcellcount, CRP, Hemoglobin (Hb), LVF, Creat, Breathing Frequency (BF), Pressure Support (PS), Tidal Volume (TV)
Variables removed:
Age, Gender, VT, SOFA, BLUE-Profile, WBC, CRP, Hb, LVF, BF, PS, TV
N=39
Nagelkerke R^2=.651

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0056

INTRODUCTION. In February 2016, we opened a 12 beds-post ICU rehabilitation center (Service de Rééducation Post Réanimation, « SRPR»), dedicated to weaning from mechanical ventilation and global post ICU rehabilitation.
OBJECTIVES. To describe the characteristics and main outcomes of patients admitted over the first year of activity.
METHODS. Retrospective analysis of prospectively collected data
RESULTS. Ninety patients were admitted (100 admissions) in the unit over 12 months from 34 different ICUs (median duration of stay in the ICU 38,5 days (IQR 29 -61)). 86 % were ventilated (11% with NIV). 85% had a tracheostomy. 64% had ICU acquired weakness ; 5% were able to walk. An underlying chronic respiratory disease was present in 53% of cases. 18% were obese. Difficult weaning was found to have one or several respiratory components in 77% of cases (including 20 post surgery diaphragmatic paralysis), cardiac in 34%, neurologic in 18%. Significant complications occured in 60% of cases. Median duration of stay was 19,5 (12-29,5) days. Ten patients died in the unit, 13 patients were re-transferred in the ICU, where 6 of them died. Over half of the patients were discharged at home, in a rehabilitation unit or in a hospital ward awaiting a rehabilitation program. The remaining 24%, that still needed some form of medical or surgical care were discharged in the ward.
In intention to treat, successful weaning from *invasive* ventilation was obtained in 70% of patients. Of the patients discharged alive from the unit after completing the rehabilitation program (n= 74), 60% were completely weaned from mechanical ventilation, 35% were discharged with NIV or CPAP ; 4 patients (5%) were considered not weanable from invasive ventilation ; decanulation of tracheostomy was obtained in 82% of cases; 87% of the patients could walk.
CONCLUSIONS. SRPRs offer a new concept of care for difficult to wean patients, with promising results.

INTRODUCTION. Weaning failure (WF) in post-surgical patients may be due to lung and diaphragm dysfunction; they can both be assessed by ultrasound (LUS and DUS), helping in predicting WF.[1]
OBJECTIVES. To assess lung aeration and diaphragm activity in post-surgical patients to early identify those at risk of WF.
METHODS. Prospective observational monocentric study. We enrolled ICU post-surgical adult patients within 24 hours after extubation. They were in spontaneous breathing and had no neuromuscular diseases. LUS score for aeration assessment was computed: sternum, anterior and posterior axillary lines define anterior, lateral and posterior regions, each divided in superior and inferior to have 12 areas per side; in each area a score from 0 (normal aeration) to 3 (complete loss of aeration) was given.[2] Global and anterolateral scores corresponded to the sum of all and anterolateral areas' score respectively. DUS analyzed right thickening fraction (TF=(expiratory - inspiratory)/inspiratory thickness*100) and caudal displacement (CD).[1] WF was defined as NIV/reintubation within 48 hours after extubation.

RESULTS. We enrolled 74 patients (60 males, age 69.0±10.0yrs, BMI 26.4±5.1, mechanical ventilation length in ICU 272.0±125.6 mins, ICU stay 2[1.0-3.0] days). Surgery was performed by laparotomy (17), sternotomy (47) and right thoracotomy (10). WF occurred in 21 patients (28.4%); WF patients differed by BMI only (30.3±5.4 vs. 24.9±4.1; p< 0.0001). WF wasn't significantly different among surgical approaches; a trend in higher WF is observed in thoracotomies (50% vs. laparotomy 23.5% and sternotomy 25.5%, p=0.284). Overall global and anterolateral LUS scores were 11.0[8.0-14.0] and 3.0[1.0-6.0] respectively. No significant differences were remarked among surgical approaches. WF patients had higher scores (global 13.0[11.0-17.0] vs. 10.5 [7.5-13-0], p=0.0089; anterolateral 5.0[3.0-8.0] vs. 3.0[1.0-4.0], p=0.0019). Relative risk of WF if anterolateral LUS≥8 was 2.9 (95% CI 1.5-5.5; p=0.0341). Anterolateral LUS alone predicted WF with AUC 0.7405 [95%CI 0.60519-0.87572] (fig. 1). Overall CD was 1.5[1.1-1.74] and 2.5[1.7-3.1] cm and TF was 17.7[8.5-29.6] and 23.1[11.0-37.3] in normal and forced inspiration respectively. No significant differences were remarked among different surgical approaches and in patients with/without WF.

CONCLUSIONS. Preliminary data suggests LUS score, but not DUS, is useful to predict WF in post-surgical extubated patients. Data need to be confirmed in a wider population.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0058

OBJCTIVES. Non-invasive mechanical ventilation (NIV) is a therapy that has gained relevance during the last decades in the treatment of patients with acute respiratory failure(ARF) and is currently part of the first line treatment of critical care patients. Our objective was to evaluate if the SpO2/FiO2 index (SaFi) could be a useful tool to indicate the need of NIV and to predict the success or failure of the NIV in critical patients with ARF.

MATERIALS AND METHODS. We performed a prospective observational study from August 2017 to March 2018, during which we calculated the SaFiand the PaO2/FiO2 (PaFi) indexes of all patients that required NIV in the ICU of a tertiary hospital. Measures were taken before NIV was started, and after 1 hour of treatment.

RESULTS. 74 patients were included, of which 59.5%were men with a median age of 61.3years (SD13.6). The median APACHE II upon intake was 18.8 (SD8.2).The main reasons for intake were respiratory tract pathology in 52.7% of the cases, sepsis in 12.2% and other causes in 35.1%. The type of ARF was of hypoxic origin in 62.2% of the patients, hypercapnic in 4.1% and mixed in 33.8%. In 32.4% NIV was unsuccessful and the patient required intubation.

In the multiple linear regression, there was a significant association between the values of pre NIV SaFi and pre NIV PaFi (p < 0.001). When comparing failure and success of NIV, the values of post NIV PaFi (p 0.26) and SaFi (p 0.09) were lower in patients in whom NIV failed, even though there was no statistical significance.

CONCLUSIONS. In our series, the values of pre NIV SaFi were positively and significantly associated with the pre NIV PaFi values and were useful as an indicator of ARF and necessity to start NIV. In patients in who NIV failed, the SaFi values had a tendency to be a better indicator of NIV failure than the PaFi values, even though there was no statistical significance.

The SaFi index is easy to obtain and is useful to evaluate if NIV is unsuccessful and determine the need for intubation and mechanical ventilation.

INTRODUCTION. Noninvasive ventilation (NIV) is among first line treatments for acute respiratory failure. Helmet is proposed to optimize tolerability, deliver higher PEEP and foster NIV success[1, 2]. No data clarify the optimal humidification strategy during Helmet NIV.

OBJECTIVES. Cross-over study to compare four different humidification strategies during helmet NIV in patients with hypoxemic respiratory failure.

METHODS. Non-hypercapnic patients with hypoxemic respiratory failure underwent 1-hour helmet pressure-support ventilation (PEEP 10cmH$_2$O, pressure support≥15 cmH$_2$O, maximum raise time) with all the following humidification settings in a random order: heating and humidification (Fisher and Paykel, MR 850) with humidification chamber temperature set at 34°C(HH34) and 37°C(HH37); bitube circuit with y-piece and heat and moisture exchanger(HME); bitube circuit with no humidification (NoH). Patients' discomfort, arterial blood

gases, ventilator performance, asynchrony index(AI), helmet temperature, absolute (AH) and relative humidity (RH) were measured. Results are expressed as medians [interquartile range].
RESULTS. Seven patients were enrolled (male 71%, age 66 [52-66] years, SAPSII 34 [30-38], duration of ICU stay before enrolment 43 [14-144] hours). Blood gases were similar in the four study steps. Patients' comfort and perception of dyspnea were optimal during NoH and they worsened during HH34 and HH37 but not during HME (VAS discomfort p=0.004; VAS dyspnea: p=0.02).
Gas temperature, RH and AH were higher during HH34, HH37 and HME vs. NoH: RH (%): respectively 100[93-100], 100[100-100], 96[45-100], 45[37-75]; p=0.005; AH (mgH2O/l): respectively 29[24-32], 32[27-32], 24[13-29], 12[11-19]; p=0.001.
Asynchrony index was lower during NoH and HME (NoH 7,5 [4-20]%, HME 5[3-21]%, HH34 15[13-24]%,.HH37 18[10-23]%; p=0.001), mainly due to a higher autotrigger rate during HH34 and HH37 (p=0.002). Ventilator performance was worsened with the use of HME and HH as compared to NoH (p=0.05).
CONCLUSIONS. In hypoxemic patients undergoing helmet PSV, a bitube circuit with no humidification allows adequate gas conditioning, optimizes ventilator performance, patient's comfort and dyspnea. HHs significantly worsens patient-ventilator interaction due to higher autotrigger rates.
These results are useful to optimize helmet pressure support ventilation in the clinical setting and in future randomized studies on the topic.

INTRODUCTION. Noninvasive ventilation (NIV) has been used frequently in the intensive care unit. In Korea a nationwide survey of NIV usage was not done yet. The Korean noninvasive mechanical ventilation study group has proposed and collected NIV use data from nationwide ICUs.
OBJECTIVES. we analyzed status and safety in the management of pain, sedation on NIV therapy in Korea.
METHODS. The eleven ICU intensivists in nationwide hospitals were participated and collected data of NIV from May 2017 to October 2017. Demographic date of patients, clinical parameters of NIV, hospital mortality were included. We analyzed using chi-square test on categorical variables and Mann-Whitney U test on continuous variables.

RESULTS. The seventy-three patients were included during those periods. Demographic characteristics and reasons of NIV were shown as table 1. We divided the intervention group that who received management of pain, sedation and control group. The pH, PaCO2 and PaO2/FoiO2 ration before NIV and 30 minutes after NIV were not different between intervention and control group. The number of failure were 5 (50%) in intervention and 21 (33%) in control (p=0.51). The hospital mortality rate was 30% in intervention and 21% in control (p=0.581).
CONCLUSIONS. The management of pain, sedation was performed in 14 percent of NIV patients. Small numbers of patients are limited. The control of pain, sedation might be safe during NIV.

The incidence and associations of acute kidney injury in trauma patients admitted to critical care: a systematic review and meta analysis

R. Haines[1,2], A. Fowler[1,2], J. Prowle[1,2]

Correspondence: R. Haines
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0061

INTRODUCTION. More patients are surviving their initial traumatic injury and are subsequently exposed to complications of critical illness including acute kidney injury (AKI). Studies suggest trauma associated AKI has unique risk factors and contributes to worse outcomes[1,2].
OBJECTIVES. To establish the incidence of AKI in patients admitted to critical care after major trauma, explore any specific risk factors and evaluate the association of AKI with outcomes.
METHODS.
Data Sources: Systematic search of MEDLINE, EMBASE and Cochrane library from January 2004 to January 2018.
Study Selection: Studies of adult major trauma patients admitted to intensive care units that applied recent consensus AKI criteria (RIFLE, AKIN or KDIGO) and reported outcomes of interest were included.
Data Extraction and Synthesis: Studies were assessed independently by two reviewers and extracted data included study design and setting, population characteristics, AKI definition and outcomes. The

pooled incidence of AKI and relative risk of death were estimated using random effects models. Results are provided with a 95% confidence interval (CI) and associated p-value. Study quality was assessed using the Newcastle-Ottawa score.

Main Outcomes and Measures: Incidence of AKI was the primary outcome. The secondary outcome was study defined mortality.

RESULTS. We included 16 articles describing AKI outcomes in 24267 patients admitted to intensive care after major trauma. In a meta-analysis of proportion using a random effects model, the pooled incidence of AKI was 20.4% (95% CI 16.5-24.9, I^2=98%). Twelve studies reported the breakdown of stages of AKI with 55.7% of patients classified as RIFLE-R or Stage 1, 30.3% as RIFLE-I or Stage 2 and 14.0% as RIFLE-F or Stage 3. Studies focused on predominantly blunt trauma had the highest pooled incidence of AKI, 31.9 % (CI 22.4-43.3%, I^2=97% p < 0.001). In a random effects model the pooled relative risk for hospital, 30 day or 90 day mortality for patients with AKI compared to patients with no AKI was 3.6 (95% CI 2.4-5.3, I^2=96%, p < 0.01).

In addition, among five studies that adjusted for multiple variables including illness severity, there was an increased odds of death compared to patients with no AKI (adjusted OR 1.6 [95% CI 1.3-1.9]; I^2=82%, n=15, 539, p< 0.01),

CONCLUSIONS. Acute kidney injury is common after major trauma and associated with increased mortality. Future research into early identification and targeted interventions is warranted to help reduce the potential for harm associated with AKI.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0062

INTRODUCTION. Acute kidney injury (AKI) is common in intensive care unit (ICU) patients and is associated with severe morbidity and mortality (1). Early prediction and diagnosis are essential to guide management. The Doppler-based Renal Resistive Index (RRI) [(peak systolic velocity - end-diastolic velocity)/peak systolic velocity] is advanced as a useful, non-invasive technique for quantifying the alterations in renal blood flow that may occur with renal disease (1).

OBJECTIVES. The objective of this study was to evaluate the correlation between RRI and ongoing deterioration of renal function, represented by AKI stages as defined by the Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guidelines (2) in ICU patients.

METHODS. We performed a prospective observational study in our multidisciplinary university ICU. Patients consecutively admitted in the ICU requiring mechanical ventilation, without pre-existing renal failure, with an expected length of stay for more than 48 hours, were enrolled. Illness severity scoring systems (APACHE II and SOFA) were calculated on the first ICU day. The RRI was measured within the first 24 hours of ICU admission, after initial hemodynamic stabilization. Clinical data including serum creatinine and urine output were collected in order to define AKI and AKI stages.

RESULTS. One hundred and sixty-eight mechanically ventilated, critically ill patients were included (median age 64 years, 58% males). Median values for APACHE II and SOFA scores were 19 and 9, respectively. AKI developed in 82 patients (52%) during the first 48h post-ICU admission; 23 patients (30%) had AKI stage I, 13 patients (14%) had AKI stage II and 46 patients (56%) had AKI stage III. Continuous renal replacement therapy (CRRT) was applied in 29% of patients with AKI. Patients with AKI stage III had statistically significantly higher RRI [0.84 (0.79-0.90) vs 0.79 (0.75-0.81), p=0.004] compared to patients with AKI stage I/II. Mortality was significantly associated with RRI (p=0.001), AKI (p=0.001) as well as AKI stage (p=0.001). RRI was statistically significantly associated with the probability of developing AKI (p< 0.001). More specifically, an increase in RRI values multiples over 50 times the probability of developing AKI (OR >50, p< 0.001 crude regression). After adjusting for potential confounders, OR remained high and statistically significant (OR >50, p< 0.001 adjusted regression). Also, ROC analysis shown that RRI could be considered as a good prognostic factor for AKI and for death (both AUCs >0.7).

CONCLUSIONS. RRI is independently associated with AKI. RRI calculation in the ICU setting enables prediction of AKI and anticipation of its severity.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0063

INTRODUCTION. Acute Kidney Injury (AKI) occurs in up to 50% of all critically ill patients and its severity is associated with increased mortality. There is a paucity of data on the role of hemodynamics in the development of AKI. Recent studies suggest the role of venous congestion, but to our best knowledge no studies investigated left versus right ventricular cardiac function objectified with ultrasonography in relation to AKI.

OBJECTIVES. The objective of this study was to investigate the association between simple hemodynamic variables, left and right cardiac function and AKI in critically ill patients.

METHODS. This study describes one of the outcomes of the Simple Intensive Care Studies - I (SICS-I: NCT02912624; Hiemstra et al. BMJ open 2017). This prospective cohort study included all consecutive adults who were acutely admitted with an intensive care unit (ICU) stay expected to last beyond 24 hours. For this substudy, we excluded patients with chronic kidney disease (CKD) defined by the National Intensive Care Evaluation criteria. Cardiac index was used as reflection of left ventricular function, tricuspid annular plane systolic excursion (TAPSE) and right ventricular systolic excursion (RV S') were used to reflect right ventricular function. AKI was defined by the KDIGO criteria within 72 hours after ICU admission. Both variables with univariate association and with known association with AKI were included in the multivariate logistic regression models.

RESULTS. From 27 March 2015 until 22 July 2017, 1075 patients were included in the SICS-I of which 72 had CKD. Of the remaining 1003 patients, 541 patients (54%) had at least AKI stage 1 within 72 hours after ICU admission (Table 1). The final multivariate model showed that higher age (OR 1.02, 95% CI 1.01-1.03 per year increase), lower mean arterial pressure (MAP) (OR 0.98, 95% CI 0.97-0.99 per mmHg), lower central temperature (OR 0.84, 95% CI 0.70-0.99 per °C), use of vasoactive medication (OR 1.46, 95% CI 1.04-2.05) and lower TAPSE (OR 0.96, 95% CI 0.93-0.98 per mm) were associated with AKI.

CONCLUSIONS. In all acutely admitted ICU patients, higher age, decreased MAP, lower central temperature, the use of vasoactive medication and lower TAPSE were independently associated with the development of AKI, whereas cardiac index was not. The former variables confirm previous findings and the association of TAPSE suggests that right ventricular function and possibly venous congestion may contribute to the high rate of AKI in critically ill patients.

INTRODUCTION. During kidney transplantation, microcirculation in implanted kidney might be affected by surgical stress, ischemia-perfusion injury, and pain stimulation. Dexmedetomidine is reported to improve intestinal microcirculation in surgical and pain animal model. [1]

OBJECTIVES. This study aims to determine whether continuous infusion of dexmedetomidine during kidney transplantation surgery can improve microcirculation and the post-operative kidney function.

METHODS. This is a single-blind randomized controlled trial. Patients who received kidney transplantation were included and randomized into the control or dexmedetomidine groups. Cardiac index and stroke volume index were recorded using bio-impedance technique. At specific time points, sublingual microcirculation was recorded by Cytocam, a third generation video microscope, and analyzed using a software, AVA 3.0. [2] Arterial blood gas analysis, blood urea nitrogen (BUN), creatinine, lactate, neutrophil gelatinase-associated lipocalin (NGAL), and diamine oxidase (DAO) levels were examined. Repeated measures ANOVA and t-test were used to compare the differences between the two groups. A p-value < 0.05 was considered significant. The error bars in all figures represent the 95% confidence intervals of means.

RESULTS. Among the 24 enrolled patients, baseline characteristics, post-operative BUN and creatinine levels did not differ significantly between the two groups. Perioperative slower heart rate, lower cardiac index (Figure 1) and lower lactate level (Figure 2) were noted in the dexmedetomidine group comparing to the control. There was a trend that total small vessel density and perfused small vessel density on day 2 and day 7 were higher in the dexmedetomidine group than in the control group (Table 1 and 2). NGAL and DAO did not differ significantly due to limited preliminary sample size.

CONCLUSIONS. Continuous infusion of dexmedetomidine might be related to slower heart rate and lower cardiac index. Meanwhile, dexmedetomidine is associated with lower lactate level, and has a trend to improve microcirculation.

INTRODUCTION. Although Sequential Organ Failure Assessment (SOFA) score is one of the most important severity scoring systems in intensive care unit (ICU), validated for predicting mortality, a change in clinical practice over time raised a problem. Renal component of SOFA score is defined by absolute serum creatinine level. However, renal dysfunction of critically ill patients in current clinical practice is commonly evaluated by acute kidney injury (AKI) defined by Kidney Disease Improving Global Outcomes (KDIGO) classification, which adopted a relative change in serum creatinine level from the baseline. Even a small increase of serum creatinine is associated with mortality and the risk for mortality increases with advancing stage of AKI. We hypothesized that modification of SOFA score using AKI classification would have a better predictive performance of mortality than the original SOFA score.

OBJECTIVES. To evaluate the prognostic validity of the SOFA score using KDIGO classification compared with the original SOFA score.

METHODS. This was a post-hoc analysis of the Japan AKI Database study, which was a multicenter prospective cohort study on AKI of all consecutive adult patients who stayed for over 24 hours in the 13 mixed ICUs in Japan from July through December in 2016. We applied KDIGO classification of AKI to determine the renal component of KDIGO-based SOFA score, with converting 3 stages of AKI in KDIGO definition to 4 stages.

The primary outcome was hospital mortality. The secondary outcome was ICU mortality. We first evaluated the construct validity of the KDIGO-based SOFA score by assessing the correlation with Acute Physiology and Chronic Health Evaluation (APACHE) II score at ICU admission by Spearman rank correlation. We then assessed the predictive validity of the original and KDIGO-based SOFA score for hospital and ICU mortality by logistic regression analysis. We compared the discriminative performance of the two scores using the areas under the curve (AUC) of the receiver operating characteristic curve.

RESULTS. Among 2292 patients eligible for the analysis, hospital mortality was 11.6% (266 patients) and ICU mortality was 5.1% (117 patients). A moderate correlation was observed between the KDIGO-based SOFA score and APACHE II score (Spearman rho = 0.476). The AUC for hospital mortality of the KDIGO-based and original SOFA score were 0.749 and 0.745, respectively (p = 0.393). The AUC for ICU mortality of the KDIGO-based and original SOFA score were 0.790 and 0.791, respectively (p = 0.892).

CONCLUSIONS. The prognostic validity of the KDIGO-based SOFA score was not superior to that of the original SOFA score.

Frailty is an important confounder of creatinine levels when studying acute kidney injury in the ICU

P.J. Gleeson[1], I.A. Crippa[1], D. Sexton[2], V. Fontana[1], F. Taccone[1], J.-L. Vincent[1], J. Creteur[1]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0066

INTRODUCTION. Retrospective observations and prospective randomized controlled trials, using creatinine based determinants, have reported contradictory results regarding the best time to start CRRT[1]. Creatinine levels are related to muscle mass, which in-turn is an index of frailty. Frailty is known to be an important predictor of ICU outcome[2].

OBJECTIVES. To determine if muscle mass interacts significantly with creatinine levels with respect to ICU mortality.

METHODS. We previously reported results (ESICM Berlin 2015) from a retrospective analysis of patients (n=157) requiring CRRT between January 2012-December 2013 in our medical-surgical ICU however, creatinine measurements were not adjusted for muscle-mass. To assess individual muscle mass, we analysed available CT-abdomen images that were taken between 1 year pre- and 5 days post-initiation of CRRT. Psoas muscle surface area was measured on axial sections at the level of mid-L3 and the vertical height of L3 vertebral body was measured on coronal sections[3]. A muscle mass index (MMI) was calculated as (Psoas Muscle Surface Area)/(L3 Height^2). Binary logistic regression analysis was performed. Multiple collinearity was tested for (VIF cut-off = 5) and eliminated using centred variables.

**RESULTS.** CT-images were available for 88/157 patients (56%). Muscle Mass Index (MMI) correlated significantly with creatinine level at the start of CRRT (start-creat) (R=0.35; p=0.001) (Fig. 1). Start-creat was an independent predictor of ICU mortality (OR 2.9 95%CI 1.6 - 5.2; p< 0.001) however, MMI also predicted ICU mortality (OR 3.6 95%CI 1.6-10.2; p=0.02) and the interaction between MMI and start-creat was a significant predictor of ICU mortality (p=0.03). When MMI was included in the model, start-creat lost its predictive power (OR 1.4 95%CI 0.6 - 3.1; p=0.38) and MMI remained the only significant predictor of ICU mortality (OR 3.3 95%CI 1.1-10; p=0.04).

CONCLUSIONS. Muscle mass, which is an index of frailty[3], is an important confounder of creatinine levels in studies of AKI and CRRT in the ICU. This should be considered in the planning and analysis of clinical studies. A bio-marker of renal function that is not dependent on muscle mass, such as cystatin C, could be more appropriate when studying AKI in the ICU.

INTRODUCTION. Mannitol is commonly used for the treatment of raised intracranial pressure in patients with traumatic brain injury (TBI). However, mannitol has side effects such as polyuria and hypovolemia possibly causing renal failure.

OBJECTIVES. To study the effect of mannitol use during the first three days of TBI on the incidence of acute kidney injury (AKI) during intensive care unit stay.

METHODS. We studied patients included in the Erythropoietin in TBI (EPO-TBI) trial who had not developed AKI or died before day 3. AKI was defined according to the creatinine criteria of the Kidney Disease Improving Global Outcome (KDIGO) staging. Severity of TBI was categorized according to the International Mission for Prognosis and Analysis of Clinical Trials (IMPACT) model. We included the amount of mannitol and hypertonic saline (HTS) administered during the first three days. Cox regression analysis was used to predict time to AKI beyond day three until discharge from the ICU.

RESULTS. Among 568 survivors without AKI at day, 72 patients developed AKI later during ICU stay. The mean time to development of AKI after day 3 was 4 days (95% confidence interval [CI] 3-5 days). Of the patients that developed AKI 19% received mannitol compared to 5% in those who did not develop AKI (p< 0.001). The corresponding figures for HTS was 50% compared to 26% (p< 0.001). The mean amount of mannitol administered during the first 2 days with and without AKI after day 3 was 64 ml (95% CI 20-108 ml) and 12 ml (95% CI 7-18 ml) respectively. The corresponding figures for HS was 359 ml (95% CI 212-507 ml) and 134 ml (98-170 ml). Independent predictors of time to AKI beyond day 3 were proportion of hours of ICP higher than 20 mmHg (HR 5.7 95% CI 2.0-16.1, p=0.001), IMPACT TBI severity (per 10% increase of poor outcome (HR 1.2 95% 1.1-1.4, p=0.007), increasing weight (per kg) (HR 1.02 95% CI 1.02- 1.03, p=0.32) and amount of administered mannitol (per 100 ml increase) (HR 1.2 95% CI 1.0-1.5, p=0.049).

CONCLUSIONS. The amount of administered mannitol during the first 3 days was independently associated with time to AKI beyond day 3. The role of mannitol in moderate to severe TBI should be studied further.

INTRODUCTION. Acute kidney injury (AKI) is a syndrome that frequently affects the critically ill. However, its pathophysiology and the predisposing factors are not completely understood. The role of genetic variability in iron metabolism pathway has been associated with AKI. Recently, a repeat length polymorphism in the *HMOX1* gene promoter sequence was associated with development of AKI in patients undergoing cardiac surgery (1). This gene encodes heme oxygenase 1 enzyme, which is inducible and expressed in response to stress.

OBJECTIVES. We investigated the association of *HMOX1* repeat length polymorphism with AKI in a Finnish cohort of critically ill septic patients (N=653).

METHODS. This prospective, observational, multicenter study was part of the FINNAKI study conducted in 17 Finnish intensive care units (ICU) in years 2011 to 2012. We defined AKI according to KDIGO criteria, with the phenotype of interest being severe AKI (KDIGO stage 2 or 3) in comparison to no AKI (KDIGO stage 0) in septic patients. We genotyped 300 patients with severe AKI and 353 without AKI, using fragment analysis. According to the number of dinucleotide (GTn) repeats in the promoter region of *HMOX1* gene, these alleles were grouped into either short, S (n< 27), or long alleles, L (n≥27).

RESULTS. The allele calling resulted in similar distribution than previously published, with peaks at 23 and 30 repeats (range 16 to 39 repeats). 85 patients had the SS, 323 patients the SL and 245 patients the LL allele combination. No significant difference in AKI incidence between these groups was observed. Moreover, the risk of the LL group compared to the SS group was 0.63-fold, suggesting a protective role of increasing number of GTn repeats (*p* value 0.077, Figure 1). In allelic analyses, the risk addition of an individual S-allele remained insignificant in additive, recessive and dominant models.

CONCLUSIONS. In septic patients, we did not detect association between the length of repeat polymorphism in *HMOX1* gene and AKI risk. Contrary to the previous findings in a cardiac surgery cohort, it appears that carriers of the short allele rather than the long one have an increased risk of AKI in this phenotype although the difference was not statistically significant.

INTRODUCTION. Hemodialysis non-tunneled catheters are currently used for critically ill patients with acute kidney injury requiring extracorporeal renal replacement therapy. Strategies to prevent catheter dysfunction and infection with catheter lock remain controversial.

OBJECTIVES. The objective is to compare the duration of event-free survival of the first non-tunneled hemodialysis catheter between trisodium citrate 4% and heparin as the catheter lock solution.

METHODS. In a multicenter, randomized, controlled, double-blind trial, we compared two strategies for catheter locking of non-tunneled hemodialysis catheters, namely trisodium citrate at 4% (intervention group) vs unfractionated heparin (control group). The primary endpoint was length of event-free survival of the first non-tunneled hemodialysis catheter. Secondary endpoints were : rate of fibrinolysis, incidence of catheter dysfunction and incidence of catheter-related bloodstream infection (CRBSI), all per 1000 catheter-days, number of hemorrhagic events requiring transfusion, length of stay in intensive care and in hospital, 28-day mortality.

RESULTS. In total, 396 patients were randomized : 199 to the citrate group and 197 to the heparin group. There was no significant different in baseline characteristics between groups. The duration of event-free survival of the first non-tunneled hemodialysis catheter was not significantly different between groups: respectively 7 days (IQR 3-10) in the citrate group and 5 days (IQR 3-11) in the heparin group (p=0.51). Rates of catheter thrombosis, CRBSI, and adverse events were not statistically different between groups.

CONCLUSIONS. In conclusion, trisodium citrate 4% as a catheter lock solution does not yield any benefit compared to heparin in the duration of event-free survival of a first non-tunneled hemodialysis catheter in critically ill patients.

INTRODUCTION. The impact of the development of acute renal failure (ARF) requiring renal replacement therapy (RRT) on the ventilatory management and outcome of patients with Acute Respiratory Distress Syndrome (ARDS) is relatively poorly understood. We wished to address these issues in this secondary analysis of the LUNG SAFE patient cohort (1-3).

OBJECTIVES. Our primary objective was to determine the effect of developing stage 3 ARF requiring RRT (4) on the outcome of patients with ARDS. A secondary objective was to examine the effect of ARF on the ventilatory management of patients with ARDS.

METHODS. The large observational study to understand the global impact of severe acute respiratory failure (LUNG SAFE) was an international, multicenter, prospective cohort study of patients with severe respiratory failure. LUNG SAFE was conducted during 4 consecutive weeks in winter 2014, in a convenience sample of 459 ICUs in 50 countries across six continents. This study examined the association between the presence of stage 3 ARF requiring RRT and demographics, management, and outcome of patients with ARDS. The study population was restricted to patients that fulfilled the Berlin criteria for ARDS on day-1 or day-2 of acute hypoxaemic respiratory failure, who did not have chronic kidney disease (i.e. creatinine clearance< 60 mL/min) at intensive-care unit (ICU) admission.

RESULTS. 2153 patients fulfilled inclusion criteria, of whom 409 (19%) patients required RRT during the 28-day follow-up period. Patients that developed ARF were more likely to have moderate-severe ARDS (78% versus 69%, RRT versus non-RRT, p< 0.001), and to have higher Sequential Organ Failure Assessment (SOFA) scores (mean ±SD, 12±4 versus 9±4, RRT versus non-RRT, p< 0.001). In regard to ventilatory management, tidal volume was similar, while PEEP was

higher (mean±SD, 9.1±3.7 versus 8.2±3.2 cmH$_2$O, RRT versus non-RRT, p< 0.001), in patients with ARF requiring RRT. Patients requiring RRT during 28-day follow up had an increased duration of ICU stay and higher crude ICU and hospital mortality rate compared to patients without RRT (see Table).

CONCLUSIONS. One fifth of patients with ARDS develop ARF requiring dialysis. These patient have greater ARDS and systemic illness severity, while mortality is substantially increased, with over half of these patients dying in hospital.

INTRODUCTION. Traditionally, CICP have been considered as low risk patients for the development of HAI. However, when HAI take place, it is associated with a large increase in mortality and ICU length of stay.

OBJECTIVES. To obtain a model that takes into account the multiple factors that intervene inthe development of HAIs in CICP admitted to the ICU, such as different diagnostic groups,the presence of invasive devices, the type of infection or the systemic inflammatory response (SIR).

METHODS. Retrospective study based on the national registry ENVIN-HELICS in the period 2006-2015. Those patients whose cause of admission was a cardiac process were selected. After data exploration (bivariate and stratified analysis) 5 nominal variables (origin of the patient, admission code, diagnoses, type of infection, and death) and 5 ordinal variables (Hospital size, APACHE 2 at 24h after admission, days of vascular catheter, artificial airway and ICU stay) were included. A first CAPTCA model was made with all the cases. A second CATCPA model was made including only infected cases in which the SIR was introduced. The study was conducted through the SPSS 20 program.

RESULTS. 67266 cases were included in the analysis. The first CATPCA generated a spatial model with 2 dimensions (dim), with an Crombach alpha value of 0,899 which guarantees the adequacy of the model. The eigenvalue was 4,1 for the first dim and 2,4 for the dim 2. The first dim was conditioned by the duration of the invasive devices and to the severity of the disease. The second has to do with the size and complexity of the hospital and the process. The diagnostic groups with less complexity (uncomplicated coronary acute syndrome) and no infection were grouped around low or negative values of both dim. At the opposite side was the cardiac arrest (CRP) and most serious infections as ventilation associated pneumonia (VAP) or CLABSI. Diagnostic groups of high complexity and low mortality, such as postoperative cardiac surgery patients were located in positive values of the first dim and negatives of the second. The second CATPCA model had an Crombach alpha value of 0,855 The eigenvalue was 2,9 for the first dim and 1,5 for the second dim. The first dim was conditioned by the duration of the devices and the second by the severity of the disease, especially by the inflammatory response and mortality, and to a lesser extent by the APACHE 2 scale. The groupings were similar to the first model: Most of the serious infections were grouped into very positive values of the first dim and positive of the second. However, a greater degree of overlap was observed in the groupings of the diagnoses.

CONCLUSIONS. The CATPCA analysis allows explaining the relationship of different clinical aspects with the HAI in cardiac patients admitted to the ICU, providing a model with an excellent fit and intuitive in its spatial representation.

INTRODUCTION. Catheter-related bloodstream infection (CRBSI) is a leading cause of nosocomial infection. Non-tunnelled central venous catheters (CVCs) are most commonly used in critically ill patients and account for >90% of all CRBSIs. Because CRBSI lacks specific clinical features, its definite diagnosis depends entirely on microbiological techniques, i.e. catheter-sparing methods versus methods requiring catheter removal.
OBJECTIVES. Sterile non-tunneled central venous catheters are frequently removed under circumstances where only methods requiring catheter removal are available. To avoid the unnecessary removal of CVCs, a clinical prediction rule (CPR) was developed to identify CRBSI cases among the patients with new-onset fever.
METHODS. A retrospective study included patients with new-onset fever during CVC placement at one university hospital between January 2011 and December 2014. The primary outcome was the occurrence of CRBSI, which was defined as isolation of the same organism simultaneously from catheter tip and peripheral blood cultures. A multiple logistic regression analysis identified predictors associated with CRBSI to develop CPR. Its calibration and discrimination performance was estimated by generating a receiver operating characteristic curve, focusing on sensitivity and negative predictive values (NPVs) to help exclusion of CRBSI.
RESULTS. A total of 426 patients were included: 39 CRBSI (9.2%) and 387 non-CRBSI (90.8%) cases. The CPR comprised age of >65 years (one point), hospital stay prior to CVC insertion of >14 days (one point), repeated CVC placements (one point), absence of pneumonia on chest radiography (two points), and duration of CVC placement of >7 days (one point). Its c statistic was 0.826 (95% confidence interval [CI]: 0.759–0.892). The sensitivity and NPV were 76.9% (95% CI: 60.3 −88.3%) and 97.1% (95% CI: 94.3–98.6%) at the score of >3. Using this CPR, 71.8% (306/426) of all cases were stratified into the low-risk group (CPR score: 0–3) and 97.0% (297/306) of low-risk patients did not have a CRBSI.
CONCLUSIONS. Prevalence of CRBSI is relatively low (9.2%) in patients with new-onset fever during CVC placement. Our CPR has a good discriminatory power for identifying CRBSI cases among febrile patients with a CVC. Because of its high NPV, the CPR scoring ≤3 may support clinical exclusion of CRBSI and thus obviate the unnecessary removal of CVCs.

INTRODUCTION. Intravenous antibiotics may exert limited therapeutic efficacy in severe pneumonia caused by multi-drug resistant (MDR) pathogens, due to incomplete pulmonary penetration. The use of nebulized antibiotics could potentially enhance bactericidal efficacy.
OBJECTIVES. The effects of nebulized amikacin combined with intravenous meropenem on lung bacterial burden and clinical parameters were tested in an animal model of mono-lateral pneumonia.
METHODS. Eighteen pigs (32.4±1.8 Kg) were anesthetized and mechanically ventilated for 102 hours. Right-sided pneumonia was induced through bronchoscopic instillation of MDR *P. aeruginosa* (1), resistant to amikacin and susceptible to meropenem. Following clinical diagnosis of pneumonia, animals were randomized to receive the following treatments: nebulized and intravenous saline (control); nebulized saline and 25 mg/kg of intravenous meropenem (IV-MER); 450 mg of nebulized amikacin (BAY41-6551, Bayer AG, Germany) and 25 mg/kg of intravenous meropenem (AMK-MER). Nebulization was performed every 12 hours through a vibrating mesh nebulizer (Nektar Lpt, Nektar Therapeutics, USA), while intravenous meropenem was administered every 8h. Every 12h, white blood cells, creatinine, arterial blood gases, lung elastance and ventilatory settings were assessed. The primary outcome was *P.aeruginosa* lung tissue burden. Tracheal secretions and bronchoalveolar lavage (BAL) fluids were cultured upon clinical diagnosis of pneumonia, and every 24h thereafter.
RESULTS. Table 1 reports primary and secondary outcomes. Of note, AMK-MER only augmented bactericidal effects in tracheal secretions; nonetheless, creatinine was higher in the AMK-MER group. In the control, IV-MER and AMK-MER groups, white blood cell count was 21.0 ± 16.4, 17.9 ± 10.3 and 19.1 ± 14.8 10^9/L, respectively (p=0.682). In addition, lung elastance was 32.4 ± 10.6, 28.8 ± 7.1 and 32.4 ± 12.8 cmH_2O/L, respectively (p=0.414). Finally, PaO_2/FIO_2 was 319.9 ± 83.9, 340.3 ± 53.3 and 340.5 ± 61.5 (p=0.202) and PEEP was 10 ± 1.1, 8.6 ± 1.3 and 9.1 ± 1.0 cmH_2O, respectively (p< 0.001).
CONCLUSIONS. In an animal model of MDR *P.aeruginosa* right-sided pneumonia, the use of inhaled amikacin as adjuvant treatment only reduced proximal airways bacterial burden, while increasing risks of renal injury.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0074

INTRODUCTION. The incidence of multi-drug resistant (MDR) Pseudomonas aeruginosa infections amongst patients with cystic fibrosis is growing and frequently requires ICU admission. Colistin has an emerging role in the treatment of these infections due to its sustained activity against MDR bacteria. However, a major obstacle to its use is the paucity of pharmacokinetic (PK) and pharmacodynamic (PD) data in this patient population.
OBJECTIVES. We aimed to evaluate colistin PK and PD in patients being treated for resistant gram negative infections.
METHODS. This study was a mult-center prospective cohort study. Cystic fibrosis patients ≥ 18 years old receiving intravenous colistimethate sodium for the treatment of infection were eligible for inclusion. Colistin was dosed according to current standards of practice: 3-5 mg/kg/day in 2-3 divided doses with adjustment for renal dysfunction. Steady-state plasma concentrations were obtained at 5 time points. Concentrations for colistin were determined via LC-MS/MS. Steady-state PK parameters were determined for each patient. Pharmacodynamic target attainment was considered acceptable if the fAUC0-24/MIC was > 35. Monte carlo simulation was utilized to determine the probability of PD target attainment.
RESULTS. Thirty patients were enrolled in this study, with 28 completing the PK analysis. Patients were 33 ± 13 years old, 50% female, 56 ± 9 kg, and had a creatinine clearance of 102 ± 35 ml/min. The mean ± SD Cmax, Cmin, half-life, Vd, Cl, and AUC0-24 were: 2.2 ± 3 mg/L, 0.9 ± 1.4 mg/L, 8.9 ± 5.4 hours, 1.9 ± 1.4 L/kg, 8.7 ± 4.0 L/hr, and 42 ± 59 mg*hr/L. Colistin A, on average, accounted for 75% of the total active colistin concentration, with colistin B representing 25% of the total concentration. Colistin total daily doses of 2.5 mg/kg/day were effective at achieving a fAUC/MIC > 35 for lower MIC organisms, but total daily doses of 6.85 mg/kg/day were necessary to reliably achieve pharmacodynamics targets for MICs up to 0.5 mg/L. Much higher total daily doses of 14.5 mg/kg and 29.5 mg/kg every 8

hours were needed to have > 90% target attainment for MICs of 1 and 2 mg/L respectively. Clinical cure or improvement was observed in 94% of patients, despite microbiologic persistence in 56% of patients. Nephrotoxicity and neurotoxicity were frequent, occurring in 38% and 19% of patients, respectively. No statistically significant difference was observed in Cmax or AUC0-24 between patients with and without nephrotoxicity.
CONCLUSIONS. Colistin exhibits considerable interpatient PK variability when administered to critically ill cystic fibrosis patients. Usual dosages of 3-5 mg/kg/day were only adequate to reliably obtain pharmacodynamics targets when treating gram negative infections with an MIC < 0.5 mg/L. We were unable to demonstrate a strong concentration effect relationship with either clinical cure or adverse effects (nephrotoxicity or neurotoxicity).

INTRODUCTION. Ventilator-associated pneumonia (VAP) is the most common healthcare associated infection (HAI) in mechanically ventilated patients[1]. Given there are many modifiable risk factors, VAP rates may be viewed as a quality indicator. The diagnostic criteria applied to detect VAP must therefore be robust and standardised[2]. There is concern that our existing diagnostic tool (HELICS) has become outdated. A sub-group of patients may therefore exist, who are being treated for VAP but not positively diagnosed or declared through our HAI screening process.
OBJECTIVES. We aim to determine the magnitude and characteristics of patients in Scottish ICU´s who are being treated for suspected VAP but not be detected using the HELICS criteria.
METHODS. A prospective national sprint audit was conducted over a one-month period. Local data collectors in Scottish ICUs were recruited and co-ordinated by the Scottish Intensive Care Society (SICS) Trainee Committee. All patients ventilated for more than 48-hours were included. Baseline HAI data was gathered for each eligible patient on a daily basis. Further collection of physiological data occurred if a new lower respiratory tract infection was suspected in order to determine whether that episode could be diagnosed as a VAP according to the HELICS definition.
RESULTS. This study included 227 patients and 1751 days of data collection. We successfully recruited 14 ICU sites from 11 Scottish NHS Health Boards. 32 patients were suspected of having a VAP (S-VAP). By applying the HELICS criteria, only 13/32 (40.6%) patients were positively diagnosed with VAP (H-posVAP). Of the 19 patients with S-VAP who failed to achieve a positive HELICS VAP diagnosis, 12 patients (63.2%) were due to the lack of radiological evidence alone. Median duration of ventilation was increased in patients with suspected VAP (14 days) compared to baseline (8 days). Hospital mortality was higher in patients with suspected VAP (42.8%) compared to baseline (33.7%). Patients who were HELICS negative had a higher hospital mortality than the HELICS positive patients (47.1% vs 36.4%).
CONCLUSIONS. We have demonstrated the existence of a sub-group of patients who are treated for suspected VAP but not diagnosed by the HELICS criteria. These patients would therefore be missed by our national HAI screening process. This population demonstrates a raised hospital mortality regardless of the HELICS screen. We believe the HELICS criteria is not compatible with modern ICU practice and an alternative tool should be sought.

Avian anti-*Pseudomonas aeruginosa* IgY-antibodies can reduce tracheal colonization with *P. aeruginosa* in mechanically ventilated piglets

A. Otterbeck, K. Hanslin, E. Lidberg Lantz, A. Larsson, J. Stålberg, M. Lipcsey
Uppsala University, Akademiska Hospital, Uppsala, Sweden
Correspondence: A. Otterbeck
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0076

INTRODUCTION. *P. aeruginosa* is a pathogen frequently resistant to antibiotics and a common cause of ventilator-associated pneumonia (VAP), VAP caused by *P. aeruginosa* has a mortality of 30-40% (1,2). Non-antibiotic strategies to treat or prevent VAP are therefore of great interest. Specific polyclonal avian IgY-antibodies have previously been shown to be effective against pneumonia caused by *P. aeruginosa* in rodents (3).

OBJECTIVES. To study the effect of *P. aeruginosa* specific polyclonal avian IgY-antibodies (IgY) on colonization of the airways in a porcine model.

METHODS. The pigs were anesthetized, mechanically ventilated and subject to invasive hemodynamic monitoring and allocated to either receive 10^9 CFU nebulized *P. aeruginosa* (n=6) or 10^9 CFU nebulized *P. aeruginosa* + 200 mg IgY antibodies (n=6). Physiological measurement, blood samples and tracheal cultures were then secured regularly for 27 hours after which the pigs were sacrificed and lung biopsies were analyzed for microbial growth.

RESULTS. After nebulization, tracheal growth of *P. aeruginosa* increased in both groups but with lower growth in the IgY-treated group (p = 0.02, mixed linear models). There was no difference between groups in respiratory function, physiological parameters or inflammatory markers during the observation period.

CONCLUSIONS. Our conclusion is that specific polyclonal avian IgY-antibodies can lessen bacterial colonisation of the airways. Further studies into the use of IgY-antibodies as a treatment for VAP are warranted.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0077

INTRODUCTION. Ventilator-Associated Pneumonia (VAP) is the most frequent infectious complication in Intensive Care Units. Its natural history is tightly linked with that of Ventilator-Associated Tracheobronchitis (VAT), which has been described as an intermediate process between tracheobronchial colonisation and VAP (1). The management of VAP currently relies on antibiotic therapy, in contrast with VAT, for which antibiotic treatment is not currently recommended (2). The Clinical Pulmonary Infection Score (CPIS) has been widely described as an early predictor of VAP (3). However, its efficiency to differentiate VAP from VAT has never been studied.

OBJECTIVES. To assess the accuracy of CPIS in differentiating VAT from VAP.

METHODS: This was a retrospective study based on the data from the large prospective multinational TAVeM study (1). Patients with a microbiologically confirmed diagnostic of VAT or VAP were systematically included in our analysis. A sensitivity analysis was performed and ROC curves were computerized. The best-cut-off point was assessed through calculation of the Youden Index.

RESULTS. ROC analysis of CPIS showed an Area Under Curve of 0.757 (95% CI 0.722 - 0.793) for the diagnostic of VAP in our population. A CPIS value ≥ 7 was associated with the best Youden index, and showed a sensitivity (Se) of 0.51 (95% CI 0.45 - 0.56), a specificity (Sp) of 0.88 (95% CI 0.84 - 0.91), a Positive Predictive Value (PPV) of 0.83

(95% CI 0.76 - 0.88), a Negative Predictive Value (NPV) of 0.61 (95% CI 0.57 - 0.64), a Positive Likelihood Ratio (LR+) of 4.13 (95% CI 2.77 - 6.3) and a Negative Likelihood Ratio (LR-) of 0.56 (95% CI 0.48 - 0.65). In this cohort, a CPIS value $\geq$ 6, usually considered as the best cut-off for the diagnostic of VAP (3), was associated with a Se of 0.68 (95% CI 0.63 - 0.73), a Sp of 0.68 (95% CI 0.63 - 0.74), a PPV of 0.71 (95% CI 0.66 - 0.76), a NPV of 0.65 (95% CI 0.6 - 0.7), a LR+ of 2.17 (95% CI 1.72 - 2.77) and a LR- of 0.46 (95% CI 0.37 - 0.58).

CONCLUSIONS. CPIS exhibited moderate accuracy for the diagnostic of VAP among patients with microbiologically confirmed ventilator associated infections. Adjunctions of supplemental variables should be tested before considering its application to initiate preemptive antimicrobial treatments in ventilated patients with criteria of ventilator associated infections.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0078

INTRODUCTION. After liver transplantation (LT),40% of patients develop an infection of which 5% are related to Extended-Spectrum β-Lactamase-Producing Enterobacteriaceae (ESBLE) (1). EBLSE colonization is a recognized risk factor for ESBLE infection. However, only 15% of ESBLE carriers develop an infection caused by these pathogens and various studies have shown a poor positive predictive value of colonization to predict infection (2). Identifying risk factors of ESBLE infection in carriers is therefore important to rationalize the choice of empirical antimicrobial therapy in case of infection suspicion.

OBJECTIVES. To identify risk factors for ESBLE-related infection after LT in patients with prior ESBLE rectal colonization.

METHODS. Retrospective observational study from a prospective database after ethics committee agreement. All patients transplanted between 2010 and 2016 were screened and those with ESBLE in systematic preoperative rectal swabs were included. Postoperative infections were followed for 3 months and those related to colonizing ESBLE identified. Risk factors for ESBLE infections in carriers were investigated by univariate analysis (non parametric tests) and then multivariate analysis (logistic regression). Results are expressed as number (percentage) and median [interquartile range].

RESULTS. 749 LT were performed during the study period. 100 (13.3%) patients were colonized with ESBLE (68 *E. Coli*, 28 *K. pneumoniae* (KP), 10 *E. cloacae*) before TH. 45 (45%) patients developed an ESBLE-related infection including 39 (39%) with the same species (13 E. Coli (33.3%), 22 KP (56.4%), 4 E. cloacae (10.3%)) within 11 (6.5-18) postoperative days. Sites of infection were pulmonary (n=10), intra-abdominal (n=10), urinary (n=14), systemic (isolated blood culture, n=5) and biliary (n=2). The factors associated with ESBLE infection in carriers in univariate analysis are described in Table 1. In multivariate analysis, preoperative antibiotic prophylaxis of spontaneous bacterial peritonitis (SBP) (OR=5.4, p=0.02), colonization with ESBL-producing

KP (OR=14.1, p< 0.001) and MELD score (OR=1.1, p< 0.001) were predictive of infection. Intraoperative administration of antibiotic prophylaxis active against colonizing ESBLE was associated with a reduced risk of infection (OR=0.2, p=0.04).

CONCLUSIONS. In liver transplant patients with preoperative digestive colonization with ESBLE, postoperative infections caused by these pathogens are common. Colonization with ESBL-producing KP, preoperative antibiotic prophylaxis against SBP and MELD score are predictive factors for postoperative ESBLE-related infection in these patients. Conversely, intraoperative antibiotic prophylaxis was protective when it was active against colonizing ESBLE. These data argues in favour of preoperative screening and tailoring antibiotic prophylaxis to colonization.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0079

INTRODUCTION. Early antifungal therapy is associated with better outcomes in patients with candidemia. Blood cultures and serological monitoring are gold standard for IC diagnosis. T2 Magnetic Resonance (T2MR) is a new diagnostic test that is able to detect in 3 to 5 hours the five clinically relevant species of Candida directly from the whole blood at a density as low as 1 colony forming unit (CFU) per ml. No study to date has demonstrated the clinical relevance for this new tool in the ICU.

OBJECTIVES. We conducted a monocentric prospective study to determine the accuracy of T2MR in diagnosing candidemia in ICU patients.

METHODS. In all patient with suspected candidemia, fungal blood culture, T2MR assay and fungal biomarkers were performed. The definite diagnosis of candidemia was based on standard fungal blood cultures.

RESULTS. Between November 1st, 2017 and February 1st 2018, 62 patients were hospitalized in our 10 beds ICU. 69 fungal blood samples were ordered in 38 patients. Median SOFA score was 10 [9-14], median SAPSII score was 54.5 [44-67] and median candida score was 2 [1,25-2]. 7 fungal blood cultures were positive in 5 patients, and 12 T2MR were positive in 9 patients with a sensitivity of 100%, a specificity of 91.8%, a

PPV of 58,3% and a NPV of 100%. All patients with positive fungal blood culture had at least one T2MR positive assay. 3 patients had a positive T2MR assay without positive blood culture. A positive manan antigen was found in 2 out of the 3 patients with no matching between blood culture and T2MR, suggesting that T2MR might be more sensitive than standard fungal blood cultures. Median time for positive culture was 5h, and 72 hours for standard fungal blood cultures and T2MR; respectively.

CONCLUSIONS. T2MR could be an interesting tool to early diagnose candidemia in ICU patients.

INTRODUCTION. Bacterial resistance has become widespread both in hospitals and the community. It is not uncommon for patients, to be carriers of MRB at admission in the ICU

OBJECTIVES. To identify risk factors (RF) that can predict which patients are carriers of multiresistant bacteria (BMR) upon admission to the ICU, including infection and colonization

METHODS. Prospective, multicenter cohort study (ENVIN registry) that included patients admitted> 24 h in ICU from 2014 to 2016. The MRB studied were S aureus meticillin resistant (MRSA), P aeruginosa (Paer), A baumannii (Acin), Enterobacteria producers of extended beta-lactamases (ESBL) and carbapenemase-producing Enterobacteriaceae (CBP). We included as intrinsic data age, gender, severity (APACHE II, GCS and neutropenia), origin (community, another ICU, ward, and long-stay centers), pathology (medical, trauma, coronary, scheduled and emergency surgery), comorbidities (diabetes, chronic renal insufficiency, COPD, Cirrhosis, Immunosuppression, neoplasia, solid organ transplantation (SOT) and malnutrition. The chi square test and a multivariate analisys were applied.

RESULTS. Among the 69,741 patients admitted> 24h in the ICU, the presence of some MRB was diagnosed in 4.830 (6.4% of the total). Of these, in 3024 patients (4.3%) the identification was on admission. The BMR upon admission were 1,508 ESBL, 1020 MRSA, 448 P aer, 227 CBP and 154 Acin.Almost all risk factors were associated with a higher proportion of patients with MRB. In the multivariate analysis, the risk factors that remained significant were: APACHE $\geq$15: OR (95% CI) 1, 9 (1.8-2.0); hospital stay before $\geq$10 days: OR (95% CI) 3.7 (3.5-4.0); long-stay center: OR (95% CI) 3.4 (2.7-4.4); coronary disease: OR (95% CI) 0.2 (0.2-0.2); Neutropenia: OR (95% CI) 3.4 (2.8-4.2), C renal faliure: OR (95% CI) 2.3-2.1-2.6), Cirrhosis: OR (95% CI %) 1.9 (1.6-2.2), COPD: OR (95% CI) 1.8 (1.7-2.0), malnutrition: OR (95% CI) 3.5 (3, 1-3,8) and TOS OR (95% CI) 3.3 (2.8-4.0).

The most significant RFs for **ESBL** were TOS: 4.0 (3.2-5.1), Pre-stay 3.7 (3.3-4.1), Malnutrition 3.6 (3.1-4.1) , origin LSC 3.3 (2,3-4,1) and neutropenia 3,2 (2,4-4,2). **MRSA** origin LSC 5,9 (4.2-8.2), Pre-stay 3.4 (3.0-

3.9), malnutrition 3.3 (2.7-3.9), neutropenia 2.9 (2.0-4.2) and IRC 2.5 (2.2-2.9); *P aeruginosa*: hospital stay 7.4 (6.0-9.1), TOS 6.2 (4.3-8.8), neutropenia 5.9 (4.0-8.7), malnutrition 4.9 (3.9-6.1) and IRC 4.7 (3.8-5.8). **CBP**: hospital stay 7.0 (5.3-9.3), TOS 5.7 (3.5-9.4), neutropenia 5.3 (3.0-9.4), malnutrition 4.2 (3.0-5.9) and chronic renal faliure 4.2 (3.1-5.7); *Acinetobacter*: malnutrition 9.3 (6.7-13.0), stay h previous 8.9 (6.2-12.7), origin LSC 4.2 (1.8-9.7), neutropenia 2, 9 (1,2-7,2) and immunosuppression 2,7 (1,8-7,2)

CONCLUSIONS. The previous hospital stay, the origin from a LSC, malnutrition, neutropenia and TOS were the RFs with the greatest significance. The MRB showed some differences between them.

New insights into post resuscitation care

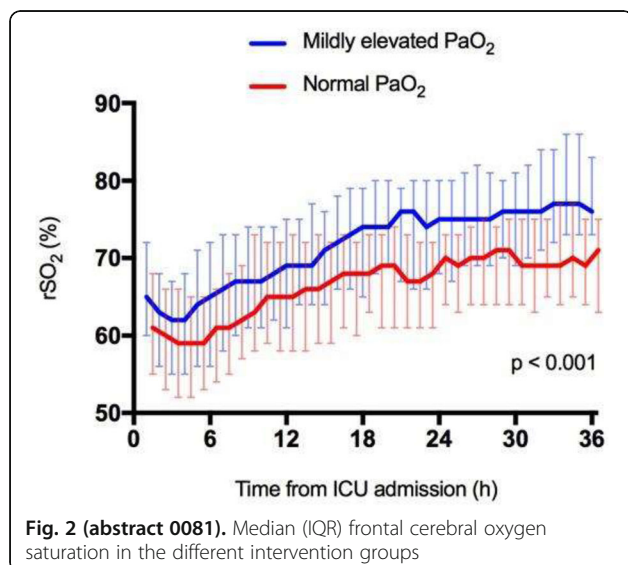
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0081

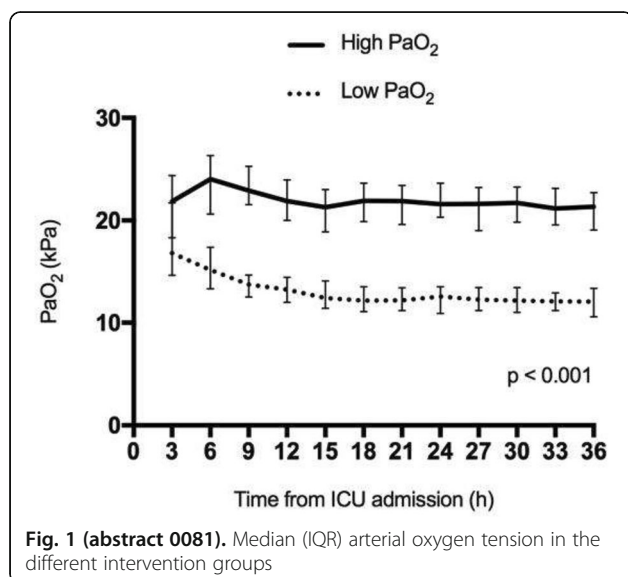
BACKGROUND. Mild hyperoxia has been associated with better neurological recovery and improved organ function after cardiac arrest and resuscitation. [1] In unconscious, mechanically ventilated patients, arterial oxygen tension (PaO_2) can be modified by changing the fraction of inspired oxygen (FiO_2) and the level of end-expiratory pressure (PEEP) but the optimal target level remains unknown. [2]

OBJECTIVES. We conducted a randomized pilot trial to assess the feasibility of targeting normal or mildly elevated PaO_2 in comatose, mechanically ventilated patients after out-of-hospital cardiac arrest. Also, we wanted to evaluate the effect of normal or mildly elevated PaO_2 on serum concentration of neuron-specific enolase (NSE) and cerebral oxygenation as measured by near-infrared spectroscopy (NIRS).

METHODS. In the Carbon dioxide, Oxygen and Mean arterial pressure After Cardiac Arrest and REsuscitation (COMACARE) trial, we used a 2^3 factorial design to randomly assign patients after OHCA and resuscitation to normal or mildly elevated levels of PaO_2, low-normal or high-normal arterial carbon dioxide tension and low-normal or high-normal mean arterial pressure. The results of normal (10-15 kPa) vs. mildly elevated (20-25 kPa) PaO_2 comparison are reported here.

The primary outcome was the serum concentration of neuron-specific enolase (NSE) at 48 h after cardiac arrest. The main feasibility outcome was the difference in PaO_2 between the groups during the first 36 h after ICU admission. Secondary outcomes included cerebral oxygenation measured with NIRS.

RESULTS. 120 patients were included in the final analysis. Although we achieved a good separation in PaO_2 between the groups (Figure 1), there was no significant difference in serum NSE concentration at 48 h after cardiac arrest (for normal PaO_2 group, 22.4 µg/l [IQR, 14.8-28.3 µg/l] and for mildly elevated PaO_2 group 20.6 µg/l [IQR, 14.2-34.9 µg/l], p = 0.649). Median cerebral oxygen saturation was significantly higher in the mild hyperoxia group as compared with the normal PaO_2 group (Figure 2).




CONCLUSIONS. Targeting a specific range of PaO_2 is feasible in comatose, mechanically ventilated patients during post-resuscitation care. Mild hyperoxia did not affect the levels of NSE at 48 h after OHCA when compared with normoxia. However, mild hyperoxia resulted in higher cerebral oxygen saturation suggesting better oxygen delivery to the brain.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0082

INTRODUCTION. Guidelines on post-resuscitation care recommend the use of short-acting agents for sedation during targeted temperature management (TTM) after cardiac arrest (CA), the potential advantages of this strategy have not been clinically demonstrated.
OBJECTIVES. Compare short and long-acting-drugs sedation regimen after CA and report proportion of patients with delayed awakening.
METHODS. We compared two sedation regimens (propofol-remifentanil, period P2, vs midazolam-fentanyl, period P1) among comatose TTM-treated CA survivors. Management protocol, apart from sedation and neuromuscular blockers use, did not change between the two periods. Baseline severity was assessed with Cardiac-Arrest-Hospital-Prognosis (CAHP) score. Time to awakening was measured starting from discontinuation of sedation at the end of rewarming. Awakening was defined as delayed when it occurred after more than 48 hours.
RESULTS. 460 patients (134 in P2, 326 in P1) were included. CAHP score did not significantly differ between P2 and P1 (P=0.93). Sixty percent of patients awoke in both periods (81/134 vs. 194/326, P=0.85). Median time to awakening was 2.5 (IQR 1-9) hours in P2 vs. 17 (IQR 7-60) hours in P1. Awakening was delayed in 6% of patients in P2 vs. 29% in P1 (p< 0.001). After adjustment, P2 was associated with significantly lower odds of delayed awakening (OR 0.08, 95% CI 0.03-0.2; P< 0.001). Patients in P2 had significantly more ventilator-free days (25 vs. 24 days; P=0.007), and lower catecholamine-free days within day 28. Survival and favorable neurologic outcome at discharge did not differ across periods.
CONCLUSIONS. During TTM following resuscitation from CA, sedation with propofol-remifentanil was associated with significantly earlier awakening and more ventilator-free days as compared with midazolam-fentanyl.

INTRODUCTION. Several case-series report controversial results of extracorporeal cardiopulmonary resuscitation (ECPR) for patients with refractory in-hospital (IHCA) and out-of-hospital cardiac arrest (OHCA); however, few data on large cohorts are available.

OBJECTIVES: To assess the survival and neurologic outcome following ECPR in five European centers.

METHODS. Retrospective analysis of database from a prospective observational cohort of patients undergoing ECPR patients in five University hospitals (Brussels, Regensburg, Pavia, Stockholm and Milan) from January 2012 to December 2016. The primary outcomes were survival to ICU discharge and 3-month favorable neurologic outcome, assessed by the Cerebral Performance Categories (CPC) of 1-2.

RESULTS. A total of 423 CA patients treated with ECPR were included (median age: 57 [48-65] years; male gender 78%) over the study period. Cause of arrest was presumed cardiac in 307 (73%) of patients and ECPR was initiated for OHCA in 258 (61%) patients. Time from arrest to ECMO implementation was 65 [48-84] minutes. ICU mortality was 76% (n=321); main causes of death were cardiovascular or multiple organ failure. A total of 80 patients (19%) had favorable neurological outcome. Median time from arrest to ECMO was significantly lower in IHCA than OHCA (42 [30-60] vs. 74 [60-90] minutes; p< 0.01). ICU mortality was significantly higher (219/258, 85% vs. 102/165, 62%, p< 0.01) and good neurological outcome rate lower (24/258, 9% vs. 56/165, 34%, p< 0.01) in ECPR for OHCA when compared to IHCA. A significant decrease in good neurological outcome rate was observed from shorter to longer time from arrest to ECMO (< 30 minutes: 55%; 31-60 minutes: 20%; 61-90 minutes: 9%, >90 minutes: 7% - p< 0.01).

CONCLUSIONS. ECPR was associated with intact neurological recovery in 19% of CA victims. Time from arrest to ECMO implementation is a significant determinant of clinical success.

EEG reactivity for prognosis in patients after cardiac arrest

M. Admiraal[1], A.-F. van Rootselaar[2], J. Hofmeijer[3], C.W.E. Hoedemaekers[4], M.J.A.M. van Putten[5], J. Horn[6]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0084

INTRODUCTION. EEG reactivity testing is often suggested to have prognostic value in patients after cardiac arrest. EEG reactivity testing regimens, however, vary and definitions for reactivity are poorly described (Admiraal et al., Eur J Neurol. 2016).

OBJECTIVE. We investigate the prognostic value of standardized EEG reactivity testing in a cohort of patients after cardiac arrest.

METHODS. This is a multicenter prospective observational study. We aim to enroll and monitor 160 patients, using continuous (c) EEG, from < 24 hours after cardiac arrest to day 3 or until the patient is awake, whatever comes first. EEG reactivity is tested twice a day according to a strict stimulation protocol comprising of five different stimuli, repeated three times for five seconds at an interval of at least 30 seconds. Three blinded experts score background activity and reactivity (yes/no) per stimulus for all EEGs. An EEG is scored as 'reactive' if at least one type of stimulus repeatedly elicits a change. The prognostic value of EEG reactivity for good and poor outcome is calculated as sensitivity and specificity. Furthermore, added prognostic value of EEG reactivity besides other known prognostic markers is given as the increased accuracy of a random forest classifier if EEG reactivity is included compared to excluded. Outcome at 6 months is defined as 'good' when the best score on the Cerebral Performance Category scale is 1-2. A score of 3-5 is considered 'poor'.

RESULTS. All 160 patients are enrolled; follow-up data is expected to be available May 2018. In an interim analysis of 80 patients an intra-class correlation coefficient of 0.78 is found for scoring an EEG as 'reactive'. Of these 80 patients, 39 (49%) have a good outcome. Mean age is 59 (±15) years in the good outcome group and 61 (±14) years in the poor outcome group. Time to return of spontaneous circulation is shorter in the good outcome group, 15 (±12) min versus 25 (±12) min in respectively good and poor outcome groups.

CONCLUSIONS. We conduct a dedicated prospective trial to determine the prognostic value of EEG reactivity and place this modality in the context of other known prognostic markers. An interim analysis showed a good correlation between raters when scoring EEG reactivity and a representative distribution of patient characteristics. Final results on the prognostic value of EEG reactivity will be presented at the conference.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0085

INTRODUCTION. Out-of-hospital cardiac arrest (OHCA) may lead to hypoxic brain injury. Cognitive impairment, with anxiety and depression, are common symptoms even in survivors with good neurological outcome. Little is known how cognitive impairment and related quality of life (QoL) change in the years after CA

OBJECTIVES. We therefore investigated, in a sub study of the Norwegian Cardio-Respiratory Arrest Study (NORCAST), how cerebral performance, QoL and psychological symptoms change from six months to four years after CA in adult OHCA survivors.

METHODS. The observational NORCAST cohort (NCT 01239420) evaluated a multimodal approach for early prognostication of the outcome in 259 comatose OHCA survivors. All patients were treated according to a standard treatment protocol, including targeted temperature management at 33°C, for 24 hours. In the present sub study, survivors eligible for follow-up investigations at both six months (T1) and 4 years or later (T2), were included. Cerebral performance categorisation (CPC) and a detailed examination protocol including cognitive and functional assessment were performed at both time points. Levels of depression and anxiety and QoL were assessed by the EuroQol EQ-5D-3L questionnaire. The questionnaire at T2 was supplemented with a visual analogue scale reflecting self-experienced health status (SEHS) over time. For the EQ-5D-3L and SEHS over time, time-series analyses using linear mixed models (LMM) were used. In addition, descriptive results were analysed using t-tests for paired samples and Wilcoxon test as appropriate. For all analyses SPSS 25 (IBM Corp, Armonk, NY, USA) was used. P-values < 0,05 were defined as statistically significant.

RESULTS. Among 259 OHCA patients (81% cardiac cause, median age 63 years, 83 % male), 137 (53%) survived to T1 and 115 (44 %) to T2. Altogether 108 patients were eligible for follow-up. So far, 83 patients have been investigated at T2. Among these, 74 (89 %) had CPC 1 at T1 and 77 (93 %) at T2 (NS). Self-experienced health status improved significantly from year to year after the 6 months control with greatest improvement over the first three years (Figure 1, p < 0,001). Time series analyses of EQ-5D results will be presented. In addition, significantly fewer patients were depressed or anxious at T2 vs T1 (Figure 2, p = 0,002).

CONCLUSIONS. Overall survival years after OHCA is good, with 93% of the patients having CPC 1 after four years. Self-experienced health status improves further even after 6 months, and levels of depression and anxietysignificantly decrease over time. Thus, a longer time horizon and more detailed assessment for cognitive impairment might to be needed to evaluate final outcome after OHCA.

Fig. 1 (abstract 0085). Self-experienced health from before until 4-years after CA

Fig. 2 (abstract 0085). Anxiety and depression at 6 month and 4 years after cardiac arrest

ST elevation myocardial infarction (STEMI) who underwent primary PCI were also recruited.

Immediately at admission, patients in both groups had a blood sample drawn and analyzed using the ROTEM® platelet and delta modules. Data regarding preadmission antiplatelet and anticoagulant use was collected. Patients were followed up for 30 days to look for bleeding complications.

RESULTS. 30 patients were recruited to each arm and were well matched (median age 65.8 years OHCA and 65.4 in STEMI groups, 22 men in each group). Immediately at admission to hospital thrombin receptor function was reduced in OHCA as compared to STEMI patients. 32% of OHCA patients demonstrated thrombin receptor activation below the lower limit of normal.

Maximum clot formation time (MCFt) was prolonged in the OHCA group. Clotting time (CT) and clot formation time (CFT) showed a tendency to prolongation post OHCA, however maximum clot firmness was the same in both groups.

Hyperfibrinolysis (maximum lysis >=15%) was common in both groups (56% in STEMI; 52% in OHCA) and was correlated to markers of hypoperfusion In the OHCA cohort.

CONCLUSIONS. Immediately post OHCA, platelet thrombin receptor activity is reduced. Coagulation suggests a prolongation in the time taken to achieve maximum clot formation but, as compared to patients post STEMI, the same clot size is eventually produced. The implications on post cardiac arrest management require further study.

INTRODUCTION. Out of hospital cardiac arrest (OHCA) is most commonly as a result of coronary disease, the mainstay treatment of which is prompt recanalization with percutaneous coronary intervention (PCI). Post PCI antiplatelet drugs are given for vessel patency. There is limited evidence as to what strategy should be employed post OHCA. Current practice is extrapolated from cardiology literature. Pertinently it is not clear as to what, if any, derangement of platelet function exists immediately post OHCA before antiplatelet drugs are delivered.

OBJECTIVES. The primary aim of this study was to assess platelet function and coagulation in Utstein cohort patients admitted to hospital with return of spontaneous circulation (ROSC) following OHCA before the administration of antiplatelet drugs.

METHODS. Any adult with ROSC following OHCA meeting Utstein criteria (witnessed, shockable arrest of presumed cardiac origin) was eligible for enrollment. A control group of patients admitted with acute

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0087

INTRODUCTION. Up to one-third of cardiac arrest (CA) survivors might experience late awakening (L-AW) from coma, defined as a time to awakening of more than 48 hours following targeted temperature management (TTM) and sedation stop. No study has sought to examine - using early neurological and neurophysiological assessment - whether late awakening is a clinical marker of increased post-anoxic cerebral injury. Furthermore, it is unclear whether late awakening may be associated with worse neurological impairment in CA survivors.

OBJECTIVES. To identify early neurophysiological predictors of L-AW in comatose CA survivors and examine its association with ICU and long-term recovery.

METHODS. Single-center observational cohort study of comatose subjects resuscitated from CA who underwent early prognostication, including Glasgow Coma Scale (GCS) motor response, brainstem reflexes, EEG and serum neuron specific enolase (NSE). Baseline demographic variables, CA characteristics and SOFA score at day 1 were analyzed. Sedation administered until first sedation stop was recorded. Awakening was identified retrospectively in medical records. Time to awakening was defined as the time from sedation stop to the first documentation of a GCS-M=6. L-AW was defined as an awakening time of more than 48 hours. Hyperactive delirium was defined as the presence of a Richmond Agitation Sedation Scale (RASS) > 2 with repeated use of anti-psychotic agents after initial sedation stop. Recovery was assessed prospectively at 3 months using the Glasgow-Pittsburgh Cerebral Performance Categories (CPC).

RESULTS. 418 patients were included : 229 (55%) awoke, of whom 214 completed 3-month outcome follow-up. L-AW occurred in 71 patients (33%). Patient demographics and CA characteristics did not differ between patients with early awakening (E-AW) and L-AW. Patients with L-AW had a higher rate of absent motor response (38 vs. 9%), absent brainstem reflexes (21 vs. 4%), discontinuous EEG (46 vs. 21% at day 1; 20 vs. 5% at day 2) and NSE > 33 ng/mL (23 vs. 8%) (all $p < 0.01$). L-AW was also associated with higher SOFA score at day 1 and greater midazolam dose during TTM. By multivariable analysis - after adjusting for cumulative midazolam dose during TTM and SOFA score - absence of motor response (odds ratio [OR] 3.35 [confidence interval 1.22-9.18], p=0.019), presence of a discontinuous EEG (OR 2.63 [1.10-6.29], p=0.029) and elevated NSE > 33 ng/mL (OR 4.71 [1.39-15.99], p=0.013), within 3 days from CA, were independent predictors of L-AW. Patients with L-AW had higher rate of hyperactive delirium (61 vs. 38% in E-AW, p=0.001) and 3-month unfavorable recovery (CPC 3-5 25 vs. 11% in E-AW, p=0.008).

CONCLUSIONS. Late awakening from post-anoxic coma is common and correlates with neurophysiological signs of increased cerebral damage and worse ICU and 3-month neurological outcomes.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0088

INTRODUCTION. Different cooling devices can be used to achieve targeted temperature management (TTM) after out-of-hospital cardiac arrest.

OBJECTIVES. The aim of this study was to explore the performance and outcomes for intravascular versus other devices for TTM after out-of-hospital cardiac arrest.

METHODS. A retrospective analysis of data from the TTH48 study (NCT01689077), which compared whether TTM at 33°C for 48 hours results in better neurologic outcomes compared with standard 24-hour duration. Devices were assessed for speed of cooling and rewarming rates. Precision was assessed by measuring temperature variability (TV), i.e. the standard deviation (SD) of all temperature measurements in the cooling phase. Main outcomes were overall mortality, and poor neurological outcome, including death, severe disability or vegetative status (i.e. Cerebral Performance Category of 3-5).

RESULTS. A total of 355 patients were included in the study; of those, 217 (61%) were managed with intravascular catheter, while the others were treated with other devices, mainly surface cooling. A total of 114 (53%) patients treated with endovascular devices and 62 (42%) with other devices were cooled for 48 hours (p=0.19). Time to target (≤34°C) was significantly shorter for patients treated with endovascular devices (2.3 [1.1-4.0] vs. 4.3 [2.8-6.7] hours, p< 0.001), but temperature was also lower on admission (35.0 [34.2-35.6] vs. 35.3 [34.5-35.8] °C; p=0.02) and cooling rate was similar between groups (endovascular, 0.4 [0.2-0.8] °C/hour vs. others, 0.4 [0.2-0.6]°C/hour; p=0.14). Temperature variability was significantly lower in the endovascular device group when compared to other methods (0.6 [0.4-0.9] °C/hour vs. 0.7 [0.5-1.0]°C/hour; p=0.007), as was rewarming rate (0.3 [0.2-0.4] °C/hour vs. 0.4 [0.3-0.5]°C/hour; p=0.02). There was no statistically significant difference in mortality (endovascular 65/217, 30% vs. others 43/155, 27%; p = 0.72) or poor neurological outcome (endovascular 69/217, 32% vs. others 50/155, 32%; p = 1.00) between type of devices.

CONCLUSIONS. Endovascular cooling devices were more precise and had a slower rewarming rate than other methods in patients cooled at 33°C after out-of-hospital cardiac arrest. Main outcomes were similar with regard of the cooling methods.

Functional recovery and quality of life after in-hospital cardiac arrest - Preliminary results. Australia and New Zealand Cardiac Arrest Outcome Determinants and ECMO suitability study (ANZ-CODE): a multi-centre prospective observational study of in-hospital cardiac arrests

G. Pound[1,2], D. Jones[1,3], G. Eastwood[1,3], C. Hodgson[1,2]
[1]Australian and New Zealand Intensive Care Research Centre, Department of Epidemiology and Preventive Medicine; Monash University, Melbourne, Australia; [2]Alfred Hospital, Department of Physiotherapy, Melbourne, Australia; [3]Austin Hospital, Intensive Care Department, Melbourne, Australia
Correspondence: G. Pound
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0089

INTRODUCTION. Reported frequency of in-hospital cardiac arrest (IHCA) in Australia and New Zealand ranges from 1.3-6.0 per 1000 admissions with an overall in-hospital mortality of 74.6%[1]. Little is known about the long-term functional outcome and health-related quality of life (HRQoL) of survivors of IHCA. It is recommended that multiple impairment and disability measures with longer term endpoints are used to characterise recovery among cardiac arrest survivors[2].

OBJECTIVES. To determine functional recovery and quality of life of survivors of IHCA at 6-months.

METHODS. A multi-centre prospective cohort study. Emergency calls were screened and data collected for all IHCA. Patients were included

if aged >18 years, unresponsive with no respiratory effort and cardiac compressions commenced. Patients were excluded if a pre-existing NFR order was in place or if the emergency call did not fit the criteria for IHCA. Patients were contacted by telephone if they survived to 6-months post IHCA. Measurements included discharge destination, re-admission to hospital, return to work, functional status (modified Rankin Scale (mRS) and Barthel Index (BI)) and HRQoL (EQ5D-5L) at 6-months.

RESULTS. There were 52 IHCA across five sites between July and November 2017 (male 61.4%, median age 76.5 years (IQR 20.0)). 15 patients (28.8%) survived to hospital discharge of which 10 were discharged home. 14 patients (26.9%) survived to 6-months. Of the 10 survivors who consented to follow-up interview (71.4%), 1 patient remains in hospital and 9 patients are residing at home. Three patients had subsequent hospital admissions, 2 were then discharged to rehabilitation. Median mRS and BI at 6 months were 3/6 (IQR 4.5) and 19/20 (IQR 6.5) respectively. In the EQ5D-5L domains there were no problems reported by 3 patients (33.3%) for mobility and self-care, 2 (22.2%) for usual activities, 1 (11.1%) for pain and 4 (44.4%) for anxiety/depression. The median EQ5D VAS score was 70/100 (IQR 30). Of the 4 patients working prior to IHCA, 2 (50%) had returned to work. Those who did not return to work reported this was due to health post IHCA.

CONCLUSIONS. Functional recovery and HRQoL at 6 months post IHCA is varied. Two thirds of patients report some level of functional disability and few patients report 'no problems' with HRQoL domains at 6 months. Only half of patients previously employed returned to work.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0090

INTRODUCTION. Neurological prognostication from cardiac arrest (CA) survivors is a current concern. The last decade was marked by the wide-spread use of electroencephalography (EEG) and Neuron specific enolase (NSE) dosage, improving the evaluation of brain injury in usual practice. Nevertheless, there is a wide degree of variability in the NSE serum threshold observed in different studies, limiting the generalization of reliable cut-off value. EEG patterns can be classified in five grades according to the Synek classification; but few data are available on the specific performances of this classification since generalization of induced hypothermia.

OBJECTIVES. We aimed to assess the performances of the combination of NSE dosage performed within the 48-72h and the Synek score to predict hard outcome defined by a CPC 3-5, in post anoxic comatose patients treated with induced hypothermia.

METHODS. We conducted a prospective monocentric study in our medical intensive care unit, between November 01, 2013 and November 01, 2017. All comatose patients having at least one early standard EEG and H48-72 NSE dosage available were included. Were excluded moribund patients, dead from post cardiac arrest shock, awoke within the first 48 hours of admission, neurological causes of CA, and patients with missing data. The primary outcome was the CPC score at 3 months or at death time.

RESULTS. Among 240 cardiac arrest survivors, 101 were analysed. All patients received sedation with midazolam and sufentanil and 33° mild therapeutic hypothermia for 24 h. Thirty-one patients had a good neurologic outcome (CPC 1-2) and 70 had a poor neurologic outcome (CPC ≥ 3). A NSE serum level > 46 μg/l was associated with a poor neurological outcome, with an AUC of 0.92 95%CI [0.85 to 0.97], a sensitivity of 77%, 95%CI [66 to 86] and a specificity of 97% 95%CI [83 to 100]. The Synek score ≥3 was also strongly associated with poor neurological outcome, with a sensitivity of 90%, 95%CI [81 to 96], a specificity of 87% 95%CI [70 to 96] and a AUC of 0.95 95%CI [0.89 to 0.98]. The multivariable log-binomial regression retained NSE (Odd ratio [OR], 2.10; 95% CI, 1.04 to 4.29; p=0.039) and the Synek grade (OR, 8.27; 95% CI, 2.63 to 25.96; p=0.0003) as independent predictors. The combination of these two parameters achieved an AUC of 0.96 95% CI [0.96 to 1.00] to predict a poor neurological outcome.

CONCLUSIONS. In the limit of this study, a NSE serum concentration > 46 μg/l at H48-72 and a Synek grade ≥3 one the early post sedation standard EEG are highly predictive of a poor neurological outcome, in post anoxic comatose patients treated with induced 33° C hypothermia. Their combination improved the discriminant capacity, independently to other prognostic factors. Nevertheless, these results should not exempt the clinician to apply a multimodal approach and need to be confirmed by a multicenter prospective study.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0091

INTRODUCTION. Bowel ischemia is a life-threatening emergency defined as an inadequate vascular perfusion leading to bowel inflammation resulting from impaired colonic/small bowel blood supply. Main issue for physicians regarding bowel ischemia diagnosis lies in the absence of informative and specific clinical or biological signs leading to delayed management, resulting in a poorer prognosis, especially after cardiac surgery.

OBJECTIVES. The aim of the present series was to propose a simple scoring system based on biological data for the diagnosis of bowel ischemia.

METHODS. In a retrospective monocentric study, patients admitted in cardiac ICU, after cardiovascular surgery, were screened for inclusion. According to a 1:2 ratio (case: control), matching between two groups was based on sex, type of cardiovascular surgery and the operative period (per month). Patients were divided into two groups: "ischemic group" corresponds to patients with confirmed bowel ischemia and "non-ischemic group" corresponds to patients without bowel ischemia. Primary objective was the conception of a scoring system for the diagnosis of bowel ischemia. Secondary objectives were to detail the post-operative morbidity and the diagnostic features for the distinction between acute mesenteric ischemia and ischemic colitis.

RESULTS. Forty-eight patients (1.3%) had confirmed bowel ischemia ("ischemic group"). According to the 2:1 matching, 96 patients were included in the "non-ischemic group". Aspartate aminotransferase >449 UI/L, lactate >4 mmol/L, procalcitonin >4.7 µg/L and myoglobin >1882 µg/L were found to be independently associated with bowel ischemia. Based on their respective odds ratios, points were assigned to each item ranging from 4 to 8. AUROCC [95% confidence interval] of the scoring system to diagnose bowel ischemia was 0.93 [0.91-0.95], p< 0.001. The optimal threshold after bootstrapping was ≥14 points; this yielded a sensitivity of 85.4%, a specificity of 94.8%, a positive likelihood ratio of 16.42, a negative likelihood ratio of 0.15, a Youden´s index of 0.802 and a diagnostic odds ratio of 106.62.

CONCLUSIONS. A biological scoring system based on PCT, ASAT, lactate and myoglobin measurement allows the diagnosis of bowel ischemia after cardiac surgery with high accuracy. This score could help clinician to propose an early diagnosis and an early treatment in this high mortality disease.

OBJECTIVES. To assess the epidemiology and clinical characteristics of acute heart failure (AHF) in the Spanish Intensive Care Units (ICU).

METHODS. Multicenter prospective observational study that analized patients older than 18 years admitted to the ICU for more than 24 hours between April and June 2017. Demographic, physiological and clinical variables, including complementary explorations of those who suffered AHF during ICU stay, were collected. Statistical analysis was made using ANOVA or chi-square test as appropriate. The multivariate study was performed by Cox regression for survival analysis and logistic regression. Values of p ≤ 0.05 were considered statistically significant.

RESULTS. During the study period 32 ICU treat a total of 4419 patients. Of these, 2971 patients met the inclusion criteria. Five hundred and eighty-seven (19.9%) patients suffered AHF, 318 (54.2%) as the main diagnosis at admission (Adm) (190 first AHF episode (AHFnew) and 128 chronic heart failure exacerbation (CHFex)) and 269(45.8%) as a complication (Com) during ICU stay for another reason (182 AHFnew and 87 CHFex). Patients with AHF were older (69 12.9 vs 60.6 16.5, P < 0.001) and presented higher severity-of- illness (SAPS III 58.6 16.4 vs 48.9 30, P < 0.001), higher BMI (29.19 vs 27.76.2, P < 0.001) and higher co-morbidity (Charlson Index 3.7 2.4 vs 2.3 2.3, P < 0.001) in terms of hypertension, diabetes, dyslipidemia, ischemic heart disease, peripheral arteriopathy, anemia and chronic renal failure. There were no significant differences in gender distribution. The Adm-ICAnew patients have shorter length of stay in hospital (18 days, 95% CI 15-21) than Com-ICAnew patients (25 days, 95% CI 21-30, P = 0.021).

The most frequent type of AHF at admission was pulmonary congestion (85.6%) followed by tissue hypoperfusion (45.7%). Ischemic heart disease (36.5%) was the main associated diagnosis, followed by atrial fibrillation (23.7%). In 47.7% of the cases, no precipitating factor was found, while in the 28% AHF was associated with infection and in the 21.1% to overhydration. ICU and hospital mortality were higher in patients with AHF (16.7% vs 9.4% and 20.6% vs 11.8%, p < 0.001), although in the multivariate study only the Com-CHFex group showed a higher mortality OR 2.99 (95% CI 1.48-6.07, p = 0.002).

CONCLUSIONS. AHF is frequent in critically ill patients, in terms of cause of admission and as a complication. The decompensation of a CHF during admission to the ICU is a factor independently related to mortality.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0093

INTRODUCTION. xtra-corporeal membrane oxygenation (ECMO) can maintain cardiopulmonary function in patient with heart failure waiting for recovery or heart transplant. A study shows that microcirculatory dysfunction is severer in the nonsurvivors than in the survivors with venoarterial ECMO (VA-ECMO) [1]. In our previous study, we found that hemodynamic parameters did not differ significantly between survivors and non-survivors, but lower perfused small vessel density (PSVD) within 12 hours after venoarterial ECMO (VA-ECMO) placement is associated with 28 days mortality.

OBJECTIVES. This study aims to investigate the effects of adjustment of VA-ECMO flow on microcirculation.

METHODS. Patients with VA-ECMO placement were enrolled in this study. Hemodynamic parameters and laboratory data were recorded. Sublingual microcirculation were obtained by using a third generation of video microscope (Cytocam) before and after the adjustment of VA-ECMO blood flow by the ECMO team within 24 hrs and 48 hrs after placement of VA-ECMO.

RESULTS. The difference of sublingual microcirculation after adjustment of VA ECMO blood flow did not correlate with any hemodynamic parameter within 24 hrs after VA-ECMO placement. At 48 hrs after VA-ECMO placement, both the differences of total small vessel density (TSVD) and PSVD after adjustment of VA-ECMO blood flow negatively correlated to systolic blood pressure (SBP) before adjustment of blood flow (TSVD-difference and SBP: Pearson correlation -0.760, P=0.018; PSVD-difference and SBP: Pearson correlation -0.678, P=0.045).
The difference of TSVD after adjustment of VA-ECMO blood flow negatively correlated to mean arterial pressure (MAP) before adjustment of VA-ECMO blood flow (TSVD-difference and MAP: Pearson correlation: -0.795, P=0.01). The difference of PSVD after adjustment of VA-ECMO blood flow had a trend to negatively correlate to MAP and pulse pressure (PP) before adjustment of VA-ECMO blood flow (PSVD-difference and MAP: Pearson correlation: -0.531, p=0.141; PSVD-difference and PP: Pearson correlation: -0.602, p=0.086).

CONCLUSIONS. At 48 hrs after V-A ECMO placement, the differences of sublingual microcirculatory parameters after adjustment of VA-ECMO blood flow have negative correlations with SBP before adjustment of VA-ECMO blood flow.

INTRODUCTION. The conditions to use adequately the pulse pressure variation (PPV) to predict fluid response are rarely all present in critically ill patients (1).
In a previous paper including elective neurosurgical patients, we demonstrated that the assessment of responder/non responder outcome of a fluid challenge (FC) could be dynamically evaluated, considering the adaptive responses of both cardiac efficiency and peripheral response to fluid administration (2).

OBJECTIVES. To investigate:

1. whether the changes in baseline PPV are associated with cardiac cycle efficiency (CCE), stroke volume index (SVI), arterial elastance (Ea) and systolic-dicrotic pressure (SYS-DIC) variations during FC infusion.
2. whether a combined model could predict the response at 10 and 30 minute to FC.

METHODS: Prospective multicentric study (Novara University Hospital; Padova University Hospital; Ankara University Hospital) enrolling hemodynamically unstable rhythmic critically ill patients. Hemodynamic measurements were performed by means of MOSTCARE^TM system (Vygon, Ecouen, Fr). FC challenge consisted in 500 ml infusion of crystalloids in 10 minutes. Responders were defined on a $\geq$ 10% increase in SVI. Variations in all hemodynamic variables were compared by analysis of variance (ANOVA). The multivariate analyses and the logistic regression were used to create a composite model to predict fluid responsiveness at 10 minutes. This was also used to compare the subgroup of responders at 10 and 30 minutes in parallel with the non-responders.

RESULTS. 87 patients having FC were analysed, with 2 excluded because of supraventricular arrhythmia during the study. The baseline classic PPV cut-off at 14% predicted fluid responsiveness with a sensitivity at 70.0% and specificity at 67.4%. The model with PPV, Ea and CCE correctly classified 90% of FC response after 5 min of infusion (7 patients misclassified). In a subgroup of 65 patients (30 responders at both 10 and 30 minutes and 35 non responders), increased CCE, SVI and SYS-DIC and reduced PPV and Ea at any measuring time as compared to the baseline in responders. In non-responders, none of these variables changed, except Ea that increased at 10 and 30 minutes (see Fig 1 and 2). The composite model included the variations of SYS-DIC, PPV and CCE at 5 minutes and Ea at 10 minutes correctly classified the changes in SVI at 30 minutes of the 93.8% of this subgroup (4 of 65 patients were misclassified, area under the curve: 0.94). Of note, Ea significantly increased at 5 10 and 30 minutes in non-responders and decreased in responders and, when evaluated at 10 minutes, this parameter alone was able to predict the 30-minute response with 80% of sensitivity and specificity.

CONCLUSIONS. The changes in PPV, Ea, CCE and SYS-DIC reliably predict the effect of FC on SVI in responders vs non-responders after 10 and 30 minutes.

INTRODUCTION. Fluid responsiveness is defined by a relative increase in cardiac output after fluid administration. The relation with microvascular perfusion has not been adequately studied.

OBJECTIVES. To assess the microvascular response to a fluid challenge (FC) in critically ill patients.

METHODS. We prospectively collected data in patients and requiring a FC between February and June 2016, whilst cardiac index (CI) was monitored. The sublingual microcirculation was assessed using the incident dark field (IDF) CytoCam device (Braedius Medical, Huizen, The Netherlands). The proportion of small perfused vessels (PSPV) was calculated using the De Backer score, according to standard formulas. Fluid responders were defined by at least 10% increase in CI during FC. Responders according to changes in microcirculation were defined by at least 10% increase in PSPV at the end of FC. Cohen´s kappa coefficient was measured to assess agreement to categorize patients as "responders" to FC according to CI and PSPV.

RESULTS. A total of 41 FC were performed in 38 patients, after a median time of 1 [0-1] days after ICU admission. Most of the fluid challenges (39/41, 95%) were performed using crystalloids and the median total amount of fluid was 500 [500-500] mL. The main raisons for fluid challenge were oliguria (n=22) and hypotension (n=10). After FC, CI significantly increased in 24 (58%) cases; a total of 19 (46%) FCs resulted in an increase in PSPV. Both CI and PPV increased in 13 responders and neither in 11; the coefficient of agreement was only 0.19. We found no correlation between absolute changes in CI and PPV after fluid challenge.

CONCLUSIONS. Microvascular response to FC cannot be predicted by changes in cardiac output.

INTRODUCTION. Extravascular Lung water (EVLW) has been identified as an independent mortality risk factor in several scenarios in critically ill patients.

OBJECTIVES. Describe the behaviour of extravascular lung water during the first 72 hours from admission in intensive care unit among survivors and not survivors critically ill patients.

METHODS. A descriptive retrospective case study was carried out. We analyzed the files of patients in wich continuous hemodynamic monitoring with the transpulmonary thermodilution technique (TPTD) was performed during january 2016 to March 2018. Extravascular Lung Water Index (EVLWi) and Pulmonary Vascular Permeability Index (PVPi) were analyzed at the beginning of the monitoring, 24 and 72 hours. The patients were classified according with otucome in survivors and not survivors; EVLWi and PVPi behaviour was described and analyzed in both groups.

RESULTS. 15 patients were included in the study, 7 females and 8 males, with an average age of 45 years, and 6.9 days average of mechanical ventilation. TPTD monitoring used for advanced monitoring in patientes with infectious diseases in more than 75% and only in one patient with severe acute pancreatitis. The global mortality rate during ICU stay was of 33%. The EVLWi average was of 11.1 ml/kg and PVPi of 2.4. In survivors EVLWi average was of 9.7 ml/kg and PVPi of 2.4 in contrast with non survivors were EVLWi average was 13.8 and PVPi average of 2.5. EVLWI´s behaviour during the 72 hours of the study was 4 ml/kg average higher among not survivors in comparation with survivors; meanwhile there was not significant difference regarding PVPi among both groups.

CONCLUSIONS. In our study, persistent values of EVLWi in critically ill patients above 13 ml/kg during the first 72 hours of ICU stay were associated with poor prognosis and mortality.

OBJECTIVES. To assess the treatment of acute heart failure (AHF) in spanish Intensive Care Units (ICU).

METHODS. Multicenter prospective observational study that included patients older than 18 years admitted to the ICU for more than 24 hours between April and June 2017. Demographic, physiological and clinical variables, including complementary explorations of those who suffered AHF during their ICU stay were collected. Comparisons were made among the different subgroups of patients according to the timing of AHF: AHF as main reason for admission vs. complication during ICU stay (Adm-AHF Vs Com-AHF) or first episode of AHF vs. exacerbation of chronic heart failure (AHFnew Vs CHFex). Statistical analysis was made using ANOVA or chi-square test as appropriate. The multivariate study was performed by Cox regression for survival analysis and logistic regression. Values of p ≤ 0.05 were considered statically significant.

RESULTS. We analyzed 587 patients with AHF admitted in 32 ICUs. The most used drugs during the first 24 hours after diagnosis were diuretics (83.1%), morphine (52.5%), noradrenaline (38%), intravenous nitrates (30.4%), amiodarone (23.5%), dobutamine (22.3%), beta-blockers (18.2%) and ACE inhibitors (9.8%). Early use of diuretics was lower in Adm-ICAnew patients (75% vs Com-ICAnew 88.5%, Adm-CHFex 85.2% and Com-CHFex 85.1%, P < 0.05). 93% of the patients required oxygen therapy, 13.3% CPAP, 28.4% non-invasive ventilation for an average of 2.55±3.37 days and 35.8% invasive mechanical ventilation (MV) for 10.2± 14.7 days, without significant differences between subgroups.

Coronary angiography was performed in 31.2% of the patients, requiring coronary revascularization in 18.7%, most frequently in first AHF episodes. Mechanical circulatory support was used in 3.1% of cases and extracorporeal renal replacement in 9.4%, without differences between subgroups. After adjusting for severity, age and confounding factors, MV was the only treatment independently associated with mortality (OR 8.29 CI 3.7-18.5, p < 0.001).

CONCLUSIONS. There are small differences between subgroups of AHF. Diuretics are the most commonly used drugs, except in patients with AHFnew, in which more coronariographies are performed. In our population, MV was independently associated with mortality.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0098

INTRODUCTION. Continuous reliable evaluating of left ventricular (LV) contractile function in patients with advanced heart failure requiring intensive care remains challenging. Recently, continual monitoring of dP/dt max from arterial line became available for hemodynamic monitoring. However, the relation between arterial dP/dt max and standard echocardiographic LV dP/dt measurement is not fully understood.

OBJECTIVES. The aim of our study was to determine the relation of arterial dP/dt max and LV dP/dt assessed by echocardiography in patients with advanced heart failure.

METHODS. Twenty patients with advanced heart failure requiring intensive care and hemodynamic monitoring were recruited into the study (mean age 63 years, 90% were males). Hemodynamic variables including dP/dt max were continually monitored using arterial line pressure waveform analysis. Left ventricular dP/dt was assessed using continuous-wave Doppler analysis of mitral regurgitation flow.

RESULTS. The values from continual arterial dP/dt max monitoring significantly correlated with the LV dP/dt max assessed by echocardiography (r=0.94, 95% confidence interval [CI] 0.82-0.98, P˂0.0001). Linear regression revealed that (LV dP/dt) = 1.073×(arterial dP/dt), P˂0.0001. Arterial dP/dt max significantly correlated also with the stroke volume (r=0.67, P˂0.0059), cardiac output (r=0.65, P˂0.0083), mean arterial blood pressure (r=0.60, P˂0.017) and systolic blood pressure (r=0.85, P˂0001). On the other hand arterial dP/dt did not correlate with the systemic vascular resistance, heart rate, dynamic arterial elastance, diastolic blood pressure or central venous pressure

CONCLUSIONS. Our results revealed that arterial dP/dt max values tightly and highly significantly correlate with LV dP/dt. Arterial dP/dt could be, therefore, used for continual monitoring of LV contractility.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0099

INTRODUCTION. Fluid responsiveness represents the ability of the cardiovascular system to increase cardiac output in response to fluid expansion (FE). Most studies have focused on the interaction between preload, cardiac output and blood pressure. Arterial load represents a force developed by the vascular system opposed to the ventricular ejection. Because arterial load depends on FE and norepinephrine (NE) use, it may have an effect on fluid responsiveness defined by an increase of stroke volume.

OBJECTIVES. To assess the impact of norepinephrine over the relationship between arterial load, FE and NE.

METHODS. We analysed the relation between arterial load, NE and SV changes following FE in 282 patients hospitalised in three ICU, monitored with a PICCO device, and for whom a 500 ml FE was performed. Arterial load was estimated by arterial elastance (E_A) : $E_A = 0.9 \times$ systolic arterial pressure (SAP) / stroke volume (SV). Arterial compliance (C_A) was calculated as pulse pressure / stroke volume (mmHg ml^{-1}), total vascular resistance (TVR) as mean arterial pressure - central venous pressure / cardiac output (mmHg ml^{-1}). Hemodynamic, arterial load and cardiac parameters were measured before and immediately after FE.

RESULTS. Among the patients, 61% were treated with NE, and 44% had sepsis. In the overall population, FE increased blood pressure, SV, cardiac output, and decreased TVR and E_A. At baseline blood pressure, SV, E_A, C_A did not differ between patients with NE and those without NE. SV and heart rate changes were similar in patients with and those without NE (-3 (-7 to 0) % vs -3 (-8 to 1) %, p=0.87, and 22 (13 to 37) % vs 20 (7 to 33) %, p=0.09. E_A changes with FE differed between patient with and those without NE (-4 (-12 to 6) % vs -10 (-18 to -1) %; p< 0.01). TVR changes differed between patient with and those without NE (-6 (-11 to 5) % vs -10 (-16 to -4) %, p < 0.01). C_A increased in patient without NE, and did not change in patient treated with NE (5 (-6 to 15) %, p< 0.01 vs -2 (-13 to 9) %, p=0.15) (Figure1). Baseline E_A was correlated with SV changes only in the absence of NE infusion (r = 0.32, p < 0.01 vs r = 0.12; p = 0.12). By using a multivariate analysis adjusted to the presence of sepsis, SV changes with FE were associated to only baseline E_A (β = 10.9 [5.2; 16.7]), NE infusion, and interaction between E_A and NE (β = -9.1 [-15.8; -2.5]). The model confirmed an effect of NE on the association between arterial load and SV changes induced by FE.

CONCLUSIONS. Those results suggest that arterial load, NE and their interactions exert an effect on fluid responsiveness. Under NE infusion, changes of arterial load with FE are mainly driven by resistive component (i.e TVR). NE fixed the pulsatile component (C_A) of arterial load. These changes were independent of sepsis.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0100

INTRODUCTION. Bedside alerts are issued whenever patient vital signs (VS) exceed a threshold but do not indicate potential severity of the emerging instability. This limits their clinical utility.

OBJECTIVES. We propose a model-based approach to differentiate cardiorespiratory instability (CRI) manifested by VS derangement that is mild and in need solely of nurse awareness or intervention (Min-CRI), versus more severe cases that require escalation of care (SevCRI).

METHODS. We collected continuous noninvasive VS monitoring data (heart rate, respiratory rate, blood pressure, SpO$_2$) from 326 step-down unit (SDU) patients and reviewed data time-plots for 1087 real alerts across normal VS thresholds defining CRI. Two clinical experts (RN and MD) independently labeled those CRI events with increasing severity (level 1: mild, nurse needs to be aware; level 2: in need of nurse encounter and intervention; level 3: in need of routine care escalation to an MD; level 4: in need of immediate care escalation to a Medical Emergency Team). We fit a multi-class random forest model to the data using statistical features extracted during the alert periods and evaluated it via cross-validation. We also tested the model on a separate sample of 85 alerts from a different patient cohort. We compared the estimated CRI severity levels with those independently provided by the experts.

RESULTS. The overall accuracy of predicting CRI severity level is 72.8% as measured with leave-one-patient-out cross validation (Figure 1). The vast majority (89.9%) of classification errors are made with respect to neighboring severity levels. By grouping levels 1 with 2 (to

form MinCRI, requiring nurse awareness/intervention) and 3 with 4 (SevCRI requiring escalation of care; the positive class), the accuracy of the resulting binarized prediction model increases to 91.6% with a true positive rate of 77.9% and false positive rate of 2.3%. If, however, we increase the tolerance level of the false positive rate to 10%, the true positive rate is 86.0%. When testing the model on the external validation set, among the 53 MinCRI identified by the model, 90.6% were correctly classified, as well as 80.3% of the 32 model-identified SevCRI cases. The overall inter-rater agreement between two experts for the severity labels is 0.83 (Weighted Cohen's kappa).

CONCLUSIONS. A model trained from annotated historical VS data can discern between instability severity patterns in need of nurse attention versus those requiring care escalation. Such models, if embedded in real-time monitoring systems, could assist bedside clinical decision making regarding care escalation and resource allocation.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0101

INTRODUCTION. Malnourished critically ill patients may derive more benefit from nutritional support. Optimizing nutrition support can improve their outcomes but this is frequently associated with hyperglycemia, a condition linked to an increased morbi-mortality. They also have altered glucose homeostasis characterized by decreased fasting blood glucose levels despite below-normal insulin levels[1]. The aim of this study was to evaluate the relationship of glycemic control with nutritional support and mortality in malnourished critical ill patients.

METHODS. In this two-center prospective cohort, malnourished critically ill patients (BMI < 20kg/m^2) had their caloric and protein intakes and their glycemic status estimated by capillary glucose (CG) evaluated in two occasions: between day 2-3 and between day 5-7 of ICU admission. CG was performed as prescribed by the assistant physician, at minimum every 6 hours. Maximum and minimum registered CG values were used to classify hyperglycemic (CG>180 mg/dl), hypoglycemic (CG< 54 mg/dl) events. The cohort was followed until death or hospital discharge.

RESULTS. Prevalence of low BMI in 4236 screened patients was 16%. Therefore, 342 patients were included (age 54.0±17.3 years, 59.9% males, BMI 17.5±2.1 kg/m^2, mortality 58.5%) and followed during 21

[11-38.3] days. In the first evaluation, median caloric/protein intakes were 864.0 [447-1223] kcal/day and 41.8 [14.0-65.0] g/day and their maximum and minimum CG (mean) were 164.2±55.9 mg/dl and 108.4±33.3 mg/dl, respectively. In the second evaluation, median caloric/protein intakes were 1197.0 [911-1500] kcal/day and 65 [45.0-80.0] g/day and their maximum and minimum CG (mean) were 160.0±57.1 mg/dl and 107.8±32.4 mg/dl, respectively. Hyperglycemia occurred in 36.3% and hypoglycemia in 3.8% of patients. Neither in the first nor in the second evaluation caloric intake correlated with hyperglycemia. In multivariate analyses, hyperglycemia event was associated with age (RR 1.02, 95%CI 1.01-1.04), previous diabetes (RR 3.70 95% CI 1.80 - 7.64) but not with severity of illness (SAPS3) nor BMI. Mortality was not associated with hyperglycemia or hypoglycemia.

CONCLUSION. In critically ill malnourished patients, different from eutrophic or overweight patients, hyperglycemia or hypoglycemia were not associated with caloric intake nor mortality.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0102

INTRODUCTION. Insulin resistance (IR) in patients without diabetes increases with age.[1] In the Intensive Care Unit (ICU), adaptive glucose-control systems target equal glucose levels irrespective of age. Whether the association of steroid use on IR varies with age in patients at the ICU is unknown.

OBJECTIVES. Determine the association of IR - as derived from glucose control data - with age in ICU patients and examine the role of disease severity, body mass index (BMI) and steroid use.

METHODS. All adult patients admitted for >12h to the ICU over a 4 year period were examined. Age (< 45,46-55,56-65,66-75,>75), sex, diabetes status (type I or II), APACHE-IV and steroid use within 18h of ICU admission were recorded. Steroid doses were typically not weight or age adjusted. During the first 24h the ICU mean glucose (G_{mean}) in mmol/L and mean insulin administration (I_{mean})rate in U/h were determined. IR was estimated as $G_{mean} \cdot (I_{mean}+1)$, where the term 1 was introduced as an estimate of endogenous insulin production as well as to avoid zero values.

RESULTS. In 9074 patients had a mean±SD age of 61±15 year and an APACHE-IV score of 53±27. Diabetes prevalence was 17% and 13% received steroids. The hospital mortality was 12%. IR was 15.0 in non-diabetics and 29.4 mmol·U·L^{-1}·h in diabetics. IR steadily increased in non-diabetics from 12.3 in patients < 45 year to 15.6 mmol·U·L^{-1}·h in patients of 66-75 year (P< 0.001). In diabetics who received steroids IR was 19.5±13.9 compared to 14. ±11.7 mmol·U·L^{-1}·h in non-diabetics who received steroids (P< 0.001). Also within this latter group an age-related increase of IR from the ≤45year group to the 66-75year group was observed (P< 0.001). In non-diabetics multivariable linear regression analysis with IR as dependent variable, age group, sex, BMI, APACHE-IV and steroid use were all independently related with IR (all P≤0.001).

CONCLUSIONS. In ICU patients, insulin resistance as estimated from computerized glucose control was independently associated with disease severity, steroid use and age. Since the combination of higher age and steroid use is associated with an increased IR, adjusted steroid doses could be considered in older patients.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0103

OBJECTIVES. Describing the main features of the liver transplant in Controlled Donation after Cardiac Death (CDCD), in which Super Rapid Extraction (SRE) and Normothermic Regional Perfusion (NRP) with premortem cannulation techniques were used, with the postoperative receptor course.
METHODS. An observational, retrospective and descriptive in patients ho received a liver transplant from CDCD were performed in our hospital from January 2014 to January 2017. Dates about surgical intervention, basal characteristics of the recipients and donors, and the recipients evolution until the end of the data collect were analyzed. Recipients had been followed-up for 1 year.
RESULTS. Twenty-nine transplants were performed in this time. Donors were mostly males (68%). Average age was 52 years. The causes wich motivate the withdrawal of the life-sustaining medical support were 14 cerebrovascular accident, 11 anoxic encephalopathy, 3 traumatic brain injury and one chronic respiratory disease. Donoros average ICU stay was 7.5 days. Average surgery duration were 40.1 min of functional warm ischemia, 46.2 min of total warm ischemia and 323.9 min of cold ischemia. In 22 cases SRE was used and in the other 7 NRP was the chosen technique.
Recipients were mostly males too, (79%), and average age was 57.9 years. The enzymatic peak of aspartate aminotransferase (AST) was 4373.47U/L and the alanine aminotransferase (ALT) one 947.03U/L. Average factor V on the first day after transplantation was 33.8% and reached 97% on the third day. Average ICU stay was 3.8 days and hospitalization stay was 11.5 days.
Regarding evolution of this recipients, there were 3 deaths (10.3%): One on the day +80, another on the day +5, both because of liver failure and acute respiratory distress syndrome, and the last one on the first day after the surgery due to humoral rejection. Regarding complications, two patients were affected by an stenosis of the bile duct, one of them was retransplanted, and the other one had to be operated with a Roux-en-Y Hepaticojejunostomy. Finally, the other 24 patients have an adequate follow-up in liver specialist consultation.
CONCLUSIONS. Our experience with liver transplantation from CDCD is positive. The most frequent complication described on de literature (bile duct stenosis) has been presented in two patients in our series. The majority of transplant were performed with Super Rapid Extraction (SRE) technique so we consider that this technique should not be reject at all until more data its available.

Prediction of outcome in severe acute pancreatitis: a prospective comparison of the BISAP-, APACHE-II- and Ranson-Score with the "quick-BISAP-score"

S. Hage, J. Höllthaler, S. Mair, V. Phillip, A. Beitz, T. Lahmer, R. Schmid, W. Huber
Klinikum rechts der Isar; Technical University of Munich, Medizinische Klinik und Poliklinik II, Munich, Germany
Correspondence: W. Huber
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0104

INTRODUCTION. Up to 15% of the patients with acute pancreatitis (AP) develop severe AP (SAP) which results in organ-failure and a mortality of up to 42%. Early identification of patients with SAP is crucial to otimize therapy. The lack of a single parameter with outstanding sensitivity and specificity resulted in a number of prognostic scores including the Ranson- and APACHE-II-score. These scores are well validated, but their calculation is cumbersome and requires data of the first 24-48h. The acronymic BISAP-score includes blood urea nitrogen (BUN), impaired mental state, SIRS, age and pleural effusion.
OBJECTIVES. Considering that SIRS is composed of 4 components, the BISAP-score includes a total of 8 parameters. Therefore, also the BISAP-score is cumbersome. Despite several studies validating the complete BISAP-score with given cut-offs, these thresholds are poorly validated and might be improved. Our study aimed to evaluate single components of the BISAP and to establish a simplified "quick-BISAP"-score.
METHODS. Analysis of a prospectively maintained database including 442 patients with AP screened for the EAGLE-study (NCT00894907). Statistics: ROC-analysis; binary regression analysis. Youden-index. IBM SPSS 24.
RESULTS. n=442 (175 f, 267 m); age 54±18 years; aetiology: 32% biliary, 27% alcoholic, 15% idiopathic, 10% post-ERCP, 3% drug-related, 13 % various. In-hospital-mortality was 13/442 (2.9%).ICU-transfer was required in 71/442 (16.1%) patients.
All five BISAP criteria BUN (AUC=0.844; p< 0.001; best cut-off 25.5mg/dl), impaired mental status (AUC=0.604; p=0.005), SIRS (AUC=0.869; p< 0.001; cut-off 2 of 4 criteria), age (AUC=0.661; p=0.047; best cut-off 63.4 years) and pleural effusion (AUC=0.663; p< 0.001) significantly predicted in-hospital mortality. Among the four SIRS criteria, heart rate >90/min had the highest sensitivity (0.846) and second highest specificity (0.834) regarding mortality. This was confirmed in binary regression analysis which demonstrated that "heart rate >90/min" was the only SIRS criterion which was independently associated with mortality. Combined binary regression analysis demonstrated an independent association of BUN>25mg/dl, pleural effusion and heart rate >90/min with mortality. A simplified model giving one point each for these criteria was termed "quick-BISAP" which provided an excellent prediction (AUC 0.946, p< 0.001) of in-hospital mortality as did APACHE-II (0.928, p< 0.001), BISAP (0.924, p< 0.001) and SIRS (0.869, p< 0.001).

CONCLUSIONS. BISAP, APACHE-II and SIRS predict mortality in SAP. Among the BISAP criteria BUN>25mg/dl, pleural effusion and heart rate>90beats/min were the best predictors of in-hospital mortality. A simplified model consisting of these 3 parameters ("quick BISAP") was a strong predictor of in-hospital mortality. Finally our data confirm the cut-offs for age and BUN of the original BISAP-score.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0105

INTRODUCTION. It has been demonstrated that high Glycemic Variability(GV) is associated with increased mortality among critically ill patients and it is not yet determined its relationship with other factors such as nosocomial infections.

OBJECTIVES. The aim of the study is to investigate high GV as a predisposing factor to present nosocomial infections in critically ill patients.

METHODS. The observational prospective study is based on a sample of critically ill patients receiving artificial nutrition(first 48h). Our exclusive criteria were patients presenting diabetic ketoacidosis or are not receiving artificial nutrition during the first 48 hours. The study was carried out at a Medical ICU, from Nov'15-Dec'18.

Data on admission: demographic, clinical characteristics, APACHEII, SOFA. Nutritional parameters during the first and seventh day. GV during the first 7 days. Infectious complications, days of mechanical ventilation(MV), ICU length of stay(LOS) and mortality.

We calculated GV as VC=SD/Mx100. We performed a univariate statistical analysis considering the significance $p < 0.05$. T-student for quantitative independent group variables and $\chi 2$ for qualitative variables. We also employed linear regression for continuous variables and binary logistic for dichotomous variables.

RESULTS. The sample consists of 77 patients, 63.6% men with a mean age of 61±12.9 years, BMI: 29.5±19.6, mean of ICU LOS 16.1±14.2 and days of MV 12.48±13.43.

On admission: APACHEII 20±7.8 and SOFA 8.25±3.7.

19.5% of the patients were diabetics, 74.7% requiring Noradrenaline,90% presented stress hyperglycemia(SHG),92% received enteral nutrition(EN) and 8% parenteral nutrition(PN).

38.5% of patients had infectious complications: Ventilated-associated pneumonia(VAP) 16.3%, tracheobronchitis 35%, bacteremia 4.7%, catheter related bacteremia 2.3% and urinary tract infection(UTI) 4.7%.

We divided our sample into quartiles depending on theGV: (1)11-16.61;(2)16.62-21.41; (3)21.42-27.41; (4)27.42-43.6. GV mean22.67±7.9. The results are presented in Table 1.

CONCLUSIONS.

- It is observed that patients with increasing GV have increasing requirements of noradrenaline
- We observe higher GV among patients receiving PN.
- Patients with higher illness severity scores (APACHEII on admission and SOFA 7th day) shows higher GV.

INTRODUCTION. Chloride abnormalities in the intensive care unit (ICU) have received considerable attention, especially hyperchloremia as a cause of metabolic acidosis and hypochloremia as a cause of metabolic alkalosis However; Cl abnormalities themselves have not been studied sufficiently.

OBJECTIVES. The aim of this study was to understand the nature of Cl abnormalities in critically ill patients.

METHODS. Retrospective study was conducted on 375 critically ill adult patients admitted to Alexandria University hospitals. The following data was collected from the patient's files. Demographics, diagnosis and cause of admission, relevant medical history, calculated APACHE-II score and laboratory data (1st 4 days after admission) including serum electrolyte level, ABG analysis (anion gap - gap/gap ratio - corrected anion gap) and serum albumin level.

According to the recorded Cl levels at days 1 and 3 from ICU admission, patients were defined as normo (99-110 mEq/L), hypo (< 99) or hyperchloremic (>110) patients. Outcome measures were all-cause mortality and length of stay (LOS) in ICU.

RESULTS. On admission 55 (14.6%) patients were hyperchloremic, 259 (69%) patients were normochloremic and 61 (16.2%) patients were hypochloremic.

There were no any statistically significant differences between the 3 groups regarding demographic data, sodium and potassium level or diagnosis.

The mean of the measured PH values was significantly higher in Hypo (7.46) than in Normo (7.41) and Hyperchloremic group (7.36) (p< 0.001).

Cl abnormalities at day 1 were associated with increased mortality. The mortality rate was significantly higher in hyperchloremic (67.3%) and hypochloremic (72.1%) than normochloremic patients (36.3%) (p< 0.001). Cl abnormalities (at days 1 and 3) were associated with increased ICU length of stay. the mean of ICU length of stay in days was significantly higher in hyperchloremic (21.29) and hypochloremic (16.38) than normochloremic patients (13.81) (p< 0.001)

CONCLUSIONS. In a mixed general intensive care population, after careful controlling for confounders, Cl abnormalities (outside 99-110 mEq/L) were independent predictors for poorer outcomes as ICU mortality and length of stay.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0107

INTRODUCTION. There is enough evidence that hyperglycemia and hypoglycemia increase morbidity and mortality in critically ill patients.[1] Recently, glycemic variability and time in target blood glucose (BG) range(TIR) have also been recognized as important domains of glycemic control in the critically ill.[2]

OBJECTIVES. In critically ill patients requiring insulin infusion to maintain blood glucose control a) Evaluation of hypoglycemic and hyperglycemic episodes b) Evaluation of glycemic lability index (GLI) c) Evaluation of TIR; i.e. between 100-180 mg/day.

METHODS. The study was approved by the Institute Ethics committee. Setting: Mixed ICU of a teaching Institute in North India. Consecutive patients > 18 years requiring insulin infusion for glycemic control included. Hyperglycemia was defined as blood glucose(BG) ≥180mg/dl and hypoglycemia as BG< 70 mg/dl.

Insulin infusion initiated when 2 consecutive BG levels ≥ 180 mg/dl and titrated according to the modified Yale insulin infusion protocol. BG measurements were done using a standard hospital glucometer (Freestyle Optium H, Abbott Ltd).

The first 7 days' glucose values were noted and the following were calculated: Median BG, mean BG, standard deviation of BG (SD), episodes of hypoglycemia and hyperglycemia, GLI and TIR. These were correlated with secondary outcomes, i.e., mortality, length of ICU stay, ventilator days, vasopressor days. All values are expressed in median (interquartile range, IQR).

RESULTS. 60 patients included between May 2017 to March 2018. 27 were female. Median age was 56 years (45-67). Median APACHE II was 18 (15.5-23.5) and SOFA score 9 (6-11). Episodes of hypoglycemia was 0.04% (15/3439) and hyperglycemia 42% (1463/3439). 28-day mortality was 25% (15/60). Median length of ICU stay was 22.5 days (13.5-36.5). Median duration of ventilation was 13 days (7-22). Median duration of vasopressor support 7.5 days (4-14)

Patients were divided into two groups based on median TIR and quartiles based on GLI. No statistical difference in any of the secondary outcomes seen in these groups but a trend was observed of better outcomes in patients with the least glycemic variability. 31 were diabetic; diabetics had worse glycemic metrics when compared to non-diabetics (SD:42 vs 37 mg/dL, p = 0.004 and TIR of 46 vs 60%, p =0.032)

CONCLUSIONS. The use of Yale insulin infusion in a set of critically ill Indian patients is feasible, safe and effective and certain modifications are suggested for the Indian setup. Patients with the least glycemic variability showed a trend of better outcomes and diabetics showed worse glucose metrics.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0109

INTRODUCTION. Acute pancreatitis (AP) is a common acute condition associated with high morbidity and mortality in severe cases

OBJECTIVES. The aim of this study is to describe the demographics and outcomes of these patients managed in critical care area (CCA) at the Complexo Hospitalario Universitario de A Coruña.

METHODS. A descriptive, retrospective and single-center observational study of 127 patients. Period study: January 1st, 2010 to December 31st, 2017. Inclusion criteria: diagnosis of AP and admission in CCA. Variables: age, gender, severity scores in the first 24 hours, need for percutaneous drainage or surgery, CCA length of stay (LOS), hospital LOS and hospital mortality. A p-value of 0.05 was considered statistically significant

RESULTS. 127 patients. 67,7% were male. The mean age of 59,9±15,6 years. 26,6±3,7 was the mean body mass index (BMI). Most frecuent comorbidities were alcohol abuse (27%), tobacco abuse (26,8%) and diabetes (16,7%). Most common etiologies included biliary (48%) and alcoholic (12,6%). According to the revised Atlanta classification of acute pancreatitis, severe pancreatitis was presented in 57,1% of cases, while moderate and mild pancreatitis were presented in 22,2% and 20,6% respectively. We collected data from organ failure (haemodynamic, kidney and respiratory) and the most common disfunction was transitory. Median Charlson Comorbidity Index was 3 (2,99 ± 2,2). Severity scores were: APACHE II score 13,8±6,6 and SOFA at the day of admission8,7±4,2. 44,8% of the patients presented necrosis collections and 46,2% of them were infected. 50% of the overall developed sepsis and the most common microorganism isolated was *E. coli* (27,8%) while 28,4% was polymicrobial. Previous antibiotherapy was used in 43,7%, antibiotic was appropriate in 94% of cases. 31 patients (24,6%) presented complications and the most prevalent included haemorrhage (51,6%), fistula (25,8%) and perforation (19,3%). 21,1% of the patients developed abdominal compartment syndrome. Different treatments were performed: ERCP-cholecystostomy (13,7%), percutaneous radiologic drainage (18,7%) and surgery (56,3%). In those who underwent surgery procedure, necrosectomy was performed in 37,9%, cholecystectomy in 57,6%, abdominal cavity cleaning in 62,3% and vacuum-assisted closure (VAC) therapy in 33,3%. Mortality rate was 34,9% and the main cause was initial SIRS (30,2%). Median CCA stay was 5 days (15,77 ± 24,64) and overall hospital stay was 27,5 days (42,79 ± 48,4).

CONCLUSIONS. Severe acute pancreatitis represents 57,1% of CCA acute pancreatitis admissions. Its clinical course is frequently complicated by infections or haemorrhage and it is associated with a high mortality rate. This epidemiological observational study may be used for calculating sample size for future multi-center interventional therapeutic studies.

Fucoidan, a natural sulfated polysaccharide, attenuates uptake of advanced glycation end-products by macrophages

S. Hamasaki[1], A. Kitaura[1], T. Kobori[2], Y. Yamazaki[2], T. Nishinaka[2], A. Niwa[2], H. Takahashi[2], S. Nakao[1]
[1]Kindai University, Anesthesiology, Osakasayama, Japan; [2]Kindai University, Pharmacology, Osakasayama, Japan

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0110

INTRODUCTION. Advanced glycation end-products (AGEs), which are formed by nonenzymatic glycation reaction of reducing sugar and proteins, accumulate in the body due to the persistence of hyperglycemia and produce reactive oxygen species and inflammatory cytokines when they bind to their receptor, RAGE (receptor for AGEs)[1]. Thus, AGEs reduction is considered to be an important treatment for hyperglycemia-induced cytotoxicity. On the other hand, macrophage is capable of eliminating AGEs possibly via its phagocytic activity, and an accumulation of AGEs-containing macrophages on the surface of blood vessels is involved in the progression of arteriosclerosis and inflammation, resulting in ischemic coronary diseases or a stroke

[2]. Fucoidan are a type of highly sulfated polysaccharides found mainly in the extracellular matrix of brown seaweeds and significantly attenuates atherosclerotic plaque formation and enhances plaque stability by decreasing serum lipids and inhibiting macrophage infiltration[3]. It remains unclear, however, whether fucoidan affects uptake of AGEs by macrophages.

OBJECTIVES. We investigated whether fucoidan influences macrophage phagocytosis of AGEs.

METHODS. RAW264.7 cells, the mouse macrophage-like cell line, were incubated with AGE-modified bovine serum albumin (BSA), glyceraldehyde-derived AGE and glycolaldehyde-derived AGE at different concentrations ranging at 200 µg/ml and fucoidan at concentrations ranging from 1-1,000 µg/ml for 1 h. The uptake level of AGEs and the expression levels of surface scavenger receptors in RAW264.7 cells were analyzed by flow cytometry. The intracellular localization of AGEs phagocytosed by RAW264.7 cell were visualized by immunofluorescence microscopy.

RESULTS. Fucoidan, at 100-1000 µg/ml, markedly inhibited AGEs uptake into RAW264.7 cells. AGEs significantly enhanced the surface expression levels of CD204, macrophage scavenger receptor type I, in RAW 264.7 cells, but the expression was markedly inhibited by fucoidan.

CONCLUSIONS. Fucoidan inhibited the facilitation of AGEs uptake into macrophages possibly by inhibiting AGEs-induced CD204 expression on their surface. The results suggest a vasculoprotective potential of fucoidan for the clinical treatment of atherosclerosis.

Sodium input in intensive care

N. Samal[1], E. O'Neill[2], M. Carpenter[2]
[1]Newcastle University, Newcastle upon Tyne, United Kingdom; [2]City Hospitals Sunderland NHS Foundation Trust, Integrated Critical Care Unit, Sunderland, United Kingdom
Correspondence: N. Samal
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0111

INTRODUCTION. Sodium is a key electrolyte that is crucial in maintaining homeostasis through the regulation of blood pressure, blood volume, and pH levels.

Administration of fluids containing sodium is an essential part of resuscitation and ongoing care. However, sodium overload is thought to be common in intensive care patients with hypernatraemia occurring in up to 25% of patients during their stay [1], potentially adding further complications to care.

OBJECTIVES. To collect the individual daily sodium intake data of all patients on a general UK ICU over a 14-day period. The sodium contents of all fluids, drugs, and nutritional sources was calculated and divided into source categories. Daily weights were recorded to calculate the recommended sodium intake for each patient according to current National Institute for Health and Care Excellence (NICE) guidelines [2]. Serum sodium results, and fluid balance data were also collected.

METHODS. Prospective audit of all patients admitted to the ICU, during a 14-day period in January 2018. Data was collected from daily charts, and e-records at the end of a 24-hour period. Sodium content

of all fluids, drugs, and nutrition was calculated using electronic Medicines Compendium, Institute of Food Research/Public Health England, and British Dietetic Association resources.

Patient days were divided into 2 phases; resuscitation and maintenance. Resuscitation was defined as administration of vasoactive therapy at any stage during the 24-hour period. All individual fluid, drug, or nutritional sources totalling less than 1mmol of sodium were excluded. Daily weights were monitored using bed scale readings.

RESULTS. 28 patients were reviewed, totalling 158 bed days. Maintenance days: n=116, resuscitation days: n=42.

2/3 of all patients were over the NICE recommended guidelines for sodium intake.

The mean sodium intake for the maintenance phase was x1.4 NICE recommendations, with a median of 1.1 (IQR 0.8-1.7). In the resuscitation phase mean average was x2.1, with a median of 1.7 (IQR 1.1-2.3).

18% of all patients were hypernatraemic (≥146 mmol: n=29, ≥155 mmol: n=11), and 4/5 of these patients had received more than their recommended daily sodium intake.

In the maintenance group 24% of sodium came from fluids, whilst 64% was from nutrition. In comparison, 41% of the sodium in the resuscitation group was from fluid, and 38% from nutrition. In both groups nearly 20% came from other sources with the potential to reduce input.

CONCLUSIONS. The majority of intensive care patients receive more than their recommended sodium intake. It may be possible to reduce sodium input from background fluids and nutrition whilst maintaining fluid homeostasis, and protein calorie intake.

Influence of complications of diabetic ketoacidosis treatment on length of stay in intensive care unit

D. Adukauskienė, L. Jazokaitė
Hospital Kaunas Clinics of Lithuanian University of Health Sciences, Intensive Care Unit, Kaunas, Lithuania
Correspondence: L. Jazokaitė
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0112

INTRODUCTION. Diabetic ketoacidosis (DKA) is an acute metabolic complication of diabetes. Hyperglycaemia and ketoacidosis is controlled by insulin, so use of sodium bicarbonate for treatment of metabolic acidosis is not suppose to be indicated, especially if hemodynamic is stable. Permanent monitoring of level of serum glucose and potassium also pH as an adequate treatment may prevent life-threatening complications of treatment of DKA.

OBJECTIVES. To estimated rate of hypokalemia, hypoglycaemia and relate these DKA treatment complications due to use of insulin also sodium bicarbonate use with length of stay in Intensive Care Unit (ICU).

METHODS. This is a single-centre at the largest Lithuanian University hospital Kaunas Clinics pilot retrospective study carried out during 2012 - 2018. Inclusion criteria: 1. patients (pt) with DKA; 2. age ≥ 18; 3. stay at ICU. Serum kalemia, glycaemia; hypokalemia, hypoglycaemia episodes; rate of insulin interruption; use of sodium bicarbonate, and

length of stay (LOS) in ICU were analysed. SPSS 25.0 was used for statistic calculations. Traits evaluated as significant as $p < 0.05$.

RESULTS. During the treatment of DKA obvious hypokalemia (2.1 - 3.4 (3.1 ± 0.3 mmol/l)) was recorded in 48/91 (52.7 %) pt, LOS in ICU was 51.9 ± 32.2 vs 32.8 ± 18.7 hr, $p < 0.05$. Also due to disregarding of blood pH (6.8 - 7.3 (7.1 ± 0.1)) it was misinterpreted as "normokalemia" or "hyperkalemia" (3.5 - 6.1 (2.5 ± 0.7 mmol/)) in 49/91(53.8 %) pt, and obvious hypokalemia occured in 20/49 (40.8 %) pt. Insulin use has caused hypoglycaemia (1.2 - 3.3 (2.5 ± 0.7 mmol/l)) in 18/91 (19.8 %) pt, LOS in ICU 63.1 ± 41.3 vs 37.9 ± 21.5 hr, $p < 0.05$. Insulin use was interrupted in case of normo - and hypoglycaemia still with persisting ketoacidosis in 31/91 (34.1 %) pt, LOS in ICU was found to be 56.6 ± 32.9 vs 35.8 ± 22.7 hr, $p < 0.05$. Sodium bicarbonate was given for symptomatic treatment of acidosis during first 10 hrs of DKA in 19/91 (20.9 %) pt with stable hemodynamic: HCO^-_3 buffer has increased (4.2 ± 3.3 - 7.4 ± 3.2 mmol/l), $p < 0.05$, but ketoacidosis has still persisted, LOS in ICU was 54.6 ± 30.4 vs 39.7 ± 26.9 hr, $p < 0.05$.

CONCLUSIONS. Obvious hypokalemia occured in half of all pt, also due to disregarding of blood pH value in half of pt hypokalemia has been interpreted as normo- or hyperkalemia. Due to insuline use hypoglycaemia was recorded in 1/5 pt. Insulin use was interrupted in case of hypo- and normoglycaemia despite of ketoacidosis almost in 1/3 pt, it's prolonged length of stay in ICU. In case of hypokalemia or hypoglycaemia length of stay in ICU for DKA treatment has increased. Sodium bicarbonate was used in 1/4 of pt and it did not control ketoacidosis, length of stay in ICU has been prolonged.

Nutrition in pancreatitis: a tertiary centre experience
S. Milton-White[1], R. Mullhi[2]
[1]Sandwell and West Birmingham Hospitals NHS Trust, Birmingham, United Kingdom; [2]University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom
Correspondence: S. Milton-White
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0113

INTRODUCTION. Patients with acute pancreatitis (AP) are at high risk of malnutrition. Current evidence supports early enteral nutrition[1] which maintains gastrointestinal mucosa integrity and is associated with reductions in mortality, organ failure, sepsis and surgical intervention[2]. NCEPOD (National Confidential Enquiry into Patient outcome and Death) found 67% of patients admitted with AP were screened for malnutrition with adequate management in 85%[3]. This recommends all patients should be assessed for risk of malnutrition using Malnutrition Universal Screening Tool (MUST) on admission. International Association of Pancreatology (IAP) and American Pancreatic Association (APA) guidelines in 2013 recommend enteral feeding with TPN reserved for failure of post-pyloric feeding[4].

OBJECTIVES. To assess compliance with NCEPOD and IPA/APA recommendations in a tertiary centre and identify reasons for delayed enteral nutrition.

METHODS. This is a retrospective audit of patients admitted to Intensive Care (ICU) between January 2015 and December 2017 with AP. Patients were identified by Intensive Care National Audit and Research Centre (ICNARC) coding and electronic patient records were used to collect data.

RESULTS. 43 patients were admitted with AP accounting for 50 admission episodes: 11 were inter-hospital transfers. ICU mortality was 11.8% with median organ support required of 2.

MUST scoring occurred during 46 (92%) admissions with 21 (42%) at ICU admission. Median MUST score was 1 and 50% were referred to dieticians. Initial nutrition on ITU was enteral for 34 (68%), nasojejunal

(NJ) for 8 patients and TPN for 3 patients. Nutrition was commenced in 70% of patients within 24 hours of admission. Reasons cited for delay included pending surgical review and patient instability. 9 patients (19%) were commenced on TPN after failure of enteral feeding.

CONCLUSIONS. Enteral nutrition was the most common form of nutrition in ITU and was commenced within 24 hours in 70%. Less than 50% of patients were screened for malnutrition on ICU admission.

In this setting, NCEPOD and IAP/APA standards are not being achieved. This is in part due to concerns regarding commencing nutrition prior to surgical review. The low conversion rate to TPN provides good evidence to support enteral nutrition. We are developing a departmental guideline on nutrition in AP to guide nutritional assessment and reinforce the role of early nutrition.

Risk factors for raised glycosylated hemoglobin at ICU admission
D. Prevedello, A. Khaldi, J.-C. Preiser
Erasme Hospital,Université Libre de Bruxelles, Intensive Care, Brussels, Belgium
Correspondence: D. Prevedello
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0114

INTRODUCTION. Individualizing the glycemic target requires the knowledge of the level of glycosylated hemoglobin HbA1c at the time of ICU admission (1,2). In the critically ill, risk factors for raised HbA1c, regardless of the preexistence of diabetes mellitus (DM), are currently not well characterized.

OBJECTIVES. The aim of this study was to assess whether the prevalence of HbA1c > 6.5% was influenced by demographic variables, type of admission, preexisting co-morbidities including DM, severity of disease, and outcome variables.

METHODS. Consecutive patients admitted over a 4- month period in a medical/surgical 32-bed ICU were included. HBA1c, age, gender, admission type, Charlson co-morbidity score, knowledge of DM, severity scores (SAPS II and SOFA) were collected at admission. ICU and hospital length of stay (LOS) and mortality were recorded. Patients were categorized according to the HbA1c admission value (< 6.5 % and ≥ 6.5%) and subcategorized according to the pre-existence of DM. A chi-square test was calculated to compare categorical variables, T-student test for age and non-parametrical tests for other variables.

RESULTS. A total of 572 patients were included (mean age 61 ±16 years). Admission HbA1C was ≥6.5% in 16% of the patients. As compared with patients whose HbA1C was < 6.5%, patients with raised HbA1C were older, more often males admitted for medical reasons, had a lower prevalence of unknown DM, and had more organ failures (table). There was no difference in LOS or mortality between the two groups.

CONCLUSIONS. In a mixed population of critically ill patients, elevated HbA1c was frequent even in patients without DM. A systematic determination of HbA1C at the time of admission could be particularly valuable in older males with several organ failures, even in the absence of known diabetes.

Serum S100B is associated with the severity of liver cirrhosis, rather than the severity of hepatic encephalopathy

J.W. Park[1], C. Kim[2]
[1]Hallym University Sacred Heart Hospital, Department of Internal Medicine, Anyang-si, Korea, Republic of; [2]Jeju National University Hospital, Department of Internal Medicine, Jeju-si, Korea, Republic of
Correspondence: C. Kim
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0115

INTRODUCTION. S100B, a Ca^{2+}-modulated protein, is predominantly found in astroglia and Schwann cells, plays important roles in central nervous system development and recovery after injury. There are very few studies that have suggested serum S100B as a diagnostic marker for hepatic encephalopathy (HE) in the patients with cirrhosis or fulminant hepatic failure.

OBJECTIVES. This study was conducted to investigate the association between serum level of S100B and the severity of liver cirrhosis and HE.

METHODS. The patients with liver cirrhosis were enrolled to the study, and their serum levels of S100B were measured by the enzyme-linked immunosorbent assay. We classified the patients into two groups based on the level of S100B and labeled those at or above the 25th percentile (51.0 pg/ml) as high S100B group and those below the 25th percentile as non-high S100B group. The patients were also divided into three groups, without HE, with minimal HE and with overt HE. The psychometric hepatic encephalopathy score was used for the diagnosis of minimal HE.

RESULTS. A total of 95 subjects were included, 70 (73.7%) males and 25 (26.3%) females. The mean age was 52.7 years. A positive linear correlation was observed between serum S100B level and the Model for End-Stage Liver Disease (MELD) score (r = 0.385, p < 0.001). High S100B was detected in 24 patients (25.3%). The MELD score was significantly higher in high S100B group compared with non-high S100B group (16.39 ± 7.91 vs 11.61 ± 6.22, p = 0.003). However, no significant differences were observed for age, BMI, platelet count, serum levels of ammonia, cholesterol, bilirubin, and albumin, protrombin time, and the Child-Pugh score. Of the 95 patients, 22 (23.2%) was diagnosed with minimal HE and 25 (26.3%) with overt HE. The mean levels of serum S100B of each group were 38.1 ± 17.2 (without HE), 36.5 ± 13.9 (with MHE), and 43.5 ± 19.7 (with overt HE) pg/ml, respectively. One-way analysis of variance revealed that serum S100B levels did not differ among these three groups (p = 0.208).

CONCLUSIONS. Cirrhotic patients with high serum S100B are associated with an increased risk of severe liver disease. However, serum S100B levels could not well discriminate the severity of HE.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0116

OBJECTIVE. Reports exist of the possible usefulness of coupled plasma filtration adsorption (CPFA) for the purification of hepatic patients but current evidence is just based on isolated clinical cases. We aim to examine the efficacy of CPFA in this situation compared with a standard treatment, MARS.

METHODS. This exploratory, case series involved four patients, two admitted for acute liver failure and two for acute on chronic liver failure. The indication for use was adjusted in all cases to the protocol used in our ICU. Alternative sessions were given with MARS (6 sessions) and CPFA (4 sessions) to compare between the patients. The duration of the sessions was 12 hours and anticoagulation was done using a mixed technique; heparin 4 U/Kg/h + epoprostenol 5 mcg/Kg/min; venous access was made with a 24 cm, 13.5F catheter via the right femoral vein. The statistical analysis was done with non-parametric tests for analysis of paired samples (Wilcoxon), with significance set at 0.05. The data are shown as the median (quartiles).

RESULTS. Of the two patients with acute liver failure, one had Wilson disease and MELD 38, and underwent transplantation; and the other HAV infection with MELD 24 and was discharged alive. Of the two with acute on chronic failure, one had autoimmune disease and MELD 25, and died; and the other NASH and MELD 34, receiving a transplant.

Technical difficulties encountered included one assembly problem in a MARS session and early coagulation in a MARS session. The reduction in platelets for MARS was 4.1% (-4.2- 7.3[IKJ1]) and for CPFA 20.7% (-3.3-20.7). We detected no bleeding problems in any patient.

Concerning the purification capacity, the reduction in creatinine was similar with both techniques: MARS 32.4 (25.9-45.9), CPFA 30.5 (7.1-30.5), p ns; as was sodium: MARS 0.7 (-2.2-1.1); CPFA 0.7 (-10.7-0.7), p ns. Direct bilirubin fell with both: MARS 23.9 (15.3-44.1), CPFA 41.1 (37.1-41.1), p ns; but indirect bilirubin only with CPFA: MARS 8.9 (-9.5-16.6); CPFA[IJ2] (-20.1-44.6), p < 0.05).

CONCLUSION. In our patients CPFA had a similar elimination profile to MARS in hepatic patients. The elimination of indirect bilirubin was only effective with CPFA but the reduction in platelets was greater with CPFA. Studies specifically addressing this disease are needed to assess the indication for CPFA as a liver purification technique.

Severe acute liver injury: etiologies and outcome

N. Foudhaili, S. Khedher, A. Khaled, K. Ben Ismail, M. Salem
Charles Nicolle Hospital, Digestive Intensive Care Unit, Tunis, Tunisia

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0117

INTRODUCTION. Severe acute liver injury is characterized by an acute liver damage without underlying chronic liver disease. It is a critical condition as it may lead to acute liver failure.
OBJECTIVES. The aim of this work was to provide epidemiological and prognostic features of this condition.
METHODS. It was a retrospective one year study. We included all patients admitted for severe acute liver injury (ALI).
RESULTS. Forty-six patients were included with a sex-ratio at 0.5 and a mean age of 48±19 years (16-87). The main comorbidities were diabetes mellitus (31%) and hypertension (28%). Principal etiologies of ALI were hepatitis (46%) and drugs (28%). Hepatitis type B was incriminated in 11 patients (24%), type A in 8 patients and type E in 2 patients. Acute liver failure (ALF) occurred in 7 patients. ALF was classified as hyperacute in 2 patients, acute in 3 patients and subacute in 2 patients. Six patients died (13%) because of ALF.Patients with unfavorable outcome (death or ALF), in whom demographic characteristics were similar to patients with favorable outcome, had lower platelet count (198.10^3/ml vs 110 .10^3/ml, p =0.025), lower prothrombin time ratio (22±11% vs 45 ±22%, p< 0.001), higher INR level (1.52±2.1 vs 3.6±0.44 p < 0.001), lower hemoglobin amount (9.5±3.4 g/dl vs 12±2.2 g/dl, p = 0.029), lower diastolic blood pressure (58±8 mmHg vs 72±13 mmHg, p = 0.015) and lower mean blood pressure (76±9 mmHg vs 89±13 mmHg, p =0.026). The results of the logistic regression analysis showed that only diastolic blood pressure level was significantly related to unfavorable outcome. ROC curve analysis showed that a diastolic blood pressure level < 60 mmHg was a predictive factor of unfavorable outcome with a sensibility of 75% and specificity of 95% (AUR=0,802, 95% IC 0,627-0,977).
CONCLUSIONS. ALI is associated with a non-negligible mortality mainly due to ALF. A diastolic blood pressure level less than 60 mmHg may help to predict unfavorable outcome.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0118

INTRODUCTION. Sepsis is characterized by an inappropriate host immune-inflammatory response including altered iron homeostasis. Increased hepatic hepcidin production leads to hypoferremia. Hepcidin inhibits macrophage iron release and intestinal iron absorption, and has been suggested to be an important link between host defense, infection, and iron metabolism.
HYPOTHESIS. We hypothesize that increased gene expression of hepcidin is protective and could be correlated with an improved survival outcome.
METHODS AND STUDY DESIGN. Prospective cohort. Settings: Adult patients with septic shock in medical and surgical ICUs. Sample: 106 patients were enrolled between January 2008 and March 2010 within 24-48 h of diagnosis. Exposure measure: hepcidin gene expression. Hepcidin was measured in PBMC by RT-PCR. Outcome measures: 60-day mortality. Statistics: To assess the prospective association of hepcidin levels with mortality, we used Cox proportional hazard models. With 60-day mortality as the outcome and hospital days as the time metric, crude models for the outcome and log2 transformed hepcidin gene expressions were run. Statistical analyses were adjusted as follows: 1) crude model; 2) model adjusted for age, gender, race, body mass index (BMI), and baseline APACHE (Acute Physiology and Chronic Health Evaluation) II score. Hazard ratios are presented.
RESULTS. At 60 days 58/106 (54.7%) patients were alive and 48/106 (45.3%) patients were dead. The hazard ratio for doubling the

hepcidin gene expression was significant in the crude model (HR = 1.12; C.I. 1.00, 1.24): for each doubling in hepcidin gene expression there is a 12% increased instant threat of dying; adjusted for age, gender, race, and body mass index (BMI): HR = 1.14; C.I. 1.02,1.28). Once adjusted for severity of illness (Apache 2 score) the effect was not anymore statistically significant: HR = 1.08; C.I. 0.95, 1.22. Ventilator days and days of vasopressor support were not statistically different between hepcidin mRNA levels.

CONCLUSIONS. Higher hepcidin mRNA expression at enrollment is associated with higher 60-day mortality based on the crude hazard ratio for hepcidin gene expression level and adjusted for age, gender, race, and BMI. Since this effect is not present once adjusted for severity of illness, we postulate that hepcidin gene expression level is a mediator in the pathophysiological cascade of sepsis that leads to increased mortality. Therefore, while we must reject our hypothesis, we are able to further corroborate a link between altered iron metabolism and sepsis, and speculate the increase in hepcidin correlates with the disease burden.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0119

INTRODUCTION. Kallistatin has anti-inflammatory effect by inhibiting tumor necrosis factor-alpha (TNF-α) and high mobility group box-1 (HMGB1) (1, 2), and it also attenuates endothelial dysfunction through TNF-α- and endothelial nitric oxide synthase (eNOS)-associated pathways (2-4).

OBJECTIVES. We performed this study to investigate whether serum levels of kallistatin, vascular cell adhesion molecule-1 (VCAM-1), and E-selectin are associated with 28-day mortality in patients with septic shock.

METHODS. Serum levels of kallistatin, VCAM-1, and E-selectin were measured by enzyme-linked immunosorbent assay using blood samples obtained at admission and at 24 h after admission from the patients with septic shock and from healthy volunteers. The primary outcome was 28-day mortality.

RESULTS. Serum kallistatin levels were significantly lower and serum VCAM-1 and E-selectin levels were significantly higher both in the survivors and the non-survivors compared with the healthy volunteers both at admission and at 24 h. Serum kallistatin level at 24 h was significantly higher in the survivors compared with the non-survivors (4.3 μg/mL [3.3-5.2] vs. 2.8 μg/mL [2.2-3.8], P = 0.002). The levels of VCAM-1 and E-selectin showed no differences between the survivors and the non-survivors at either time point. In a multivariable logistic regression analysis with stepwise selection, the serum kallistatin level at 24 h was independently associated with 28-day mortality (odds ratio 0.45, 95% confidence interval 0.21-0.82, P = 0.025).

CONCLUSIONS. The lower serum kallistatin level at 24 h was independently associated with 28-day mortality in patients with septic shock.

The effects of septic state on plasma orexin concentrations in human: a preliminary study

M. Akaishi[1], E. Hashiba[2], T. Suganuma[1], H. Niwa[2], T. Kushikata[3], K. Hirota[3]
[1]Hirosaki University Hospital, Hirosaki-shi, Japan, [2]Hirosaki University Hospital, ICU, Hirosaki-shi, Japan, [3]Hirosaki University Postgraduate School of Medicine, Hirosaki-shi, Japan
Correspondence: M. Akaishi
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0120

INTRODUCTION. Orexinergic system plays an important role not only on sleep-awake cycle, but also on analgesia and autonomic function (1). In animal study orexinergic activity was reduced during sepsis and exogenous administration of orexin restored the hemodynamic depressions (2). However, few study have focused on the interaction between septic state and orexinergic activity in septic patients.

OBJECTIVES. The aim of this study was to investigate the effects of septic state or non-septic inflammatory state on plasma orexin A (OXA) concentrations in human.

METHODS. This study was approved by our university ethical committee and registered in the Japan Primary Registries Network (UMIN000018427). The written informed consents were taken from patients and adult volunteers. Septic patients (S group) and non-septic surgical patients (NS group) who were treated in our ICU and adult healthy volunteers (V group) were enrolled. Plasma concentrations of OXA for all groups and septic markers of procalcitonin(PCT), presepsin(P-SEP) and C-reactive protein (CRP) for S- and NS- groups were measured. The chronological changes in those parameters through the treatments were also investigated in S group on ICU-admission day 0, 1, 2, 3, 5, 7 and 14 and in NS group before the anesthesia induction, on ICU day 1, 2, 3. The correlations between plasma OXA concentrations and the 3 biomarkers were analyzed. Statistical analysis was performed with Kruskal Wallis test followed by Dunn's multiple comparison test. Data were expressed as median (interquartile range, IQR) and a p value less than 0.05 was considered as significant.

RESULTS. Twenty-six septic patients, 31 non-septic surgical patients and 6 volunteers were enrolled.Median (IQR) values of plasma OXA concentrations in S-, NS- and V- groups were 0.087(0.052-0.122)ng/ml, 0.09(0.061-0.146)ng/ml and 0.059(0.048-0.084) ng/ml, respectively (figure 1). There was no statistical significance among them. In S group P-SEP, PCT and CRP markedly increased on ICU day 0 and PCT and CRP gradually and significantly decreased through the treatments (figure 2A). In NS group CRP and PCT significantly increased, compared with preoperative values, but the median values of PCT and P-SEP did not become more than those cut-off values which suggested infections, 0.5 ng/ml and 500 pg/ml, respectively (figure 2B). Orexin A did not show significant changes through the treatments in S group and NS group (Figure 3A&B).

CONCLUSION. It was suggested that plasma concentrations of OXA in septic patients were not different from those of healthy volunteers and preoperative awake patients. Furthermore, non-septic inflammation did not affect plasma concentrations of OXA.

Study of the changes and roles of BMP-2 and BMP-4 in early phase of sepsis

Y. Wen, M. Zhang
The First Affiliated Hospital of Xiamen University, ICU, Xiamen, China
Correspondence: Y. Wen
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0122

INTRODUCTION. Endothelial dysfunction is confirmed to be involved in the development of sepsis[1]. In vivo and in vitro experiments have shown that bone morphogenetic protein (BMP)-2 and BMP-4 (BMP-2/4 subgroup is one of BMPs' subgroups) both exist in human microvascular endothelial cells (ECs) and indeed modulate EC migration and capillary tube formation[2, 3]. However, the roles of BMP-2/4 on the development of endothelial dysfunction in sepsis have not been determined.
OBJECTIVES. To study the changes and roles of serum BMP-2 and BMP-4 in the development of sepsis.
METHODS. Blood was collected for determining the levels of serum BMP-2 and BMP-4 from patients with strictly defined sepsis (group sepsis, n=28), patients without sepsis admitted in intensive care unit (ICU) (group non-sepsis, n=25), and healthy volunteers (group control, n=24). ELISA was used to determine the values of serum BMP-2 and BMP-4.
RESULTS. Compared with the controls, the serum BMP-2 and BMP-4 were significantly increased in early phase of sepsis (BMP-2: 568.3 ± 193.6 pg/ml *vs.* 23.94 ± 3.366 pg/ml, P=0.0122; and BMP-4: 81.67 ± 21.6 pg/ml *vs.* 24.53 ± 3.412 pg/ml, P=0.0191, Fig 1), and the serum BMP-2 was significantly higher in group sepsis than those of group non-sepsis (568.3 ± 193.6 pg/ml *vs.* 78.52 ± 33.56 pg/ml, P= 0.0221, Fig 1). Pearson correlation analysis showed that BMP-2 of group sepsis was significantly associated with serum lactate (r= 0.481, P= 0.013) within 24 hours after admitted in ICU, and counts of platelet on the third day after admitted in ICU (r= -0.459, P=0.018). The serum BMP-2 showed good diagnostic performance (area under ROC=0.95, P< 0.0001, cutoff value=50.30 pg/ml, sensitivity=89.29 % and specificity=95.83 %, Fig 2 and Fig 3) in separating sepsis from healthy volunteers, and also showed good diagnostic performance in separating sepsis from non-sepsis in ICU (area under ROC= 0.83, P< 0.0001, cutoff value=54.57 pg/ml, sensitivity=89.29 % and specificity= 72 %, Fig 2-3), but the level of serum BMP-4 did not show good diagnostic performance in separating sepsis from healthy volunteers (area under ROC= 0.68, sensitivity=57.14 % and specificity= 83.33 %, Fig 2-3) or sepsis from non-sepsis in ICU (area under ROC= 0.54, sensitivity=60.00 % and specificity= 53.57 %, Fig 2-3).
CONCLUSIONS. The level of serum BMP-2 was significantly increased and might be a potential diagnostic marker in early phase of sepsis.

Prognostic value of serum cholinesterase activity in septic shock

S. Bradai, M. Bahloul, O. Turki, M. Dlela, M. Bouaziz
Habib Bourguiba University Hospital, Intensive Care Departement, Sfax, Tunisia
Correspondence: S. Bradai

INTRODUCTION. Although biomarkers could help clinicians in the early diagnosis of septic shock and immediate onset of antibiotics, there are always questions to be answered about their usefulness in the prognosis of septic shock.

OBJECTIVE. Recently, it was demonstrated that Serum Cholinesterase activity (SChEA) can be useful in the diagnosis of septic shock related to bacterial infection. We aimed to analyse it kinetic in patients with septic shock in order to explore if it has a prognostic value.

METHODS. It is a prospective analytical study, conducted at the intensive care unit (ICU) of Habib Bourguiba university hospital, Sfax, Tunisia, between January 01, 2017, and December 31, 2017. All Patients who developed septic shock due to bacterial infection during the study period were enrolled. The SChEA was measured on day of admission, next on days 1, 3 and 5 of the shock. Then, we compare it kinetic on patients who survived and those who died.

RESULTS. There were 60 cases of septic shock, admitted to the ICU during the study. Sex ratio (male/female) was 3.3. The mean age was 47.7±19 years with extremes of 12 and 83 years. Mean SAPS II on ICU admission was 40.7±16.1 (median: 40). Mean SOFA on ICU admission was 16±4 (median: 7). Mean onset delay of shock was 6.3±9.2 days. The main infection was pneumonia in 36 patients (60%). The most identified pathogen was *Klebsiella pneumoniae* in 12 patients (20%).

The analysis of SChEA's kinetic showed that in survivors the value of this biomarker increase in the third day then in the 5th day, in comparison with it value on the day of the shock. However in dead patients, there was a decrease in SChEA in comparison with it value on the day when septic shock was settled **(Figure1)**. A SChEA > 3270 UI /l on the 5th day predicted a good prognosis with sensitivity of 71%, specificity of 91% and an area under the curve =0.83 **(Figure2)**.

CONCLUSIONS. SChEA can be used as a biomarker to predict the prognosis of patients with septic shock due to bacterial infection. Other studies are needed on this subject.

MR proadrenomedulin, procalcitonin, C-reactive protein as prognostic biomarkers of mortality in abdominal sepsis after surgery admitted to the ICU

B. Valenzuela-Méndez[1], F. Valenzuela-Sánchez[2], L. Fernandez Ruiz[2], J.F. Rodríguez Gutiérrez[2], R. Bohollo de Austria[2], A. Estella García[2], J. Rello[3]
[1]Hospital Universitario Germans Trias i Pujol, Badalona, Spain; [2]Hospital Universitario del SAS de Jerez, Jerez de la Frontera, Spain; [3]CIBERES. Vall d´Hebron Institut of Research, Barcelona, Spain
Correspondence: F. Valenzuela-Sánchez

INTRODUCTION. Secondary abdominal sepsis has an important incidence and high mortality rate. It is more dramatic when it is in context of an inadvertent perforation or suture dehiscence after a schedule surgery. Finding a biomarker that anticipate early severity in this patients is very important for their prognosis.

OBJECTIVES. The objective of this study is to evaluate the utility of MR-proadrenomedullin (MR-ProADM), Procalcitonin (PCT) and C-reactive protein (CRP) levels in the manage and prognosis of severe sepsis after a abdominal surgery admitted to the ICU.

METHODS. Prospective observational study. A total of 262 consecutive surgical patients with suspected abdominal sepsis were recruited in the ICU. Epidemiological, clinical, clinical, laboratory and MR-proADM, Procalcitonin (PCT), C-reactive protein (CRP) and lactate levels were collected at the time of admission, at 48 hours, on the 5th day and the day of discharge from the UCI. The values are expressed in Median (Confidence Intervals at 95%).

RESULTS. We included 262 patients in the study. Mortality was 24% (63/262). Upon admission to the ICU, the levels of biomarkers in the survivors were statistically higher in the septic patients who died in the ICU: CRP 31.5 (24-35.5) vs 26 (23.2-28.8) mg/dl (p = 0.0230); PCT 11 (6.6- 8.15) vs 5.9 (3.9-9.25) ng/ml (p=0.0229);MR-proADM 5.24 (4.11-7.05;) vs 2.94 (2.58-3.95) nmol/l (p=0.0011). At 48 hours only MR-proADM levels were significantly higher in thenon survivors: 3.76 (2.5-5.1) vs 1.8 (1.42-2.29) (p = 0.0002). The incidence of intestinal complications as dehiscence and perforation after abdominal surgery was 34%.The area under the ROC curve (AUC) for the prediction of mortality at admission was CRP of 0.660, PCT of 0.705 and MR-proADM of 0.713 (Figure 1), and at 48 hours the AUC for the MR pro ADM was 7.24. The optimal cut-off point to predict the mortality of

the MR-proADM levels at admission was 3.15 and at 48 hours of 1.9, both with a sensitivity of 80% and a specificity of 53%. In patients with surgical complications, the AUC-ROC at admission was 0.792 for the MR pro ADM and 0.578 for the PCT (Figure 2). In the multivariate analysis (Cox proportional hazards models) MR-proADM levels at admission, were statistically significant predictive factors for mortality in the ICU and at 90 days, in the total group and in the subgroup of surgical complications (Figure 3).

CONCLUSIONS. High levels of CPR, PCT and proADM on admission are related to poor prognosis in septic patients due to abdominal origin , but the levels of MR-proADM are the most effective to determine the unfavorable evolution and risk of mortality, especially followed a scheduled surgery.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0125

INTRODUCTION. The identification of septic patients at high risk of death remains a challenge. Early and aggressive resuscitation is an important factor in reducing sepsis mortality. The role of prognosis of N-terminal pro-B-type natriuretic peptide (NT-proBNP) in septic patients remains controversial

OBJECTIVES. The objective was to determine NT-proBNP values of septic patients admitted to the ICU and relate them to mortality, presence of cardiac dysfunction and severity parameters.

METHODS. Prospective observational single-center study. 621 consecutive septic patients were admitted to the ICU. Epidemiological, clinical and laboratory data and NT-proBNP, MRproADM, Procalcitonin (PCT), C-reactive protein (CRP) and lactate levels were collected at the time of admission, at 48 hours, on the 5th day and the day of discharge from the ICU

RESULTS. During 5 years, 621 patients were admitted to the ICU with the diagnosis of severe sepsis. The mortality rate was 33%. The origin of the patients was mainly from the emergency room (50%), followed by the medical department in 22%. The biomarker levels are shown in Figure 1. The average levels of NT-proBN P on admission were 2700 (2025.8-3334.1) pg / ml (median and 95% CI) , at 48 hours these values decrease to 2268 (1776.7- 2817.7 pg / ml (ns) , coinciding with the highest incidence of heart failure and with the highest volume replacement;On the 5th day, a significant decrease in the levels was observed: 1535 (1169.3-2108.8) pg / ml (median and 95% CI) (p < 0.05), which were kept to discharge: 1188.5 (789.4-1705 , 5) pg / ml. The incidence at discharge of elevated levels of NT-proBNP (> 400 pg / ml) was 86% and they were discharged without signs of cardiac dysfunction or positive balance. These values are similar to the maximum showed during the acute phase of a control group studied in patients with acute ischemic heart disease, which was 1847 ± 3733 pg / ml. In the survival groups there was a significant increase in the levels in the non survivors compared to the survivors at admission 3980 pg / ml (3195-6150.3) vs 1818 pg / ml (1541-2691) (median and 95% CI) (p < 0.0001) . In the ROC curve as a predictor of mortality, the AUC was 0.650 on admission and 0.660 on the 2nd day.

In the multivariate analysis (Cox proportional hazards models) high levels of NT-proBNP were significantly associated with increased mortality, together with the Apache II score and lactate levels.

CONCLUSIONS. The determination of NT-proBNP is a useful initial prognostic biomarker in septic patients but is not related to the diagnosis of cardiac dysfunction in sepsis.

Fig. 1 (abstract 0125). Levels of biomarkers and severity scores

Biomarker / Score	Median	95% CI
Lactate mMol/l	1.8	1.7 – 1.98
NT-ProBNP pg / ml at admission	2700	2025.8 – 3334.15
NT-ProBNP pg / ml at 48 hours	2268	1776.74 – 2817.75
NT-ProBNP pg / ml at 5º day	1535	1169.38 – 2108.82
NT-ProBNP pg / ml at discharge	1188.5	789.44 – 1705.52
CRP (mg/dl) admission	23.4	21.8 – 24.6
PCT (μg/l) admission	4.1	3.1- 5.9
MR-proADM (nmol/l) admission	2.67	2.53 – 3.01

Role of novel biomarker MR-proADM in diagnosis and prognosis of sepsis

R. Cicuéndez[1], L. Nogales[1], C. Andrés[2], E. Zarca[2], D. Calvo[2], D. Andaluz Ojeda[1]
[1]Hospital Clínico Universitario Valladolid, Adult Intensive Care Medicine Department, Valladolid, Spain; [2]Hospital Clínico Universitario Valladolid, Clinical Analysis Department, Valladolid, Spain
Correspondence: R. Cicuéndez

INTRODUCTION. Early diagnosis and severity assessment in sepsis is crucial, increasing the possibility of starting specific treatment and adequate management. Novel biomarker mid regional proadrenomedullin (MR-ProADM) has been used successfully to assess prognosis in patients with pneumonia. Here we evaluate its utility as sepsis diagnosis and prognosis biomarker.

OBJECTIVES. Evaluate the ability of MR-ProADM to predict mortality and facilitate diagnosis of sepsis and septic shock in a cohort of critically ill patients admitted to the ICU.

METHODS. 170 patients with sepsis or septic shock (SS) and 69 patients with SIRS without sepsis criteria admitted to ICU were evaluated. Clinical data, SOFA, APACHE II, leucogram data and levels of PCR, PCT, lactate, MR-proADM, were measured at admission. $\chi 2$ test for categorical and Mann Withney U- test for continuous variables were used. To evaluate accuracy of sepsis diagnosis and ICU mortality, the area under the ROC curve (AUROC) was employed. A p-value of < 0.05 was considered significant.

RESULTS. Data from 239 adult patients were collected. Patients were 63-year-old on average and 63.4% males. It showed a SOFA score of 7.4 and APACHE II of 20.2 at admission with 25.4% of ICU mortality. When all clinical variables and biomarkers were analyzed in global cohort for mortality ICU accuracy, only MR-proADM, SOFA, and APACHE showed statistical significance: AUROC (IC 95%, p)= 0.72 (0.62-0.81, 0.04); 073 (0.64-0.82, 0.04); 0.70 (0.60-0.8, 0.05) respectively. When ICU mortality was analyzed in sepsis subgroup alone, only SOFA, APACHE, and two biomarkers, MR-ProADM and lactate; showed significative accuracy: AUROC (IC 95%, p): 0.74 (0.60-0.88, 0.004); 0.75 (0,62-0.89, 0.002); 0.74 (0.59-0,88, 0.002); 0.69 (0.56-0.86, 0.02) respectively. When patients were classified as septic or SIRS,

only PCT, PCR and MR-ProADM showed diagnosis accuracy to distinguish both diseases with AUROC (IC 95%, p): 0,83 (0.75-0.91, < 0.01); 0.79 (0.68-0.89, < 0.01); 0.75 (0.68-0.83, < 0.01) respectively. Neither the lactate nor other parameters of the leucogram like such as white blood cell or neutrophils count showed diagnostic utility.

CONCLUSIONS. Our results suggest that MR-ProADM is better prognostic marker than the rest of the biomarkers used routinely, not only in septic patients but also in overall critically ill patient. It also behaves as a good diagnosis marker of sepsis, although other molecules such as PCR or PCT have equal or better diagnostic accuracy in this field. Its usefulness in the future must be confirmed by new larger studies.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0127

INTRODUCTION. ELABELA (ELA) and Apelin-13 (APL-13) bind to the apelin receptor (APJ), a GPCR highly expressed in the cardiovascular system, and are of the strongest inotropic and dominant apelinergic (APL) ligands in human heart which improve heart performance during sepsis. Apelins have been also clearly committed in improving insulin sensitivity and glucose handling, including in the heart.

OBJECTIVES. To establish the metabolic impact of APL infusion in an experimental model of rat septic shock (*i.e.* cecal ligation and puncture: CLP).

METHODS. Sepsis-related myocardial dysfunction was induced by CLP with APL infusion (APL-13 15µg/kg/hr, ELA 39µg/kg/hr) and saline resuscitation (2.5mL/kg/hr) started afterwards for 24hrs. Outcomes as well as indirect calorimetric assays (Promethion) were recorded and arterial lactates measured at the endpoint. The major cellular glucose transporter GLUT4 expression and dynamic membrane translocation under these APL infusion(s)/exposure(s) were measured by Western blotting (in whole hearts) and by confocal fluorescence microscopy in rat cardiomyocytes (CM) (neonatal ventricular: RNVC, trans-RA phenotypically differentiated H9C2) -with or without induced human APJ overexpression-, respectively.

RESULTS. Arterial lactates (mmol/L) rose in CLP + saline (NS) at 24 hrs (2.5 vs. 1.7 ± 0.2mmol/L, p< 0.05 vs. Sham), but less with APL infusions (CLP + APL 13 1.9 ±, CLP + ELA 2.2 ± 0.20.17mmol/L, NS vs CLP + saline). CLP induced a significant decrease of the respiratory quotient (RQ) in the dark phase, as defined by the ratio of CO_2 production (VCO2)/O2 consumption (VO2) (Sham 0.90 ± 0.003, CLP + NS 0.72 ± 0.001, CLP + ELA 0.73 ± 0.001, p< 0.001 vs Sham), and of energy expenditure (EE) (kcal/hr) (Sham 3.40 ± 0.02, CLP + NS 1.83 ± 0.01, CLP + ELA 1.99 ± 0.01, p< 0.001 vs Sham). APL-13 infusion enhanced RQ (CLP + APL-13 0.72 ± 0.001, p< 0.01 vs CLP + NS), and EE energy (CLP + APL-13 2.50 ± 0.01, p< 0.001 vs CLP + NS). Substrates utilization calculated from the RQ after CLP induction revealed a metabolic switch from a major use of fatty acids to a higher use of carbohydrates with APL infusions (Sham 67% carbohydrates - 33% fat, CLP + NS 4.76% - 95.24%, CLP + ELA 8.4% - 91.6%, CLP + APL-13 15.6% - 84.4%). GLUT4 myocardial expression slightly down-regulated 24hrs after CLP was not affected by APL infusions. However, APL-13 but not ELA incubation triggered a 1.75-to-2 fold enhanced GLUT4 translocation to APJ-overexpressing RNVC membranes at 2 hrs (p< 0.05 vs control and APJ-overexpressing cells).

CONCLUSIONS. CLP induced major metabolic changes with increased arterial lactates and decreased RQ & EE. APL infusions modified substrate utilization. APL-13 over ELA administration/exposure promoted the use of carbohydrates and improved the availability of membrane GLUT4 location in CM.

INTRODUCTION. Accurately diagnosing sepsis remains a challenge. The absence of specific diagnostic markers can result in delays in recognition and treatment, or over-diagnosis and over use of broad-spectrum antibiotics.

Abundant proteins such as albumin reduce the resolution of mass spectroscopy in high-throughput biomarker discovery.[1] Elimination of these proteins ahead of analysis is key to uncovering less abundant proteins that are more likely to represent potential biomarkers. Current state-of-the-art immunoaffinity depletion techniques eliminate both abundant and scarce proteins indiscriminately.[1]

A complex bioshell known as the 'protein corona' forms around nanoparticles when immersed in plasma.[2] This corona is comparatively enriched with less abundant proteins, and as such may be a source of novel candidate biomarkers.

We hypothesise that the composition of the protein corona that forms around AmBisome (a liposomal nanoparticle), which has been incubated in *ex vivo* plasma from patients with sepsis will differ to that which forms in plasma from patients with sterile inflammation or healthy control plasma, revealing potential biomarkers.

OBJECTIVES.

- Characterize the protein corona formed around AmBisome following ex vivo incubation with human plasma.
- Identify potential candidate biomarkers for future clinical validation.

METHODS. AmBisome was incubated in plasma samples from patients with sepsis, sterile inflammation or healthy control plasma for one hour. A two stage purification process separated the corona coated AmBisome and ensured no contamination from free unbound proteins. The protein corona was quantitatively and qualitatively characterized using dynamic light scattering, gel electrophoresis, and mass spectroscopy.

RESULTS. AmBisome that was incubated with plasma samples from sepsis patients had a significantly higher concentration of protein within the corona when compared to healthy control plasma (figure 1). Gel electrophoresis demonstrated the protein corona eliminating the effect of 'albumin masking' (figure 2), increasing the number of proteins identified on mass spectroscopy. Identified proteins were analysed to provide a panel of novel potential biomarkers.

CONCLUSIONS. New technologies are urgently needed to provide rapid diagnostic information in sepsis. This study provides evidence for the potential exploitation of the protein corona in aiding comprehensive analysis of the blood proteome, and facilitating the discovery of sepsis-specific proteins that may represent novel diagnostic biomarkers.

Cholesterol oxidation in sepsis

A. Kleyman[1], M. Singer[2]
[1]UCL, London, United Kingdom; [2]UCL, London, United Nations Interim Administration Mission in Kosovo
Correspondence: A. Kleyman

INTRODUCTION. Hypocholesterolaemia is both a hallmark of sepsis and a prognosticator of poor outcome. However, mechanisms underlying this fall and any impact on tissue cholesterol levels are unknown. As cholesterol has well-recognized antioxidant properties, we hypothesized that increased ROS production in sepsis leads to cholesterol oxidation and decreases in plasma and tissue cholesterol levels.

OBJECTIVES. We used a well-characterized rat faecal peritonitis model and an H9C2 rat cardiomyocyte cell line to assess

(i) concentrations of cholesterol in plasma and different tissues taken from sham and septic animals at 24 hours post-sepsis, and
(ii) the effect of hydrogen peroxide on cholesterol levels in H9C2 cells.

METHODS. Awake, instrumented male Wistar rats (325±15g) received an i.p. injection of faecal slurry with i.v. fluid resuscitation commencing from 2h. Control animals were treated identically other than not receiving slurry. A heart rate cut-off of 460 bpm at 6h was used to classify animals into predicted survivors or non-survivors (1). [SM1] At 24h post-sepsis animals were killed and organs were immediately collected into liquid nitrogen. Cholesterol in plasma, organs and cells was measured either with Amplex Red assay or by mass spectrometry. In H9C2 cell studies, cells were either incubated with H_2O_2 or septic plasma (pooled from 6 rats after 24h sepsis) for 2h. Results are presented as mean ± SE, analysed using Student's t-test and considered statistically significant when p < 0.05.

RESULTS. A marked, severity-dependent decrease in cholesterol concentration was seen in plasma at 6h and 24h and membrane fraction of heart at 24h following induction of sepsis. Treatment of H9C2 cells with either septic plasma or hydrogen peroxide resulted in marked falls in cell cholesterol after 2h or 5 minutes correspondingly.

CONCLUSIONS. Cholesterol levels in both plasma and tissue fall rapidly after induction of sepsis in this rat peritonitis model, the magnitude of which is dependent on illness severity. This fall could be reproduced in a cardiomyocyte cell line incubated with either H_2O_2 or septic plasma. This suggests oxidation of cholesterol by intracellular ROS production. Further investigations of cholesterol oxidation and the influence of altered cholesterol membrane content on cellular processes in sepsis are ongoing.

The effects of epinephrine and propranolol on the expression of tumor necrosis factor-α mRNA induced by lipopolysaccharide in RAW 264.7 cells

Y. Fujiwara, G.-G. Feng, K. Tanaka, R. Ishihara, N. Hatakeyama, A. Hashimoto, Y. Fujita
Aichi Medical University, Department of Anesthesiology, Nagakute, Japan
Correspondence: Y. Fujiwara

INTRODUCTION. Catecholamine has been reported to precipitate immune dysfunction and modulate inflammatory respose after infection (1). Recent studies suggested that β-blockers may improve outcome after sepsis by attenuating the deleterious effect of catecholamine on immune and inflammatory system (2).

OBJECTIVES. The objective of this study was to determine the effects of epinephrine on the expression of tumor necrosis factor-α (TNF-α) mRNA induced by lipopolysaccharide (LPS) in RAW 264.7 cells. We also tried to find out if propranolol attenuates the effect of epinephrine on TNF-α expression.

METHODS. RAW 264.7 cells were cultured in growth media Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin, and 100 mg/mL streptomycin in a 5% CO2 atmosphere at 37°C. Expression of TNF-a mRNA levels were determined by real-time polymerase chain reaction after each treatment as follows. First, cumulative dose of epinephrine (0.01, 0.1, 1, 10, 100 µM) were added to the medium without LPS. Then, after the application of LPS (1µg/ml) , the same doses of epinephrine were added. Finally, 100 and 200 µM of propranolol were added after LPS and 1 µM epinephrine were administered.

RESULTS. TNF-a mRNA induction after each treatment was shown in Fig 1-3.

CONCLUSIONS. Epinephrine decreased basal TNF-α mRNA expression of RAW 264.7 cells. In contrast to the results of previous studies, epinephrine attenuated the expression of TNF-α mRNA induced by LPS. Propranolol reversed the effect of epinephrine on the expression of TNF-α mRNA.

INTRODUCTION. Sepsis is a multi-system syndrome that remains the leading cause of mortality and critical illness worldwide. Hemodynamic support is one of the cornerstones of the acute management of sepsis however, the ideal strategy remains under debate. Acute lung injury and ARDS are common complications of sepsis. It is unclear if the observed incidence of ARDS in sepsis is wholly attributable to the response to infection, or partially due to iatrogenic injury from fluid resuscitation.
OBJECTIVES. We used an ovine model of endotoxemic shock to determine if 0.9% saline resuscitation contributes to lung inflammation and injury in ARDS, and investigated the potential role of cytokines and matrix metalloproteinases in this process.

METHODS. Sheep were randomly divided into no endotoxemia (control) (n=5) or endotoxemia groups (n=16) with an escalating dose of lipopolysaccharide (LPS) up to 4 μg/kg/hr. Endotoxemia sheep received either no saline resuscitation (n=8) or a 0.9% saline bolus (40 mL/kg over 60 minutes) (n=8). Control animals underwent fluid resuscitation with a 0.9% bolus of saline. Lung tissue, bronchoalveolar lavage fluid and plasma were analysed by real-time PCR and ELISA to assess cytokines and matrix metalloproteinases.
RESULTS. Quantitative real-time PCR studies showed higher expression of IL-6 (p=0.03), IL-8 (p=0.01), IL-1β (p=0.02), MMP-1 (p=0.03) and TIMP-1 (p=0.003) in lung tissue of endotoxemia + saline animals compared to controls, while the level of TIMP-2 was decreased with endotoxemia (p< 0.05). BAL and tissue homogenate levels of IL-6 (p< 0.01), IL-8 (p< 0.05) and IL-1β (p< 0.05) were also elevated.
CONCLUSIONS. Endotoxemia results in inflammation and lung injury. Saline resuscitation augments this dysfunctional physiology with increased intra-pulmonary levels of inflammatory cytokines, and up-regulation of matrix metalloproteinases. These results suggest fluid resuscitation may be an independent contributor to lung injury in sepsis and a potentially modifiable factor in the prevention of ARDS in septic patients.

INTRODUCTION. The ideal sepsis biomarker still has to be born. The need of a useful and reliable clinical tool, nourish clinical and experimental research.
OBJECTIVE. Retrospective analysis of prospectively collected data to compare the clinical informative value of Procalcitonin (PCT) and C-Reactive protein (CPR) plasma concentrations in the detection of infection and sepsis and in the assessment of severity of sepsis in a medico-sukrgical intensive care unit (ICU).
METHODS. We collected all clinical data, drug administration, scores and PCT values of 927 consecutive adult patients who were admitted to the intensive care unit for an expected stay >48hours. PCT and PCR plasma concentrations were measured daily during the intensive care unit stay. Each patient was examined daily for signs and symptoms of infection and was classified daily in one of the following six categories: negative, localized infection, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis or septic shock. The severity of sepsis-related organ failure was assessed by the sepsis-related organ failure assessment (SOFA) score.
RESULTS. A total of 8538 patient days were classified into the six categories. The median plasma PCT concentrations in each class was respectively: negative 0.62 ng/ml, localized infection: 0.69 ng/ml, SIRS: 2.29 ng/ml, sepsis: 4.34 ng/ml, severe sepsis 17.30 ng/ml and septic shock 26.80 ng/ml. The median plasma PCR concentrations in each class were negative 49.6 mg/dl, localized infection 68.6 mg/dl, SIRS 86.3 mg/dl, sepsis 125.6 mg/dl, severe sepsis 154.4 mg/dl and septic shock 183.5 mg/dl. The linear correlation between PCT plasma concentrations and the six categories was much stronger than in the case of PCR (Spearman´s rho, 0.668 vs. 0.489; p< 0.0001). The area under the receiver operating characteristic curve was 0.846 for PCT (95% CI, 0.838-0.854), compared with 0.751 for PCR (95% CI 0.742-0.760) (p < 0.0001).
CONCLUSIONS. PCT is a better marker of sepsis than PCR. The course of PCT shows a closer correlation than PCR with the severity of infection and organ dysfunction.

INTRODUCTION. Plasma cell-free hemoglobin (PHb) has been reported to be associated with poor outcomes in acute kidney injury, pulmonary hypertension, acute respiratory distress syndrome and myocardial infarction.[1-3] In sepsis, alterations in red blood cell membrane occur and PHb could be elevated in sepsis.[4-5]

OBJECTIVES. This study was performed to investigate the association between PHb and mortality in sepsis and septic shock.

METHODS. We performed a retrospective analysis of prospective collected data of patients with sepsis and septic shock. Patients were divided into 4 groups according to the PHb concentrations using an adjusted cubic spline: $PHb \leq 20$ mg/dL, $20 < PHb \leq 40$ mg/dL, $40 < PHb \leq 60$ mg/dL and $PHb > 60$ mg/dL. The primary outcome was the 28-day mortality and a multivariate Cox proportional hazard regression method was used.

RESULTS. A total of 372 patients were included and the overall 28-day mortality rate was 16.7%. The median PHb concentration in the overall patients was 24.8 mg/dL (reference range, 0 - 5). The mortality rate did not increase in proportion to the PHb concentration and was the lowest in the $20 < PHb \leq 40$ mg/dL group (20.3%, 11.0%, 16.3% and 26.7% in the $PHb \leq 20$ mg/dL, $20 < PHb \leq 40$ mg/dL, $40 < PHb \leq 60$ mg/dL and $PHb > 60$ mg/dL groups, respectively). In the Cox proportional hazard regression analysis, the $PHb \leq 20$ mg/dL group was independently associated with 28-day mortality compared with the $20 < PHb \leq 40$ mg/dL group (hazard ratio, 2.19; 95% confidence interval, 1.18 - 4.07). The $PHb > 60$ mg/dL group was associated with 28-day mortality, but it was not statistically significant (hazard ratio, 2.17; 95% confidence interval, 0.85 - 5.56).

CONCLUSIONS. The low concentration as well as high concentration of PHb was associated with 28-day mortality in patients with sepsis and septic shock.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0134

BACKGROUND. Concentrations of respective biomarkers are time-dependent, even under uncomplicated conditions; therefore, a suitable method should be used for the evaluation of serial measurements. Nonparametric quantile regression can be used for such purposes instead of simple point reference values.

The aim of our work was to monitor the response of the studied biomarkers (presepsin, procalcitonin, CRP, and leukocytes) to postoperative SIRS after major cardiac and abdominal surgery without systemic infectious complications and to define acceptable time-dependent reference limits for the respective biomarkers during the postoperative course (up to 7 days after surgery).

METHODS. A group of 24 patients (19 men and 5 women) was retrospectively evaluated. The median of age of the patients was 66 years, and the interquartile range was 63.0-73.0 years (minimum 52 years, maximum The median total length of surgery was 225 minutes (interquartile range of 180-263 minutes).

43 patients underwent cardiopulmonary bypass surgery (median CPB of 83 minutes, interquartile range of 70.0-100.0 minutes). Multiple comorbidities were present in all patients. All (large or small intestine surgery, resection of the liver or stomach, pancreatectomy, or multi-organ surgery) were performed at the Institute for Clinical and Experimental Medicine, Prague, Czech Republic (IKEM).

All patients survived 30 days, and there were no cases of sepsis, septic shock, peritonitis or other infectious complication during this period. Only one patient was treated with immunosuppressants (cyclosporine and prednisone). None of the patients needed renal replacement therapy in the postoperative course. There were three cases of transient postoperative left ventricle insufficiency and one of decompensation of diabetes mellitus. Blood samples were taken immediately before the surgery, at the 3 hour, and on the 1 , 3 and 7 days following the surgery.

RESULTS. Early peaks were found in presepsin and leukocyte concentrations (median concentrations of 819 ng/L and 11.4 x 109/L with 95th percentiles of 2017 and 17.8, respectively, both within the first 24 hours postoperatively). Procalcitonin peaked on the 1st day after surgery (median 0.54 μg/L, 95th percentile 4.76), while CRP peaked on the 3rd day after surgery (median of 133.3 mg/L, 95th percentile of 287.5). The peak values were 1.5, 9, 66, and 1.9 times higher than the basal values for presepsin, procalcitonin, CRP, and leukocytes, respectively.

CONCLUSIONS. Presepsin is less influenced by postoperative SIRS than procalcitonin or CRP and may therefore act as a valuable biomarker for the detection of infectious complications in patients after major surgery.

INTRODUCTION. Weaning from mechanical ventilation (MV) is an important issue for all patients who undergo MV. A previous simple classification known as the International Consensus Conference classification (ICC) has several limitations, which include that it ignores weaning failure, gives unclear approach with tracheostomy patients, and requires the performance of spontaneous breathing trials (SBT). In 2017, the WIND Study Group and the REVA Network proposed a new definition that groups patients according to the number of days between the first separation attempt (SA) from MV and successful weaning.

OBJECTIVES. This study aimed to evaluate whether the WIND classification (WIND) is able to predict patient outcomes more accurately than the ICC in clinical practice.

METHODS. We retrospectively reviewed 1,601 patients who received MV in medical intensive care units (ICU) (Jul 2010 to Sep 2013). Patients who transferred-in from another hospital more than 48 hours after intubation (n=42) or who succeeded on non-invasive ventilation (n=71) were excluded. The applicability of the ICC and the WIND was assessed in 1488 patients. After using both the ICC and the WIND to classify patients, we compared the weaning outcomes of each group to determine which classification better reflected the weaning outcome.

RESULTS. First, tracheostomized patients (n=33) and patients who did not undergo SBT (n=680) were not classifiable under the ICC. In contrast, all patients were able to be included in the WIND. Second, according to the ICC, 744 patients were grouped as simple weaning (n=505), difficult weaning (n=145), and prolonged weaning (n=94). Patients with a repeated SBT or increase in the number of days, the patients were more likely to have higher ICU and hospital mortality, and they also have an increased length of stay (LOS) in both the ICU and hospital (P< 0.001). According to the WIND, 1488 patients were grouped as Group 1 (short, n=593), Group 2 (difficult, n=187), Group 3 (prolonged, n=204), and no weaning (n=504). As the days after the first SA from MV increased, the patients were more likely to have higher ICU and hospital mortality, as well as, increased LOS in both the ICU and hospital (P< 0.001). Group 1 and Group 2 by the WIND showed a clearer difference in ICU mortality (2.7% vs 16.0%, P < 0.001) and hospital mortality (19.9% vs 34.2%, P < 0.001) compared to simple weaning group and difficult weaning group in the ICC (5.1% vs 5.5%, P = 0.860 in ICU mortality; 22.4% vs 25.5%, P = 0.429 in-hospital mortality).

CONCLUSIONS. Our study suggests that the WIND could be a good classification tool for predicting patient weaning outcomes because it is applicable to all weaning situations and identifies the clear difference in outcomes in patients who tolerate early weaning.

The use of the WIND classification for weaning from mechanical ventilation applied to Brazilian critically ill patients

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0136

INTRODUCTION. Weaning from mechanical ventilation (MV) is an important clinical issue in the care of critically ill patients. The knowledge of this period is fundamental to understanding the causes and consequences of the prolonged weaning. In April 2005 an International Consensus Conference (ICC) defined a classification of the weaning. However, in 2016 a new definition for the weaning (WIND) was suggested.

OBJECTIVES. To compare the weaning from MV in a Brazilian intensive care unit according to the ICC and the WIND classification.

METHODS. This study was a retrospective cohort study in an intensive care unit (ICU) in a tertiary University Hospital. Patient data such as population characteristics, MV duration, weaning classification, SAPS III and death probability were obtained from a medical records database of all patients, who were admitted at this ICU between January, 2016 and July, 2017. The analyses were made with statistics software R (Foundation for Statistical Computing, Austria) and SAS Statistical Software (version 9.3; SAS Institute, USA). ANOVA was used for multiples comparisons of quantitative variables. Equal letters on the top right side of the numbers express evidence of no differences between the groups and different letters show evidence of differences between them. P values lower than 0.05 express evidence that at least one group differs from the others. The logistic regression analysis was used to identify variables that are associated with extubation failure.

RESULTS. A total of 327 patients under MV were enrolled. The patients characteristics are shown in table 1. The number of patients belonging to ICC and WIND classification is shown in table 2. By applying the WIND classification it was possible to classify 100% of the patients and to identify that the probability of death and the number of days of MV increased significantly from patients of group 1 to patients of groups 3a, 3b and no weaning, p< 0.0001 (table 3). The logistic regression analysis identified the days of MV as being associated with extubation failure (OR= 1.23; 95% CI= 1.11-1.38).

CONCLUSIONS. The present study demonstrated that the WIND classification allows categorising all patients into 4 groups, different from ICC classification, in which only 17% of the whole cohort could be categorised. The probability of death and the number of days of MV increased according to the difficulty of the weaning. Finally the number of days of MV was associated with extubation failure.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0137

INTRODUCTION. Weaning is the process by which a patient is liberated from mechanical ventilation and extubation is the process of liberation from endotracheal tube[1]. Extubation failure is defined as the need for reintubation within a specific time period : either within 24 - 72 hours or up to 7 days[1,2]. Failed extubation, is common in intensive care units (ICU). This can lead to higher morbidity and mortality, higher cost and increased length of hospital stay. There is limited literature available on weaning/extubation predictors and outcomes. Main objective of the study was to identify the rate, causes and predictors of extubation failure and to identify the rate of reintubation across 3 Intensive care units(ICU) at King's College Hospital, London.
OBJECTIVES.

1. To determine the reintubation rate.
2. To determine the causes and predictors of reintubation.

METHODS. This was a prospective study. A standard questionnaire was filled by the auditors by direct observation, observation of daily chart or by direct questioning from the person who decided to extubate. The study was carried out over 1 month across 3 ICU s. All elective extubations during this period was analysed. Patients over 18 years of age, intubated and mechanically ventilated for more than 24 hours and extubated electively were included in the study. Patients less than 18 years of age and all self extubations were excluded. The results were statistically analysed.
RESULTS. A total of 49 (male 77.6%) elective extubations were analysed. 49% were more than 61 years of age. Patient with cardiovascular diseases were the commonest indication for intubation (24.5%). The mean heart rate, systolic and diastolic blood pressure, PaO_2 and FiO_2 were 86.2 ± 20.64p/min, 138.9 ± 23.77mmHg, 87.72 ± 26.59mmHg, 11.28 ± 1.90mmHg, 27.27 ± 7.26% respectively prior to extubation. 36 (73.4%) patients were extubated successfully and 13(26.5%) were re-intubated. Acute respiratory failure/ respiratory distress was the commonest indication for re-intubation (33.3%). 10 (76.9 %) of reintubations took place within 48 hours of extubation and the rest within 72 hours.

Based on logistic regression analysis (adjusted) patients who were agitated had higher risk of re-intubation than non (EXP (B) =4.195, p=0.0.015). Higher the age there was 16% more risk of re-intubation (EXP (B) =1.159, p=0.042).
CONCLUSIONS. Extubation success was significantly influenced by the age of the patient and the mental status.

Thoracic fluid content: a novel parameter for predicting failure of weaning from mechanical ventilation

M. Raafat, A. Hasanin, S. Fathy, A. Fouad, A. El-adawy, M. Beshara, H. Kamal
Cairo University, Anesthesia and Critical Care Medicine, Cairo, Egypt
Correspondence: M. Raafat
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0138

INTRODUCTION. Weaning of mechanically ventilated patients is a daily decision in intensive care practice. Failure of weaning is associated with poor outcome; thus, several tools are used to predict successful liberation from the ventilator.
OBJECTIVES. The aim of this work is to evaluate total fluid content (TFC) as a predictor for failure of weaning from mechanical ventilation.
METHODS. A prospective observational study was conducted in surgical intensive care unit (ICU), Cairo University hospital including 37 mechanically ventilated patients scheduled for weaning. During spontaneous breathing trial (SBT), Electrical cardiometry (ICON[R] monitor) device was used to measure TFC. Other hemodynamic variables (arterial blood pressure, ventral venous pressure, and heart rate) were also recorded. Successful weaning was defined as passing a 48-hour period without the need for re-connection to the ventilator. Predictive properties for TFC for failed weaning were estimated using area under receiver operating characteristic (AUROC) curve. Subgroup analysis for patients with impaired cardiac contractility was also performed.
RESULTS. The incidence of weaning failure was 38%. TFC showed good predictive ability for weaning failure {AUROC: 0.767, sensitivity: 50, specificity: 96%, cutoff value >63 Kohm[-1]}. In the subgroup of cardiac patients, TFC showed excellent predictive ability for weaning failure {AUROC: 0.917, sensitivity: 83%, specificity: 89%, cutoff value >48 Kohm[-1]}.
CONCLUSIONS. TFC measured by electrical cardiometry during SBT is a useful predictor for failure of weaning from mechanical ventilation. TFC showed excellent predictive properties in the subgroup of patients with impaired cardiac contractility. The best cutoff value for predicting weaning failure is >63 Kohm[-1] in general patients and >48 Kohm[-1] in cardiac patients.

A pilot study to develop the feasibility of patient-controlled ventilatory weaning using neutrally adjusted ventilatory assist

D. Hadfield, J. Smith, C. Donegan, H. Noble, L. Grieg, E. Corcoran, E. Clarey, C. Bell, C. Harris, P. Hopkins
King's College Hospital, London, King's Critical Care, London, United Kingdom

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0139

INTRODUCTION. Neurally-adjusted ventilatory assist (NAVA) utilises diaphragmatic monitoring and a proportional, neurally triggered ventilatory support (1). Small efficacy studies have demonstrated the benefit of NAVA on patient ventilator interactions and prevention of lung over-inflation, however clinical effectiveness has not been demonstrated, Here we describe novel pilot data examining the feasibility of 'patient-controlled' weaning using this technology.

OBJECTIVES. To test the feasibility of patient-controlled ventilatory support weaning using NAVA technology.

METHODS. HRA/ethics approval was obtained Adult patients with prolonged ventilatory weaning on NAVA mode were screened for the ability to trial patient-controlled NAVA gain selection. Patients were excluded if they had cognitive impairment, psychological injury, treatment limitation, delirium, neuromuscular weakness of upper limbs, significant visual impairment or were part of another research study. Following consent, patients received a 10-minute explanation of the technology including a 1 minute period at reduced NAVA gain (50% reduction) which was clinician led. This was followed by a one-hour trial of patient-controlled NAVA gain setting with medical and nursing supervision throughout. Patients were encouraged to set NAVA gain at a level they would be happy to breathe at for at least two hours. NAVA gain, neural drive (EAdi) and dyspnea by visual analogue scale was assessed at baseline and at the end of the patient control hour. Following, one hour of patient controlled ventilation, the patient was returned to baseline support levels.

RESULTS. 10/634 patients with prolonged weaning screened, met the inclusion criteria. All 10 patients reported better understanding of NAVA versus pressure support ventilation and support for the concept of patient control as a component of the weaning strategy. Patients set NAVA gain at lower levels than critical care staff (Figure 1), associated with a small rise in neural drive (Mean EAdi 18 vs 20.1) and respiratory rate (26.4 vs 29.5 BPM). No adverse incidents were reported during the patient control phase or 24 hours post the patient control hour. Despite slightly elevated EAdi and respiratory rate, levels of dyspnea were not increased during the patient-control hour.

CONCLUSIONS. We have reported the novel use of patient controlled ventilatory support using NAVA technology. Patients found NAVA understandable; the introduction of patient control was safe and we have established the potential for acceleration of weaning through selection and tolerance of reduced support compared to that set by healthcare professionals.

Role of lung aeration pattern using ultrasonography in predicting failure of spontaneous breathing trial in mechanically ventilated patients

A. Fayed, W. Mohamed, M. Osman
Alexandria University, Critical Care Medicine, Alexandria, Egypt
Correspondence: A. Fayed
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0140

INTRODUCTION. Discontinuing Mechanical Ventilation (MV) is a time when the load associated with breathing is returned from the ventilator to the patient´s respiratory muscles. Failure of weaning from MV occurs in up to 25-30% of patients. It is associated with high mortality rates. Indexes predicting success can be clinically helpful. However, the predictive capacity may be low and there are a lot of controversies about which ones should be used.

OBJECTIVE. This study evaluated the role of lung ultrasound (LUS) in predicting the failure of spontaneous breathing trials (SBTs) in critically ill patients on MV using LUS aeration score (LAS) 30 minutes before and after the start of SBT. It was calculated according to numeric rating scale ranging from 0 to 32 (low =0 to10, moderate = 11 to 20 and high = 21+).

METHODS. This prospective study was conducted on 55 adult MV patients whom were eligible for SBT during their stay in the critical care units of Alexandria main university hospital. LUS was performed using a 2- to 4-MHZ convex probe (Mindray DP-3300). LAS was recorded. Then, all patients were followed up for success or failure of their SBT.

RESULTS. Results after follow up showed a high successful rate of SBTs performed. 60% (33) of all enrolled patients showed successful SBT, 40% (22) showed failed one. Regarding demographic data, 32 males and 23 females were enrolled. There was no difference in sex between both groups wasn't statistically significant ($p = 0.911$). The mean age of all enrolled patients was 56.91 years. in group A ranged between 19 and 84 with a mean of 53.82 ± 20.91 years. There were no significant differences in demographics between patients of successful SBT group and failed group.

Regarding LUS assessment, the mean of LAS 30 minutes before SBT was significantly higher in the group of failed SBT (16.77 Vs 6.06, $p< 0.001$). The mean of LAS 30 minutes after start of SBT was higher than before in both groups but it was still significantly higher in the group of failed SBT (20.73 Vs 8.67, $p< 0.001$).

Data analysis showed that LAS after SBT was associated with higher sensitivity in predicting failure of SBT than the LAS before SBT (90.91 Vs 81.82%) but with lower specificity (69.70 Vs 78.79). LAS before SBT was associated with higher accuracy (80%) than after SBT (78.18%).

CONCLUSIONS. To date, there are no easy clinical indices can be powerful predictors of weaning failure. LUS may predict weaning success or failure through detection of aeration pattern before SBT through LUS scoring system.

Clinical outcome of difficult-to-wean patients with ventilator dependency at intensive care unit discharge

INTRODUCTION. Patients who are difficult to wean from invasive mechanical ventilator (IMV) in intensive care unit (ICU) with ventilator dependency have been increasing.1-2 However, specialized ventilator weaning unit is not available in the tertiary hospitals in Korea, and data on the clinical outcome of difficult-to-wean patients is lacking.

OBJECTIVES. We aimed to evaluate clinical outcome in patients who were discharged from ICU with tracheostomy and ventilator dependency.

METHODS. We retrospectively investigated clinical course and survival in patients requiring home mechanical ventilator (HMV) with tracheostomy for difficult weaning from IMV during medical ICU admission between September 2013 and Augustin 2016 at Severance Hospital, Yonsei University.

RESULTS. Of 84 difficult-to-wean patients who started on HMV in medical ICU, a total of 72 patients who survived and discharged from the ICU were identified and included for this analysis. HMV was initiated after a median of 23 days of IMV, and successful weaning rate was 46% (n = 33): all but one were successfully weaned at hospital discharge after a median of 31 days of HV. In-hospital mortality rate was significantly lower in successfully weaned group (0% vs. 23.1%; P = 0.003). Weaning rate was similar according to the main diagnosis. After a median follow-up of 4.6 months (range, 1 - 27) for survivors, 3- (n = 57) and 6-(n=54) months survival rates were 82.5% and 72.2%, respectively. The respective survival rates were better for successfully weaned group at 3 months (96.4% vs. 69.0%; P = 0.012) and 6-months (84.0% vs. 62.1%; P = 0.073) following ICU discharge.

CONCLUSIONS. Post-ICU survival for the difficult-to-wean patients with ventilator dependency was moderate with the use of HMV as a bridge to liberation from ventilator.

INTRODUCTION. Liberation from mechanical ventilation is a common procedure in intensive care units. Several studies published in the last decades have change the way to perform weaning.

OBJECTIVES. To evaluate the changes observed in the liberation from mechanical ventilation from 1998 to 2016.

METHODS. Analysis of four prospective, observational, multicenter international studies on mechanical ventilation, in 1998, 2004, 2010 and 2016. For the purpose of this secondary analysis we selected patients who were successfully weaned and scheduled extubated. The onset of weaning was the time that the physician in charge considered the patient likely to resume and sustain spontaneous breathing after a patient met standard criteria for weaning readiness. We registered the method of weaning: spontaneous breathing trial (T-tube circuit, pressure support ventilation of 7 cm of water, continuous positive airway pressure of 5 cm of water, other mode) or gradual reduction of support (pressure support, synchronized intermittent mandatory ventilation with or without pressure support, other mode), days of weaning and reintubation. Patients were classified into one of three weaning groups: simple weaning group, difficult weaning group and prolonged weaning group.

RESULTS. In the table 1 and Figure 1 are showed the changes observed over the time. In the table 2 the comparison of outcomes.

CONCLUSIONS. These data showed a significant clinical variability over the time, however it is possible to observe that in last study there is a change toward a higher use of gradual reduction of pressure support to start the liberation of mechanical ventilation and to wean difficult/prolonged-weaning patients.

Heart rate variability evaluation during weaning from mechanical ventilation

B. Simon, C. Fasquel, V. Pateau, E. Lher
Brest University Hospital, MICU, Brest, France
Correspondence: B. Simon
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0143

Determinants of weaning or extubation failure are difficult to assess and are not solely related to respiratory condition. Heart rate variability is presumed to be an indicator of the patients' clinical status [1].

OBJECTIVES. The main purpose of this study was to evaluate whether heart rate variability evaluation before, during and after a

weaning procedure may enable to discriminate the determinants of either weaning and extubation success.

METHODS. This project is based on a prospective physiological tracing data-warehousing program (Rea STOC, clinicaltrials.gov #NCT02893462) that aims to record 1500 consecutive ICU patients, over a 3-years period. This study was approved by our local ethical committee.

All ICU patients that were considered as candidates for a T-tube testing could be included. First continuous ECG recording was performed at 126 Hz for half an hour prior to the test itself. Same recordings were performed during the entire test duration (max 30 min), and after extubation if considered positive. Heart rate variability was assessed either in the time, frequency and Pointcare domain using Kubios.

RESULTS. 34 patients were included (age 62 ±11 yr; 25 male/ 9 female; SAPS II 48±17), and 40 weaning tests were recorded. Main associated diseases were cardiopathy (n=11), COPD (n=13), and neurological disease (epilepsy, stroke, multiple sclerosis). Main diagnoses related to mechanical ventilation requirement were acute respiratory failure (56%) and neurological failure (35%).

Most significant difference in between groups was a mean initial HRV value (prior to the beginning of the test) difference in between success and failure of the T-tube test, whatever the domain of consideration.

CONCLUSIONS. HRV evaluation, prior to a T-tube test, may help discriminate patients that will be considered as a success and deemed to be extubated.

Table 1 (abstract 0143). HRV values in the different domains

Long-term mechanical ventilation-dependent patients in ICU transferred to a home mechanical ventilation unit

O. Moreno Romero, M. Muñoz Garach, M.E. Poyatos Aguilera
Hospital Universitario San Cecilio, Granada, Spain
Correspondence: O. Moreno Romero
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0144

OBJECTIVES. To analyse the transfer of the long-term mechanical ventilation-dependent patients from an intensive carte unit to a home mechanical ventilation unit (HMVU).

PATIENTS AND METHODS. Observational restrospectively study of all patients who underwent mechanical ventilation (MV) therapy in our intensive care unit of 18 beds and became ventilatory dependent and were transfered to our HMVU, situated in a different hospital in the same city, in a 22 year period (1995-2017). Variables analyzed: age, sex, cause for prolonged MV, type of IMV dependency (full-time, parcial), NIMV, if they were still mechanically dependent at the time of discharge from HMVU, ICU and HMVU length of stay, overall survival.

RESULTS. In 22 years of study, 41 patients ventilatory dependent were transfered from ICU to our HMVU as a long term weaning process. 24 were male (58.56%), mean age 53 year, and 17 female (41.46%), mean age 54 years. Cause for prolonged MV: 25 (60.9%) neuromuscular disease, 8 (19.5%) chronic pulmonary disease, 6 (14.6%) complicated surgery, 2 (4.8%) neurovascular disease. ICU length of stay of 75 days (6-322).

At the time to transfer to HMVU: 38 (92%) patients with IVM, from these, 25 (65.7%) were full-time ventilated and 13 (34.3%) only parcially ventilated (12 hours at night). 3 (8%) patients with NIMV. At the time of discharged from the HMVU and thuss the length of stay was, depending of the type of ventilation: 9 months (93-144) in full-time IMV, 134 days (3-2880) in parcially IMV and 15 days (10-22) in NIMV.

Overall survival: 33 (80.5%) of the patients outlive more than 2 years and 20 (48.8%) of them outlive 5 years (2-16). 13 (31.7%) of the patients still alive today, with a mean time of 4.5 years.

CONCLUSIONS. The HMVU has become part of the process for treating mechanical ventilation dependent patients and thuss offloads intensive care unit longterm patients. From the ICU income until discharge from the HMVU it takes from 15 days in patients with NIMV to 134 days in those depending of IMV parcially and extends until the 9 months in the ones totally dependent. 80% of the patients survive more tan 2 years, and half of them outlive 5 years.

INTRODUCTION. Difficult weaning from mechanical ventilation remains a major challenge for the ICU physicians. The ideal weaning prediction test remains to be defined. Many weaning predictors have been proposed since the introduction of rapid shallow breathing index (RSBI), but their usefulness or superiority remains unclear.

OBJECTIVES. In a prospective observational study, we compared the performance of four already known weaning prediction tests, and a new one, the peak relaxation velocity of the diaphragm, acquired sonographically using Tissue Doppler Imaging (TDI).

METHODS. Seventy-one ICU patients ventilated for more than 48 hours were screened for weaning success or failure while performing a T-piece trial for 20 min.The following weaning prediction tests, with their respective cutoff points for weaning failure, were studied: RSBI>80 breaths/lit, diaphragmatic displacement < 1cm, diaphragmatic thickness ratio < 25%, diaphragmatic - rapid shallow breathing index (D-RSBI) > 1.3 breaths/mm of diaphragmatic displacement, and TDI-acquired diaphragmatic peak relaxation velocity < 4cm/sec. Diaphragmatic ultrasound measurements were performed on the right hemi-diaphragm. Weaning success was defined as no need for re-intubation or noninvasive ventilation for 48 hours after extubation. Receiver operator characteristic (ROC) curves and logistic regression were used to evaluate the diagnostic accuracy of these indices.

RESULTS. Mean duration of mechanical ventilation was not different between the weaning success and weaning failure groups (6.4±3 and 5.8±3 days respectively).Concerning the ROC curves, RSBI, D-RSBI and peak relaxation velocity performed more or less equally (0.7). Logistic regression confirmed the above mentioned data: Odds ratio for RSBI was 0.98 (95% CI 0.96-0.99), for peak relaxation velocity was 0.11 (95% CI 0.06-0.08) and for D-RSBI was 0.54 (95%CI 0.3-9.97); the significance level was similar (p< 0.04) for all three indices. Diaphragmatic displacement and thickness ratio were not found to be statistically significant predictors of weaning outcome.

CONCLUSIONS. Our study demonstrates that RSBI remains the simplest weaning predictor test to perform; D-RSBI and TDI -acquired diaphragmatic peak relaxation velocity could also be used in everyday ICU practice for the same purpose. Surprisingly, the current study did not establish significance for diaphragmatic displacement and thickness ratio.

The effect of total thoracic content assessed by cadiometery on anticipating the deterioration of trial of weaning from mechanical ventilation

A. Wahdan
Cairo University Hospitals, Anesthesia, SICU and Pain Management, Cairo, Egypt
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0147

INTRODUCTION. Weaning from mechanical ventilation is a serious and challenging process in critical care practice. Weaning failure is associated with poor patient outcomes. I Fluid overload and positive cumulative fluid balance is a risk factor of weaning failure.

PATIENT AND METHOD. A prospective cohort study. : The study was conducted in24-bed trauma and surgical ICU Cairo University hospital. : Patients scheduled for a 2-h spontaneous weaning trial (SBT) . During the weaning trial , Total thoracic fluid content will be measured using electrical cardiometry connected to the patient before starting the weaning trial, during the trial at 30 minutes and 2 hours and at 30 minutes, 2, 6, 12, 24 and 48 hours after the end of the trial however success or failure. Also, cardiac output, cardiac index, stroke volume and ICON . The use of diuretics or nitrates will be considered and recorded. These data will be measured with the first weaning trial and with each subsequent trial

Primary outcome TFC (Total thoracic fluid content): absolute TFC value before SBT and the change in TFC by the end of SBT.

Secondary outcome(s) Any adverse events. and Cardiometry variables: stroke volume (SV), cardiac output (CO) and ICON (Index of contractility). and Lung Ultrasound: To validate that the total thoracic fluid content measured by cardiometry is a good predictor of weaning outcome from mechanical ventilation in comparison to lung ultrasound.

RESULT. Hemodynamic variables, ultrasound variables, and cardiometry variables for patients with impaired cardiac contractility: In the subgroup of patients with impaired cardiac contractility , TFC was higher in the group of failed weaning patients compared to the group of successful weaning patients. CVP was also higher in the group of failed weaning compared to the group of successful weaning.

DISCUSSION. Weaning induced pulmonary edema (WIPE) has been reported in both cardiac and non-cardiac patients.Many tools for prediction of weaning induced cardiac edema have been reported. The use of electrical velocimetry in measurement of TFC has the advantage of being non-invasive with no need for advanced skills. So , In this work we tried to validate the use of TFC measured by electrical velocimetry in prediction of weaning success. Total thoracic fluid content was measured using electrical cardiometry connected to the patient before starting the weaning trial, during and after the trial. Lung ultrasound was performed, patients was investigated in a supine position before the start, during and after the trial. We found that total thoracic fluid content measured by electrical cardiometry and Lung ultrasound score showed good predictive ability for weaning failure especially in the subgroub of patients with impaired cardiac contractility. Positive fluid balance showed moderate predictive value for weaning failure.

Physiologic comparison of the diaphragm behavior on spontaneous breathing (SB), pressure support ventilation (PSV) and proportional assisted ventilation with load-adjustable gain factor (PAV +) on acute increase of the ventilatory demand

P. Nery de Souza, M. Henrique Claro dos Santos, L. Pastore Junior, S. Elaine Uhlig, R. Florentina Scardua, E. Leite Costa
Hospital Sírio Libanes, São Paulo, Brazil
Correspondence: P. Nery de Souza
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0148

INTRODUCTION. Pressures support ventilation (PSV) is an assisted modality in which the airway pressure level is independent of the system impedance and patient effort. Conversely, Proportional assisted ventilation (PAV+) uses load gain factor to deliver a level of assistance that depends on both the mechanical properties of the respiratory system and on patient effort.

OBJECTIVES. To asses the effect of increased demand on patient effort and on diaphragmatic neuromechanical coupling in healthy volunteers during spontaneous breathing (SB) in PSV or PAV+ mode.

METHODS. This study was conducted at Sírio Libanês Hospital Education and Research Institute. The hospital ethics committee approved the study and Informed consent was obtained from all subjects.

Airway pressure (Paw) and flow were recorded at the mouth. Esophageal (Pes) and gastric (Pgas) pressures were measured with balloon-tiped catheters. Transdiaphragmatic pressure (Pdi) was obtained as Pgas -ΔPes, and transpulmonary pressure (PL), as Paw-Pes. Diaphragm electrical activity (EAdi) was recorded using electrodes attached to a nasogastric tube (NAVA, Maquet). Proper positioning of the esophageal and gastric balloons and NAVA electrodes was verified using standard tests [1]. Electrical impedance tomography was used to determine end-expiratory lung impedance (ELIC), as a surrogate for lung volume [2]. Amplitude of the diaphragmatic excursion (DE) was evaluated with the ultrasonography by a blinded investigator [3].

Six subjects were studied in semi-recumbent position breathing with a nose clip through a mouthpiece. Baseline measurements were obtained with unassisted breathing. PAV+ with 50% of assistance was adjusted in ZEEP, followed by PSV set to the same level of ΔPdi obtained in the PAV+. The level of assistance in PAV+ or PSV remained unaltered throughout the study. Thereafter, in random order, the volunteers were ventilated in SB, PAV+ or PSV with the increase of workload with sandbags over the abdomen (load1) or 150mL of dead space(load2)[1].

RESULTS. The ΔPDI and ΔP$_L$ was lower on PAV+ while the ΔPes was higher compared to PSV(Tab.1). PAV+ resulted in a greater reduction in ΔEAdi and DE as compared with PSV, especially with the addition of dead space (Fig. 1).

CONCLUSIONS. PAV+ compared to SB and PSV was more efficient in terms of unloading the respiratory muscles. Neuromechanical coupling was better in PAV+ compared to PSV.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0149

INTRODUCTION. Extubation failure is an important quality indicator and is independently associated with mortality and increase in length of stay in mechanically ventilated critically ill patients.[1] The introduction of standardised protocols that include spontaneous breathing trials (SBT) on a T-piece are associated with a reduction in adverse outcomes. [2] In 2014, a standardised weaning protocol was introduced in our critical care unit which included an SBT on a T-piece for 2 hours in 2014.
OBJECTIVES. We aimed to study the factors that may influence the success of extubation in patients that passed an SBT in their first attempt compared to those that failed.
METHODS. We performed a retrospective observational study looking at patients admitted to our 7 bedded Level 3 critical care unit (370 patients a year) for a period of 9 months between January and September 2016. We included patients over 16 years of age who were mechanically ventilated and length of stay was greater than 48 hours. Data was collected from WardWatcher, a SICSAG database and electronic patient records. Data included fluid balance, haemoglobin, neurological status at time when an SBT was performed. Statistical analysis of data was performed using the Mann-Whitney U test.
RESULTS. There were 84 patients who met the eligibility criteria. Of those, 55 patients underwent an SBT prior to assessment for extubation. 38 patients passed their first SBT and 17 failed.

Between these two groups there was no significant difference in median haemoglobin, Richmond Agitation-Sedation Scale (RASS), fluid balance at time of SBT and time from intubation to 1st SBT. However, median time from intubation to extubation was significantly greater in those who failed their first SBT, 5.49 days vs. 8.13 days (p< 0.007). 16% of those extubated after passing their 1st SBT required reintubation. No patients were reintubated after planned extubation in those who failed their 1st SBT.
CONCLUSIONS. Many factors contribute to extubation failure in critically ill patients. This study failed to show differences in a few of these factors that may have affected their ability to wean from mechanical ventilation. The SBT, although not perfect in predicting a successful extubation, does appear to highlight those patients who require more time intubated.

Carbon dioxide production and ventilatory inefficiency along a T-piece spontaneous breathing trial are associated with difficult weaning

R. López[1,2], R. Pérez[1,2], I. Caviedes[2,3], J. Graf[1,2]
[1]Clínica Alemana de Santiago, Departamento de Paciente Crítico, Santiago, Chile; [2]Facultad de Medicina Clínica Alemana - Universidad del Desarrollo, Santiago, Chile; [3]Clínica Alemana de Santiago, Unidad de Enfermedades Respiratorias, Santiago, Chile

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0150

INTRODUCTION. Ventilatory monitoring along a T-piece spontaneous breathing trial (SBT) is limited. Carbon dioxide (CO_2) monitoring with time capnography has been used to identify hypoventilation along the weaning process, but with high number of false positives [1]. Volumetric capnography (VC) can provide direct or derivate physiological variables that may be associated with difficult weaning, such as CO_2 production (VCO_2) and ventilatory inefficiency calculated from the slope between minute ventilation and VCO2 (VE/VCO2). Furthermore a good correlation between VE/VCO2 and physiological dead space has been recently reported in mechanically ventilated patients [2].
OBJECTIVES. To evaluate if VCO2 and/or VE/VCO2 along a T-piece SBT are associated with difficult weaning.
METHODS. We prospectively performed a one-hour SBT with a CO2/flow sensor between the endotracheal tube and the T-piece. Data was continuously recorded on a personal computer connected to a VC monitor (NICO2, Wallinford, CT, USA). Mean VCO2

and VE/VCO2 slopes were calculated. Difficult weaning included 3 categories: SBT failure (SBT-F) defined as inability to complete the trial or to extubate upon its completion, post extubation respiratory failure (PERF) defined as the need of non-invasive ventilation within 48 hours after extubation and extubation failure (EF) defined as the need for reintubation within 48 hours after extubation. Associations between VC variables and weaning outcomes were explored with t-test and ROC curves.

RESULTS. Twenty seven T-piece SBT were performed on 24 patients mechanically ventilated for 6 ± 5 days with an APACHE II of 17 ± 11 and a SOFA score 8 ± 3 points. 46% had sepsis/shock, 33% had acute respiratory failure and 21% were trauma/surgical. Sixteen trials presented difficult weaning; 5 with SBT-F, 7 with PERF and 4 with EF.

Patients with difficult weaning had a higher mean VCO2 or VE/VCO2 slope (table 1).

The AUC of the ROC curves of meanVCO2 and VE/VCO2 slope for difficult weaning were 0.73 [0.54-0.92] and 0.75 [0.55-0.94], respectively (figure 1).

Patients with SBT-F only had a higher mean VCO2 (table 2) while patients with PERF only had a higher VE/VCO2 slope (table 2).

CONCLUSIONS. Mean carbon dioxide production and ventilatory inefficiency are associated to difficult weaning; specifically a higher VCO2 is related to inability to tolerate a SBT and ventilatory inefficiency to the need for non-invasive ventilation after extubation.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0151

INTRODUCTION. Recent study has raised questions about the existence of contrast-induced kidney injury in the condition of relatively normal renal function. However, it is undetermined whether contrast media induce additional deterioration of renal function in patients with acute kidney injury (AKI). Furthermore, its influence on septic AKI patients is unclear. In this study, we examined the effect of contrast media on patients with septic AKI, compared with patients not receiving contrast media.

OBJECTIVES. This retrospective observational cohort study aimed to explore the outcomes for sepsis patient on our ICU over a 7-year period and determine the effect of contrast media.

METHODS. Using our database of sepsis patient records from 2011 to 2017 were investigated. Patients with septic AKI (according to the Sepsis-3 and KDIGO criteria) were divided into two groups (Group C, who administered contrast media within 24 hours of admission) and Group NC, not receiving contrast media and underwent propensity score analysis. The primary outcome was deterioration of kidney function (DRF) defined as elevation of serum Cre level (>0.5mg/dL or 1.25-fold from baseline) or induction of renal replacement therapy.

RESULTS. A total of 354 septic AKI patients were included. After propensity score adjustment, matching 80 couples of patients were analyzed. The rates of DRF were similar (37.5 vs 33.8%, OR 0.84 (95% CI 0.44-1.62), P= 0.870) between group C and group NC. ICU length of stay (8(5-15) vs 7(5-12)days, P = 0.220), ventilation days (7(5-13.5) vs 6(4-10.5)days, P=0.139), 7-day-mortality and 28-day-mortality (2.5 vs 6.3%, OR 0.39 (95%CI 0.08-1.78), P =0.443 and 8.7 vs 19.4% OR 0.40 (95%CI 0.15-1.09) P =0.086, respectively) were similar between two groups.

CONCLUSIONS. This study suggests that administration of contrast media was not associated with deterioration of AKI and poor outcome of septic AKI patient.

Impact of dexmedetomidine on acute kidney injury following living donor liver transplantation: a randomized controlled pilot study

K.-W. Jung, H.-M. Kwon, Y.-J. Moon, I.-G. Jun, J.-G. Song, G.-S. Hwang
Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Republic of
Correspondence: K.-W. Jung
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0152

INTRODUCTION. The incidence of acute kidney injury (AKI) has shown a wide range of 51% and 94% following liver transplantation (LT), [1-3] and is associated with increased morbidity, and mortality. [4] Dexmedetomidine has been noted as a highly selective agonist of α2-adrenergic receptors with a potential protective anti-inflammatory effect. [5,6] However, the impact of dexmedetomidine on AKI has not been determined yet after living donor LT (LDLT).

OBJECTIVES. The primary aim of the present study was to assess the relationship between the use of dexmedetomidine and the incidence of AKI in patients undergoing LDLT. The secondary aim was to assess the incidence of early graft dysfunction (EAD).

METHODS. Forty two recipients were randomly assigned into two groups: Group I (Control, n=20) and Group II (Treatment, n=22). The treatment group was given dexmedetomidine by constant intravenous (IV) infusion at a rate of 0.4mcg/kg/hour. The incidence of AKI was defined by Kidney Disease Improving Global Outcomes (KDIGO) classification.

RESULTS. There was no difference in demographic data such as age, sex, underlying disease and MELD score between the two groups. Of 42 patients, 40.5% developed AKI following LT. The incidence of AKI was lower in the treatment group (50.0% vs. 31.8), although there was no statistical significance (*P*=0.377). In addition, no difference was found in the incidence of EAD between the two groups.

CONCLUSION. Our demonstrated that dexmedetomidine may not have protective effects on AKI and EAD in patients after LDLT.

Is CKD-EPI equation appropriate for the estimation of glomerular filtration in critically ill patients with augmented renal clearance?

V. Philibert[1], Y. Rovira[1], S. Triginer[1], M. Sánchez-Satorra[1], A. Campos[1], J.M. Manciño[1], P. Marcos[1], J. Roca[2], T.M. Tomasa[1]

INTRODUCTION. There are several formulas to estimate glomerular filtration rate (eGFR). These formulas, however, are questioned under certain conditions: clinically unstable patients, acute renal failure, severe hepatopathy, generalized edema or ascites, pregnancy, significant alterations in muscle mass or the presence of body mass index < 19 Kg / m^2 or> 35 Kg / m^2 and liver kidney donors. In such conditions these equations are inadequate and glomerular filtration should be measured by the gold standar collection of urine (mGFR).

We investigated whether Augmented Renal Clearance (ARC) (mGFR > 130 ml / min/1.73 m^2) could be another condition in which these formulas should be reconsidered.

OBJECTIVES. To compare the validity of the Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI) with the gold standard (mGFR) in 24-hour urine collection: 1) In critically ill patients with ARC and 2) In all critically ill patients.

METHODS. Observational study in a tertiary ICU hospital during 15 months period (January 2016 / March -September 2017). We studied the Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI) as eGFR and the gold standard (mGFR) in 24-hour urine collection.

RESULTS. A total of 595 samples of 329 patients were studied. Pearson correlation coefficient was used for the statistical tests.

1) When we analized all the samples we obtained a good correlation (r = 0.78) between the eGFR and mGFR.
2) However, when we analized separately only the samples of critically ill patients with ARC (mGFR> 130 ml / min) a very bad correlation (r = 0.20) was obtained.

CONCLUSIONS. The CKD-EPI equation is not valid for the estimation of eGFR in critically ill patients with ARC, while it seems appropriate to estimate GFR in the general ICU population.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0154

INTRODUCTION. As patients who undergo cardiac surgery under cardiopulmonary bypass (CPB) experience increased capillary leakage in the immediate postoperative period, 6% hydroxyethyl starch (HES) may be very effective volume expander in addition to crystalloids with less pulmonary fluid accumulation. Main concerns about the use of HES were potential harmful effects on renal function and co-agulation. However, there was lack of reliable evidence.
OBJECTIVES. We aimed to evaluate the effect of limited volume of HES administration on postoperative renal function in patients undergoing cardiac surgery under CPB.
METHODS. Consecutive 1,657 patients undergoing cardiac surgery over two years were evaluated retrospectively. The patients were divided into high dose HES (n = 418, 18.8%) and low dose HES (n = 1,239, 81.2%) groups during the first two days after cardiac surgery. Outcomes were compared by using propensity scores and inverse probability weighting (IPTW) to adjust bias.
RESULTS. Incidence of AKI, the primary outcome, was higher in the high dose HES group (p=0.02). However, new renal replacement therapy (RRT) (P=0.30) and early mortality (p=0.97) were similar between the groups. When the baseline characteristics were adjusted by IPTW model, the high dose HES use was associated with increased risks of AKI (odds ratio, 1.66; 95% confidence interval (CI), 1.12-2.44; p = 0.01), but did not increase the risk of new RRT (OR, 1.27; 95% CI, 0.71-2.18; p = 0.40) or early mortality (Hazard ratio, 0.73; 95% CI, 0.29-1.81; p = 0.50), and these results were also validated by further adjustments for significant covariates.
CONCLUSIONS. The high dose administration of HES (≥20ml/kg) in the postoperative period following cardiac surgery may increase the risk of AKI. However, it did not increase the risk of new RRT or mortality. Benefits and risks should be weighed in the administration of HES. Further randomized controlled studies are needed to validate study results.

INTRODUCTION. Augmented renal clearance (ARC) incidence varies from 20-80% in critically ill patients. ARC is considered if GFR is greater than 130 mL / min / 1.73 m^2. ARC is associated with drug under dosage.
OBJECTIVES. To analyze the prevalence of ARC in our environment and determine the characteristics of these patients.
METHODS. An Epidemiological Multicenter Study was conducted in Catalonia, Spain. GFR was measured by 24-hour urine collection. Patients were followed for 3 months. We compared ARC patients with non-ARC patients (GFR lower than 130 mL / min / 1.73 m^2). Preliminary data is shown from Phase 1 of the study.
RESULTS. 128 patients were included. Median age was 64.25 years old. SOFA score at ICU admission was 5.36. ICU length of stay (ICU LOS) was 23.03 days; hospital length of stay (HOSP LOS) was 35.37 days. We found ARC in 38.46% of the patients, with an average of GFR of 163.92 mL / min.
ARC patients were less severe (SOFA 3 vs. 6, p 0.0004) and younger (57.5 vs. 70.5 years, p 0.0000) and than non-ARC. Male sex was 73.91% in ARC group vs. 59.26% in non-ARC, p 0.070.
We found less septic patients at admission in ARC patients (30.43% vs. 48.15%, p 0.039). ARC patients were treated with fewer vasoactive agents (13.04% vs. 29.63%, p 0.026) and fewer diuretics (21.74% vs. 39.51%, p 0.031) than in non-ARC. Mechanical ventilation was used in 44.44% ARC patients vs. 30.43%, p 0.086 in non-ARC. The neurological cause of admission had a tendency to be higher in ARC patients (32.61% vs. 22.22%, p 0.142) and the same happened with anti epileptic drugs (23.91% vs. 16.05%, p 0.196), however it was not statistically significant different, probably because of the sample size. ICU LOS was lower in ARC patients (8 vs. 18.5 days, p 0.0014) so as ICU mortality (2.17% vs. 14.81%, p 0.019) than in non-ARC. HOSP LOS was not statistically significant different (21 vs. 25 days, p 0.0614).

CONCLUSIONS. ARC was recorded in 38.46% of patients with a median measured GFR of 163.92 mL / min. ARC patients were younger and less severe, and ICU LOS and ICU mortality were lower.

The use of renal doppler ultrasonography in critically ill patients with acute kidney injury

R. Passos, É.B. Melo, L.V. Freire, J.G.R. Ramos, J. Caldas, P. Batista, E. Mendonça, M. Peixoto, M. Dutra

Hospital Portugues da Bahia, Salvador, Brazil

Correspondence: R. Passos

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0156

INTRODUCTION. Acute kidney injury is one of the major organic dysfunctions that occur in critically ill patients. Ultrasonography of the kidneys and urinary tract is always a tool used by nephorologists as a way of evaluating this patology. Despite this practice, its clinical utility in determining the cause of acute kidney injury is poorly established.

METHODS. Prospective cohort study of critically ill patients that underwent renal ultrasound for acute kidney injury over a 5-year period at Hospital Português da Bahia. Renal Resistive Index was determined by the doppler sonography.

RESULTS. Over the 5-year period, 350 renal ultrasounds were perfomed for evaluation of acute kidney injury. Renal ultrasound was normal in 76% of patients. Hydronephorosis was detected in only 6% of studies and in only 2% of the cases was obstructive uropathy considered the cause of acute kidney injury. Less than 1% of patients had urinary tract obstruction on ultrasound without a suggestive medical history. Median renal RIs were 0,68 (o,62-o,75) in patients with sepsis related AKI and 0,74 (0,72-0,80) in patients with non sepsis related AKI (P=0,001). RIs were 0,72 (0,70-0,79) in transient AKI and 0,76 (0,70-0,80) in persistent AKI (P=0,64).

CONCLUSIONS. The role of renal ultrasonography in every critically ill patients with acute renal injury still needs to be determined in patients with history suggestive of urinary tract obstruction renal ultrasound for evaluation of acute kidney injury should be indicated. The use renal resistive index could to be a tool to reflect vasomotor tone in patients with AKI related to sepsis.

Base deficit is a predictive factor of AKI in major trauma patients

J.Y. Lee[1], S.H. Lee[2]

[1]Chungbuk National University Hospital, Department of Trauma Surgery, Cheongju-si, Korea, Republic of; [2]Yonsei University College of Medicine, Department of Surgery, Seoul, Korea, Republic of

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0157

INTRODUCTION. Acute kidney injury (AKI) is common in trauma patients and associated with poor clinical outcomes. Base deficit (BD) are well known marker of global tissue acidosis and correlated with the magnitude of blood loss. Hence, persistent elevations in BD might be associated with a prelude to organ failure in trauma patients. The purpose of this study was to determine whether initial BD was associated with AKI development in patients who had sustained major trauma.

OBJECTIVES. This study enrolled 284 major trauma patients by retrospective chart review, from January 2011 to December 2015. Patients were older than 16 years; were admitted to an intensive care unit; survived more than 48 hours; and had sustained major trauma, which defined as an injury severity score ≥ 16. Acute kidney injury (AKI) was defined according to the consensus Risk, Injury, Failure, Loss and End-Stage Renal Disease (RIFLE) definition. BD was categorized with level ≤ -7 mmol/L

METHODS. Clinical and laboratory variables were compared between AKI group (n = 87) and non-AKI group (n = 197). A multivariate logistic regression analysis was performed to assess the association between initial BD and AKI.

RESULTS. AKI developed in 87 (31%) patients, and significantly associated with higher mortality (33% vs. 5%, p < 0.001). Multivariate logistic analysis identified BD (adjusted odds ratio [OR] = 2.326, 95% confidence interval [CI] = 1.207 - 4.482, p = 0.012) with Age (OR, 1.020; CI, 1.002 - 1.039; p = 0.032), transfusion (OR, 3.554; CI, 1.746 - 7.234; p < 0.001), and use of vasopressor (OR, 2.217; CI, 1.082 - 4.390; p = 0.029) as independent predictive factors for AKI development in major trauma patients.

CONCLUSIONS. BD (initial base deficit ≤ -7 mmol/L) was independently associated with AKI development in major trauma patients, and it may be a useful predictive marker.

Description of nephrotoxicity and infections associated with colistin in a intensive care unit

M.S. Costantini[1], N. Pires[1,2], C. Lovesio[1]

[1]Sanatorio Parque, Rosario, Argentina; [2]Universidad Nacional de Rosario, Rosario, Argentina

Correspondence: M.S. Costantini

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0158

INTRODUCTION. The use of colistin for the treatment of multidrug resistant (MDR) infections has led to an increase of colistin-associated acute kidney injury (AKI) and mortality.

OBJECTIVES. The aim of this study is to describe the colistin treated infections and the AKI colistin associated use onset of in the intensive care unit.

METHODS. A prospective study in a surgical and medical intensive care unit (ICU) carried out from March to November 2017. Patients on 48 hours colistin treatment (DC 300 UI and DM: 150 UI/12hs) and normal serum creatinine (Scr< 1,5mg/dl) at the beginning of the treatment, were included. Patients with chronic renal failure were excluded. Serum Creatinine was measured daily and AKI was defined as an SCr increase greater than or equal to 1,5 in baseline SCr.

RESULTS. Forty three patients aged 61 years old (DE: 16) were included, thirty-three (76,3%) of them were male.The basal Scr was 0,98 mg/dl (DE: 0,49 mg/dl) and the treatment´s day media

was 8 days.Ten patients died (23,6%). Twenty six (60,47%) developed AKI and in nineteen of them (73%) was between the 1st and the 4th days of antibiotic (table 3). None of them required hemodialysis and all recovered complete renal function.

Tables 1 and 2 show the most frequent infection focus and bacteria founded. The exposure to drugs which could cause AKI was analyzed by a chi square test, none of them was associated with the AKI. Also, the relationship between AKI, the cultivated microorganisms, the infection focus and mortality was analyzed. Both, the microorganism and infections focus, have been associated with AKI: PS (OR: 1,22), KN (OR: 1,33), SW (OR: 2,40) and UC (OR: 2,90). On the other hand, PS (OR: 1,81) and KN (OR: 1,92) were associated with death and all the infection focus, except UC, have been associated with higher mortality. In addition, we found than renal failure was associated with a higher mortality (OR: 3,33). Dispite of this, none of them has a statistical significance.

CONCLUSIONS. Although we obtained results similar to those demonstrated in other studies about the incidence of renal failure in the use of colistin, in our population, AKI occurs in the first days of treatment. This could mean that patients require more control at the beginning of treatment and dose adjustments in that period could prevent future kidney damage.

Both the microorganism and the infections focus have been associated to renal fail and death. PS and KN seems to be wich have assosiattion with AKI and mortality in our population. About infections foci, HQ is associated with both renal failure and mortality of patients studied. On the other hand, UC is related with AKI but is not assosiated to mortality. However, none of this was statistically significant.

INTRODUCTION. Ischemia and reperfusion during the stages of cardiac arrest, resuscitation and post-resuscitation can particularly affect the kidney. It causes incomplete repair of tubular cells and the development of fibrosis.
OBJECTIVES. To evaluate the impact of Ischemia-Reperfusion Injury on incidence of Acute Kidney Injury (AKI) and renal outcome in Cardiac Arrest (CA) Survivors treated with TTM 35°C versus no treatement
METHODS. We performed a retrospective study of consecutive comatose patients resuscitated from CA and admitted to our ICU from March 2016 to March 2017. The surface cooling device used for patient with GCS< 8 and treated TTM 35° was Arctic Sun® 5000. Patients with GCS> 8 did not performed TTM 35 ℃ treatment. Data obtained at baseline and at 24,48 and 72 hours were: temperature trend and rate, serum creatinine,diuretic use, urine output, fluid balance. AKI was defined according to KDIGO criteria.
RESULTS. We included 44 patients out of 95 ICU admissions. Twenty-one patients were treated with TTM 35°, while 23 patients did not performed the treament beacuse of GCS >8. In TTM 35° group, according to KDIGO classification, 10 (48%) had no evidence of AKI while 11 (52%) presented AKI during the treatment. In particular, the incidence of AKI was 52% at 24 h, 29% at 48 h and 25% at 72 h from the treatment. In the no treated group, according to KDIGO classification, 11 (49%) had no evidence of AKI while 12 (51%) presented AKI during the observation period. In particular, the incidence of AKI was 21% at 24 h, 16% at 48 h and 28% at 72 h. In overall populaziont, only one patient required renal replacement therapy (2.3%) and he was part of TTM 35° group. Median cumulative FB was -1100 [-6859-3517] ml for all patients; 1120 [-6859-2209] and -443 [-6796-3517] specifically for TTM 35° and not-treated patients. In overall population, ICU mortality was 45 %, and specifically 47.6 % in TTM 35° group and 43.4 % in no TTM group.
CONCLUSIONS. Treatment with a target temperature of 35 degrees can be affected by difficult temperature control and cause damage due to temperature increase. Unfortunately, the beneficial effects of the treatment could be canceled and lead to a worsening of renal function. In those who did not undergo temperature control, a deterioration in renal function is present with a similar mortality rate compared to those treated with TTM 35 degrees and with worse GCS.

Evaluation of high oxygen affinity of bovine PEGylated Carboxyhemoglobin (PEG-COHb) on the renal oxygenation and function in septic rats

B. Ergin[1], P. Guerci[2], C. Ince[1]
[1]Academic Medical Center, Department of Translational Physiology, Amsterdam, Netherlands; [2]University Hospital of Nancy, Department of Anesthesiology and Critical Care Medicine, Nancy, France
Correspondence: B. Ergin

INTRODUCTION. Sepsis is defined as a life-threatening organ dysfunction accompanied with systemic hypotension, microcirculatory disturbance, tissue hypoxia and an unregulated systemic inflammation in response to infection. Hemoglobin-based oxygen carrier's (HBOC's) might be able to provide an extra oxygen carrying capacity as well as fluid replacement in septic patients.

OBJECTIVE. The primary outcome for this study is to improve in microcirculatory perfusion and oxygenation by use of hemoglobin-based oxygen carrier additional to fluid, and provide a better organ perfusion, oxygenation and function in sepsis induced renal microcirculatory disturbance.

METHODS. 36 fully instrumented, mechanically ventilated and anesthetized male *Wistar albino* rats were subjected 6 groups as sham, LPS (25mg/kg LPS i.v), LPS + Ringer acetate (RA, 30ml/kg/h, 1 hours), LPS+ RA+ Norepinephrine (NE, 5mg/kg/min), LPS + RA in addition to 320 mg/kg/h bovine PEG-COHb, and LPS + RA with 320 mg/kg/h PEG-COHb + NE. Systemic and renal hemodynamic, renal oxygenation (Pd-porphyrine phosphorescence life-time technique), blood gas and electrolytes, and biochemistry of PEG-COHb were assessed.

RESULTS. The fluid supplemented with PEG-COHb caused an increase in MAP and CVP levels compared to LPS+RA ($p < .05$) and LPS+RA+NE ($p < .05$) groups during late resuscitation phase (Fig 1).

Despite an improvement of the urine output ($p < .05$), PEG-COHb did not correct the depletion of renal oxygenation and renal blood flow (Fig 2).

Lactate level was depleted by RA+PEG-CO-Hb resuscitation compared to RA alone ($p < .05$) in late resuscitation (Fig 3).

$SvrO_2$ was enhanced after PEG-COHb ($p < .05$) and NE ($p < .05$) treatments but not RA alone. Base excess, HCO_3^-, pH and anion gab K^+ were improved by the fluid resuscitation supplemented with PEG-COHb ($p < .05$) and NE ($p < .05$).

CONCLUSION. To conclude, high oxygen affinity of PEG-COHb appears to have a systemic and peripheral vasoactive property, in oppose to general believe it did not release its oxygen in hypoxic renal tissue and also reduce the oxygen bioavailability in renal cortex. Therefore, we suggested that blood substitute with low oxygen affinity would provide a better microcirculation and re-oxygenation in hypoxic organs.

INTRODUCTION. Sepsis-induced acute kidney injury (AKI) causes high mortality in critical ill patients owing to elevated levels of endotoxin. This situation might be partially attributed to the delayed recognition of AKI when the current diagnosis is based on either an elevation of serum creatinine levels or the detection of oliguria. Metabolomics, possessing diverse detection platforms and multiple analysis methods, is a potential tool for identifying small molecule biomarkers of renal diseases.

OBJECTIVES. This study aimed to explore new early diagnostic markers of septic AKI in rats by metabolomics methods.

METHODS. A rat model of septic AKI was established by intraperitoneal injection of Lipopolysaccharide (LPS, 5 mg/kg). Concentrations of serum creatinine(Scr), blood urea nitrogen(BUN), alanine aminotransferase(ALT), aspartate aminotransferase(AST) and histopathological changes of kidney were determined at 2h and 6h after LPS administration respectively. At the same time, serum metabolites were detected and analyzed by gas chromatography-time-of-flight /mass spectrometry (GC-TOF/MS) to find early diagnostic markers of septic AKI.

RESULTS. 2h after LPS intraperitoneal injection, serum levels of ALT and AST stayed normal, indicating serum metabolites were not affected by liver function and the histopathological analysis revealed renal damage and tubular injury score also increased significantly while Scr and BUN levels had no significant change until 6h after LPS treatment. Meanwhile, at the time of 2h post LPS injection, 24 statistically altered metabolites were detected by GC-TOF/MS, mainly from amino acid metabolism and organic acid metabolism. Among them, 9 metabolites having a larger fold change such as malic acid, glycolic acid, ratio of asparagine/ aspartic acid, acetylglycine, alanine, urea, α-aminobutyric acid, aminomalonic acid and methionine sulfoxide were more sensitive than Scr and BUN.

CONCLUSIONS. Our findings demonstrated that 9 representative differential metabolites above are expected to be candidates for early diagnosis of sepsis-induced AKI in rats.

OBJECTIVE. Acute kidney injury (AKI) is a major complication that affects 20 to 30% of patients undergoing cardiac surgery with cardiopulmonary bypass (CBP). None of the current serum biomarkers (creatinine, NGAL) appears capable to predict AKI following CBP. An Analysis of the urinary metabolomic signatures of patients undergoing CPB using proton-based nuclear magnetic resonance (1H-NMR) spectroscopy could provide a rapid diagnostic approach to AKI. Our goal was to analyze urinary metabolomics and biomarkers variations in patients after CBP and to check their association with postoperative AKI.

MATERIAL AND METHODS. All consecutive patients undergoing elective cardiac surgery with CBP between 17/02/17 and 26/04/17 were studied. Exclusion criteria were: an eGFR < 30 ml/min/1.73 m^2 and a preoperative left ventricular ejection fraction < 40%. AKI was determined according to the KDIGO classification. Continuous mean arterial pressure (MAP) was digitally acquired during CPB. Urine samples were collected at 3 different time points: before the start of CPB, at the end of the CPB procedure, and on the day after surgery in the ICU.

The urinary metabolites changes were analyzed by magnetic resonance spectrometry. Urinary NGAL was assayed by ELISA. A French ethical committee approved this study. All patients provided written consent for study participation and for the biological analysis before inclusion.

RESULTS. 42 patients were included. AKI occurred in 28% (n = 12) of patients. The main characteristics are shown in Table 1.The mean CPB duration was 99 ± 36 min and the mean aortic cross-clamp duration was 75 ± 30 min. There was no correlation between MAP during CBP and KDIGO class after surgery. Baseline renal function (before CPB) influenced the occurrence of AKI. The mean estimated glomerular filtration rate was 78 ± 24 ml/min/1.73 m^2 in individuals without AKI compared with 63 ± 13, 78 ± 24 ml/min/1.73 m^2 in individuals with AKI (p = 0.01). None of the other parameters that could impact renal function after CBP did influence AKI occurrence. Analysis of the urinary metabolomes of the 42 patients before CPB, at the end of the CPB, and on the day after shows that CPB promotes renal metabolic reprogramming and profoundly alters the urinary metabolome (figure 1). We observed 46% of AKI in patients who did not modify their urinary metabolites vs. 10% in those who did, p = 0.02. Urinary NGAL did not vary during the CBP, urinary NGAL (pg/l) was 12±30 before CBP, 16±31 at the end of CBP and 22±27 on the day after CBP (p=0.6).

CONCLUSIONS. A change in urinary metabolomics, indicating renal adaptation, characterized patients whose renal function did not deteriorate after CBP. Neither the per-CBP MAP level nor the post-CBP urinary NGAL values were associated with the occurrence of an AKI.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0165

INTRODUCTION. Calculating Kinetic Glomerular Filtration Rate (GFR) In the Intensive Care Unit (ICU) could improve early detection of acute kidney injury (AKI), as compared to KDGO (kidney improving Global outcomes) classification that only takes into account creatinine and urine output. Creatinine increase could take as much as 36 hrs and urine output can be variable in a non steady state as in ICU patients. Different formulas have been elaborated to provide a mathematical description of the GFR in a non steady state.

OBJECTIVES. To compare different kinetic GFR formulas in critically ill patients with AKI as a way to detect AKI earlier.

METHODS. We enrole 84 patients over 18 years old who developed AKI 3 during their hospitalization and calculate three different kinetic formulas of GFR in a non steady state and compare their results to the GFR calculated by the MDRD (modification in diet in renal desase) and the CKD EPI (Chronic Kidney Disease Epidemiology Collaboration) formulas of the 24 and 48 hours posterior to the day of the kinetic calculation.

We search the electronic records of the patients the maximum value of creatinine (Cr) during their hospitalization in the intensive care, from which, retrospectively, we took the Cr value at the previous 72 h (Cr1) and at the previous 48 h (Cr2) to calculate the Kinetic GFR.

RESULTS. We use Pearson´s r to search for a correlation between kinetic GFR to CKD EPI formula at 24 hrs with an r: 0.637 p=0.001 and at 48 hrs r:0.465, p: 0.001, and to the MDRD formula with an r:0.688, p:0.001 at 24 hrs, and at 48 hrs r:0.526, p=0.001. The best correlation found was the formula from Jelliffe with an r at 24 hrs of 0.696; p= 0.001 and at 48 hrs with and r: 0.501; p=0.001 to MDRD and to CKD EPI at 24 hrs with an r: 0.648; p=0.001 and at 48 hrs with an r: 0.463; p=0.001.

CONCLUSIONS. The results we find in our study and the correlation of the formula from Jelliffe and S. Cheng (Kinetic GFR) with MDRD and CKD EPI make both of them a good option to estimate GFR in patients in the ICU, plus the calculation of the GFR whit a kinetic formula on a daily basis could improve the time of the diagnosis of AKI in patients in the ICU.

Using serum creatinine to estimate glomerular flitration rate (GFR) may be inadecuate in patients with rapidly-changing renal function

M. Herrera-Gutiérrez[1], M.D. Arias-Verdu[1], J. Barrueco-Francioni[1], M. Monsalud Arrebola[2], M.J. Diez de los Rios[3], G. Seller-Perez[1]

OBJECTIVE. To assess whether estimation of the GFR using the CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration)in patients with rapid changes in thefiltration rate can be considered adequate for monitoring.

METHODS. We undertook a retrospective exploratory study of a series of patients undergoing kidney-pancreas transplantation. After

admission to the ICU we determined the GFR by creatinine clearance (CrCl) in a one-hour urine collection and compared it with the GFR reported by the laboratory (CKD-EPI). We selected these patients as they showed rapid recovery of the GFR after transplantation, requiring adjustment of drugs (immunosuppressants, antivirals, etc.) based on their GFR and because they had their CrCl measured during follow-up in our unit. For the statistical analysis we used paired sample tests (Wilcoxon) for a significance of 0.05. The data are shown as mean (standard error of the mean). Signed informed consent was obtained accepting use of the data obtained during this process.

RESULTS. We studied 16 patients (43.8% women, mean age 41.2±4.3 years) with a total of 37 determinations of CrCL in the immediate post-operative transplant period. On admission the average APACHE II was 21.7±1.01 and SOFA 4.9±0.3. Median ICU stay was 4 days (interquartile range 4).

The mean GFR using CrCl on day 1 was 39.9±7.5 mL/min versus CKD-EPI 20.1±2.1, p 0.029; day 2: 58.3±8.9 versus 37.4±5.2, p 0.002; day 3: 74.1±16.9 versus 52.6±11.9, p 0.016; and day 4: 63.9±20.9 versus 59.6±14.2, p ns. Figure 1.

CONCLUSION. Creatinine kinetics makes estimation of the GFR erroneous when there are rapid changes in the filtration rate. Contrary to what is generally accepted, we propose that in this setting the use of serum creatinine or formulas derived from it prove inadequate and that estimation by creatinine clearance with short time intervals is the only means that can reflect in a practical way the changes in GFR. This conclusion may be relevant for adjusting drug dosing according to the GFR.

Right dose, right now: volume-based urine collection to assess creatinine clearance in the critically ill

L. Fleuren[1], H. Lemmens[1], H.J. de Grooth[1], L. Roggeveen[1], T. Guo[1,2], P. Thoral[1], K. Jorna[1], H. Oudemans-van Straaten[1], P.W.G. Elbers[1]

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0167

INTRODUCTION. Glomerular filtration rate (GFR) is a pivotal parameter for guiding antibiotic dosing to prevent toxic and subtherapeutic concentrations in ICU patients. Plasma creatinine-based formulas to estimate GFR, however, are unreliable in the critically ill. Additionally, the clinical gold standard of 24-hour creatinine clearance (CrCl) is error prone and delays decision making. Shorter time windows have shown reasonable agreement with 24-hour CrCl but require strong nursing commitment. Lastly, shorter time windows potentially introduce sampling

errors by yielding low or very low volumes, especially in renal dysfunction. Therefore, we propose the concept of volume-based urine collection to improve sampling accuracy, ease of collection, and readiness to serve clinical decision making. We hypothesize that this concept could improve personalized antibiotic dosing.

OBJECTIVES. The volume based urine collection concept involves nurses to collect a predetermined volume of urine and record its collection time in order to calculate CrCl. Our main goal was to identify patients with very low and augmented CrCl as they are likely to benefit most from dosing adaptations.

METHODS. We included non-anuric adult patients that were admitted to our 24-bed tertiary ICU. For each patient, total urine produced in a two-hour time window was collected. At midpoint, i.e. after one hour, serum creatinine was determined. At that same time point, collection of a 10mL sample started and its collection time was recorded. Subsequently, the additional time it took to fill up the initial sample to a total of 30mL was recorded. Predictive performance of CrCl in the 10mL and 30mL samples to identify very low and augmented renal function was determined and compared to the two-hour samples. In addition, correlation and agreement between methods was assessed.

RESULTS. Data were obtained from 95 patients. A positive correlation was observed for CrCl in 10mL and 30mL samples compared to the 2-hour samples, although Bland-Altman analysis showed a percentage of error greater than 30%. The positive predictive value for patients with CrCl < 30mL/min/1.73m^2 was 88% in the 10mL and 73.8% in the 30mL sample. For CrCl >130mL/min/1.73m^2, the positive predictive values were 85.7% and 79.1% for the 10mL and 30mL sample, respectively.

CONCLUSIONS. The concept of volume-based urine collection for determination of creatinine clearance is feasible and helpful. Using a volume as low as 10 mL, very low as well as augmented creatinine clearance could be predicted. This could benefit bedside adjustment of antibiotic dosing. Interestingly, the volume-based method does not provide the same information as the time-based method in our sample. Possible explanations include inaccuracies in sample collection, but also rapid fluctuations in renal function.

Managing ICU infections

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0168

INTRODUCTION. The incidence of severe malaria increased since early 2000. Patients at risk, clinical characteristics and prognosis changed during the last decade with the approval of artesunate in 2012.

OBJECTIVES. To describe the epidemiology of patients admitted in a referral Intensive Care Unit (ICU) in France for severe malaria and to analyze changes in clinical presentation and outcomes since artesunate became first-choice treatment.

METHODS. Retrospective observational single-center study in the medical ICU of a referral university hospital conducting on patients admitted for severe malaria over a 14-year period (2004-2017). Demographic variables, severity scores, WHOs severity criteria on

admission, treatment, ICU and hospital lengths of stay were collected. Patients' characteristics and outcomes were compared between two periods, namely 2004-2012 and 2013-2017 when artesunate has become first-choice treatment. A poor outcome was defined as the composite endpoint of death, or ICU length of stay >2 days, or requirement for vasopressors, invasive mechanical ventilation and/or renal replacement therapy started after the first day in ICU. Univariate analysis and stepwise multivariate logistic regression stratified by period were performed to identify factors associated with a poor outcome. Data are presented as median (interquartile range) or numbers (%).

RESULTS. 189 patients were included, 98 before and 91 after 2013. Infection was acquired mainly in countries from West and Central Africa (93.6%). Main epidemiological and clinical characteristics are on Table. Even if the number of WHO criteria for severe malaria was comparable in both groups, SAPS II, SOFA and ICU length of stay were significantly higher before 2013. Treatment started before ICU admission was similar between periods. Patients visiting friends or relatives (VFR) in their home country or living in endemic areas were more frequent after 2013 (p = 0.07).

Poor outcome occurred in 63 cases before 2013 and 32 cases after 2013 (p< .01). Risk factors of poor outcome were impaired consciousness (adjOR = 3.25 ; 95%CI(1.50-7.07), p = 0.003), shock (adjOR = 3.46 ; 95%CI(1.36-8.85), p = 0.01) and creatinine >265 µmol/L (adjOR = 14.16 ; 95%CI(4.95-40.48), p< .001). Patients VFR or living in endemic areas were associated with a better outcome (adjOR = 0.34 ; 95%CI(0.15-0.77), p = 0.01). In the final model, artesunate therapy did not significantly improve the outcome as compared to quinine-based therapy (adjOR = 0.53 ; 95%CI(0.16-1.71), p = 0.28).

CONCLUSION. Patients with malaria admitted in our ICU after 2013 were less severe than those before 2013. These trends could be partially explained by the increasing proportion of immune patients VFR or living in endemic areas. After adjustment on severity and stratification by period, artesunate was not significantly associated with a better outcome than IV quinine. Other factors such as changes in virulence of plasmodium should be studied.

Diagnostic and prognostic value of HMGB1 for patients with late-onset ventilator-associated pneumonia

L. Dong, L. Li
Wuxi People's Hospital affiliated to Nanjing Medical University, Intensive Care Unit, Wuxi, China
Correspondence: L. Dong
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0169

INTRODUCTION. The diagnostic and prognostic value of HMGB1 for patients with late-onset ventilator-associated pneumonia (VAP) remains unclear

OBJECTIVES. To explore the diagnostic and prognostic value of high mobility group box-1(HMGB1) for patients with late-onset VAP.

METHODS. A total of 164 late-onset VAP patients were enrolled from June 2013 to May 2015 in the ICU of Wuxi People's Hospital affiliated to Nanjing Medical University. The basic characteristics and clinical data were collected, while serum HMGB1, procalcitonin (PCT), C-reactive protein(CRP), clinical pulmonary infection score(CPIS) and acute physiology and chronic health evaluation II(APACHEII) were measured. Patients were divided into the death group and the survival group according to 28 d survival status. The basic characteristics and clinical data between groups were compared. The values of sTREM-1, PCT, CPIS and APACHEIIfor predicting 28 d death were evaluated by receiver operating curves(ROC). The surviving curve was drawn by Kaplan-Meier method. The possible prognostic factors were analyzed by univariate and logistic multivariate analysis.

RESULTS. There were 88 patients in the survival group and 76 patients in the death group, the basic characteristics between groups exhibited no difference(P>0.05). The serum s HMGB1, PCT, CPIS and APACHEII were higher in the death group[(289.50±18.45) pg/ml, (123.86±12.74) pg/ml, (17.20±1.74) and (16.58±3.43)] than in the survival group[(154.11±12.61) pg/ml, (79.81±193.45) pg/ml, (11.79 ±1.93) and (7.23±1.12), all P< 0.05].The areas under the ROC of HMGB1, PCT, CPIS and APACHEII for predicting 28 d death were 0.84 ±0.04(95%CI:0.75-0.92, P< 0.01), 0.65±0.05(95%CI:0.55-0.74, P=0.49), 0.67±0.06(95%CI:0.55-0.79, P< 0.01), 0.79±0.04(95%CI:0.70-0.87, P=0.03) respectively. Patients were assigned into two groups by the best cutoff point of HMGB1=175.00 pg/ml, Kaplan-Meier survival analysis showed that 28 d survival rate in the low HMGB1 group was significantly higher than that in the high HMGB1 group (82.5% vs 63.4%, χ^2=3.96, P< 0.05). Multivariate logistic regression analysis showed that HMGB1 (OR=1.08,95%CI:1.04-1.13,P< 0.01) and APACHEII (OR=1.39,95%CI:1.15-1.67,P< 0.01) were both risk factors associated with 28 d death.

CONCLUSIONS. Serum HMGB1 can be used as a reliable predictor for the outcome of patients with late-onset VAP.

Catheter associated urinary tract infections in an intensive care unit of a teaching hospital in Istanbul

A. Inan[1], A. Ozgultekin[2], S. Aksaray[3]
[1]University of Health Sciences , Haydarpasa Numune Training and Research Hospital, Infectious Diseases, Istanbul, Turkey; [2]University of Health Sciences , Haydarpasa Numune Training and Research Hospital, Anaesthesiology and Intensive Care, Istanbul, Turkey; [3]University of Health Sciences , Haydarpasa Numune Training and Research Hospital, Microbiology, Istanbul, Turkey
Correspondence: A. Inan
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0170

INTRODUCTION. Catheter associated-urinary infections (CAUTI) are one of the most frequent hospital acquired infections in ICU. The infections increase morbidity, mortality, length of hospital stay, and cost. Therefore, early and effective empiric antimicrobial therapy are essential and unit-spesific CAUTI rates and CAUTI causing organisms should be determined.

OBJECTIVES. The aim of the study was to evaluate the rate of hospital acquired (CAUTI) and the change of profiles causative microorganisms in an intensive care unit (ICU) of a teaching hospital.

METHODS. CAUTI was diagnosed by using the clinical criteria of the Centers for Disease Control and Prevention. Isolated strains was identified and antibiotic resistance of species was determined by the disk diffusion method according to the The European Committee on Antimicrobial Susceptibility Testing criteria and Vitek 2 system. Fisher exact test was used for the statistical analysis.

RESULTS. Between January 2010 and December 2017, a total of 8756 patients hospitalized for 59,317 patient days in ICU and acquired 184 urinary infection (2.10 per 100 patients, and 3.13 per 1,000 patient days). The most frequently isolated microorganisms were *Candida spp*, *Enterococcus spp*. and *Enterobacteriacea spp*. The incidence densities of infections decreased from 5.79 to 0.81 per 1,000 device-days (p< 0,05) for catheter-associated urinary tract infection (CAUTI) during the study period. It was found that an increase in the proportion of *Enterococcus spp.* isolated from CAUTI (from 17.0 % to 20.0 %, p=0.716), and a decrease in the proportion of *Candida spp.* isolated from CAUTI (from 45.5% to 20.0%, p< 0.05).

CONCLUSIONS. In conclusion, CAUTI rates are decreasing in our ICU. An increasing trend of infections caused by *Enterococcus spp.* and a decrease in the proportion of *Candida* isolates is the striking findings of this study.

Diagnostic and prognostic value of HMGB1 for patients with abdominal infection of severe acute pancreatitis

L. Dong, L. Li
Wuxi People's Hospital affiliated to Nanjing Medical University, Intensive Care Unit, Wuxi, China
Correspondence: L. Dong
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0171

INTRODUCTION. The diagnostic and prognostic value of HMGB1 for patients with abdominal infection of severe acute pancreatitis (SAP) remains unclear

OBJECTIVES. To explore the diagnostic and prognostic value of high mobility group box-1(HMGB1) for patients with abdominal infection of SAP.

METHODS. A total of 103 SAP patients were enrolled from June 2013 to May 2015 in the ICU of Wuxi People's Hospital affiliated to Nanjing Medical University. The basic characteristics and clinical data were collected, while serum HMGB1, procalcitonin (PCT), Ranson score and acute physiology and chronic health evaluation II(APACHEII) were measured. Patients were divided into the death group and the survival group according to 28 d survival status. The basic characteristics and clinical data between groups were compared. The values of HMGB1, PCT, Ranson and APACHEIIfor predicting 28 d death were evaluated by receiver operating curves(ROC). The surviving curve was drawn by Kaplan-Meier method. The possible prognostic factors were analyzed by univariate and logistic multivariate analysis.

RESULTS. There were 76 patients in the survival group and 27 patients in the death group, the basic characteristics between groups showed no difference(P>0.05). The serum HMGB1, PCT, Ranson and APACHEII were higher in the death group[(289.50±18.45) pg/ml, (823.86±182.74) pg/ml, (7.20±1.74) and (19.58±3.43)] than in the survival group[(154.09±12.71) pg/ml, (579.81±193.45) pg/ml, (4.79±1.93) and (17.23±3.12), all *P*< 0.05]. The areas under the ROC of HMGB1, PCT, Ranson and APACHEII for predicting 28 d death were 0.84±0.04

(95%CI:0.75-0.92, *P*< 0.01), 0.65±0.05(95%CI:0.55-0.74, *P*=0.49), 0.67 ±0.06(95%CI:0.55-0.79, *P*< 0.01), 0.79±0.04(95%CI:0.70-0.87, *P*=0.03) respectively. Patients were assigned into two groups by the best cutoff point of HMGB1=200.00 pg/ml, Kaplan-Meier survival analysis showed that 28 d survival rate in the low HMGB1 group was significantly higher than that in the high HMGB1 group (82.5% vs 63.4%, χ^2=3.96, *P*< 0.05). Multivariate logistic regression analysis showed that HMGB1 (OR=1.08,95%CI:1.04-1.13,*P*< 0.01) and APACHEII (OR=1.39,95%CI:1.15-1.67,*P*< 0.01) were both risk factors associated with 28 d death.

CONCLUSIONS. Serum HMGB1 can be used as a reliable predictor for the diagnosis and outcome of patients with abdominal infection of SAP.

INTRODUCTION. Influenza is an acute respiratory disease which can cause local outbreaks or seasonal epidemics. Although the clinical presentation is mostly asymptomatic or mild, it can be fulminant requiring intensive care.

OBJECTIVES. To evaluate outcome of patients admitted to intensive care unit (ICU) due to influenza in 2017-2018 flu season in Turkey.

METHODS. This is the preliminary results of a retrospective multicenter study conducted in 10 medical ICUs. From October 1st 2017 to April 5th 2018, all adult patients with confirmed influenza infection admitted to ICUs were included and demographic and clinical features and ICU outcome were evaluated.

RESULTS. A total of 99 patients were included. The mean (±SD) age was 64.2±16.8 years and 51.4% were male. The mean body mass index (BMI) was 27.3±7.4 kg/m². Chronic cardiac disease (56.6%), lung disease (45.5%), and diabetes (33.3%) were the most common underlying diseases. The mean APACHE II, first day SOFA scores and PaO₂/FiO₂ ratio were 19.7±8.1, 6.0±4.1 and 132.4±80.8, respectively. Of them, 70.7% received noninvasive mechanical ventilation, 29.0% received high flow nasal oxygen and 52.5% required invasive mechanical ventilation. 56.6% of the patients had sepsis, 44.4% shock and 40.5% acute renal failure. 65.7% patients were infected with Influenza A, 30.3% with Influenza B and 4% with both. 20.7% of the patients had concomitant positive viral serology for RSV and rhinovirus. 29.3% of patients had positive respiratory bacterial cultures within 72 hours of admission. The mean ICU and hospital length of stay were 13.8 ±13.9 and 23.4±21.8 days, respectively. ICU mortality rate was 31.3%.

Hospital mortality rate was 33.3%. In bi-variate analysis, increased age, APACHE II and SOFA scores; presence of sepsis, shock, chronic renal failure and malignancy; and invasive mechanical ventilation were associated with ICU mortality. However, in logistic regression analysis, presence of malignancy and invasive mechanical ventilation were the only factors affecting mortality (OR [95% CI] 6.57 [1.18-36.43]; p=0.031 and 50.03 [5.34-468.60]; p=:0.001, respectively).

CONCLUSIONS. ICU and hospital mortality rates in patients admitted to 10 ICUs in Turkey due to Influenza in 2017-2018 flu season were 31.3% and 33.3%. Presence of malignancy and invasive mechanical ventilation were related with increased ICU mortality.

Intensive care in tetanus: management, complications and mortality in 13 cases

S. Bradai, O. Turki, M. Dlela, K. Bouchaala, M. Bahloul, M. Bouaziz
Habib Bourguiba University Hospital, Intensive Care Departement, Sfax, Tunisia
Correspondence: S. Bradai
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0173

INTRODUCTION. Tetanus is an acute infectious disease caused by toxigenic strains of *Clostridium tetani*. The spores enter the body through contaminated skin wounds. This disease is associated with poor outcomes.

OBJECTIVES. To study the demographic and clinical features, outcome, complications and treatment of tetanus patients requiring intensive care unit (ICU) admission in Habib Bourguiba University Hospital, Sfax, Tunisia.

METHODS. It is a retrospective, descriptive and observational study conducted at ICU between January 01, 2006 and December 31, 2017. All Patients suffering from tetanus, admitted during the study period, were enrolled.

RESULTS. There were 13 cases of tetanus. The Sex ratio (male/female) was 1.6. The mean age was 62.1±11.3 years (range 46-82). Regarding the vaccination status, 11 patients were either unvaccinated or didn't know their immunization status. The incubation period was on average 10 days (range 3-20). The period of onset was on average 2 days (range1-5). All patients developed lock jaw, neck stiffness, dysphagia and muscle rigidity. Ten patients developed spasms. Only one patient hadn't developed autonomic instability. All patients needed mechanical ventilation and sedation with a mean duration of 20±15 days (range 0-57). Ten patients needed tracheotomy. The APACHEII score ranged between 3 and 19 with an average of 8. The mean DAKAR score was 2. The mean PHILIP score was 15 (range 7-19). The mean M.Thwaites score was 3 (range 0-11). According to Ablett classification, the majority of our patients (6 patients) belonged to grade II, 1 patient had grade I, 2 patients had grade III and 3 patients had grade IV. Pulmonary complications were dominated by ventilator-associated pneumonia (9 patients). Eight patients had autonomic cardiovascular disturbances. Other systemic complications were observed: gastro-intestinal stasis in 3 patients, acute kidney failure in 3 patients, myopathies and neuropathies in 3 patients. All patients received the following specific treatment. All wounds were cleaned and debrided. Immunotherapy and vaccination were administrated by intramuscular injections in two different sites. The association of Penicilline G and Metronidazole remains the antibiotic most frequently used (11 patients). To control muscle spasm, Benzodiazepines were used with mean dosage of 200mg and mean period of 12 days. Mean ICU stay was 26.6±15.8 days. Five patients died. The mortality rate was 38.5%.

CONCLUSIONS. Tetanus is fortunately a rare disease in Tunisia and is entirely preventable by vaccination. Major therapeutic challenges lie in the control of spasms and muscular rigidity, autonomic dysfunction and the prevention of complications associated with prolonged critical illness.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0174

INTRODUCTION. The increasing problem of antimicrobial resistence (AMR) in the intensive care units, constitutes a serius threat to public health of global reach,

OBJECTIVES. To identify and to describe the MDR map in our ICU and its evolucion among the last six years (from 2012 to 2017), as well as analyce several epidemiological and clinical factors associated.

METHODS. Retrospective study including all patients admitted from 2012 to 2017 in the ICU in a tertiary hospital. Data concerning demographic characteristics and clinical history were collected from each patient. We analysed the MDR bacteria infection and colonization cases in our ICU. We used the MDR pathogens cataloged as such by "Resistencia-Zero" project. We do also analysed the percentage use of several antibiotics, as well as its possible association with resistance map changes.

RESULTS. There were 269 patiens with infection by MDROs in these period, of these, 68.57% were male. The length of stay in ICU was 8.11 days. The average age was 62.73 years, with an APACHE II average of 13.48. The global mortality in these patiens was 18.83%.

A situation of a very high rate of Imipenem-Resistant *Acinetobacter* was detected, we could say this is an *endemic* infection. This situation changes in 2016 when the number of cases decreases, although a high percentage of cases still persists in comparation with the nationally data . In the same year there was a increase in the appearance of *Enterobacteriaceae ESBL*, being similar to the national registry. A decrease of more than 50% in carbapenem use is also detected this year.

Our *MRSA* cases are anecdotal. Also noteworthy is the absence of Vancomicin resistant *Enterococcus*.

In 2017 *Carbapenem-R GN* makes its appearance on stage, a fact that we intent to analyse later.

CONCLUSIONS. This study shows a turnaround in the pattern of antimicrobial resistance in our intensive care unit, which consists in a progreive decrease in cases of *Acinetobacter* R infection, and an increase in infections by *Enterobacteriaceae ESBL* (the same data were found also in the national registry). We think it could be related to a decrease use of carbapenem, as well as the aplication of selective decontamination of the digestive tract (SDD). The frecuency of infections by the rest of the multidrug-resistant microorganisms analysed remains practically unchanged or with minimal changes over the years. It is remarkable the appereance in 2017 of *Carbapenem-R GN*. This is an alarming fact, wich we should analyse in the future. We consider that knowing own patterns, their changes and relationed factors is esential to prevent and control AMR, and may help to reduce the burden of MDR in the ICUs.

MDR colonization: what´s the matter in the perioperative setting?

A. Lerose, K. Donadello, D. Cigolini, L. Gottin, E. Polati
University of Verona, Department of Surgery, Dentistry, Pediatrics and
Gynaecology, Verona, Italy
Correspondence: A. Lerose
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0175

INTRODUCTION. Multi-Drug-Resistant (MDR) colonization is an actual
major issue in intensive care units (ICUs) and perioperative medicine,
frequently resulting in life-threatening infections.
OBJECTIVES. The aim of this study was to evaluate the post-
operative course of patients requiring ICU admission after surgery
and to compare MDR colonized patients (pts) undergoing abdominal
surgery to non colonized ones.
METHODS. We retrospectively analyzed all consecutive patients
undergoing surgery in our hospital for a three-month period (July-
September 2017) who required admission to our 12-bed-medico-
surgical ICU on post-operative day (POD) 0 (Dept Anesthesia and
Intensive Care B, Policlinico GB Rossi). We then compared MDR col-
onized (rectal and/or pharyngeal swab) patients (MDR+) to non col-
onized patients (MDR-) for post operative complications, ICU and
hospital length of stay (LOS) and mortality. We also investigated
the impact of administered targeted perioperative antibiotic ther-
apy compared to empiric antibiotic prophylaxis.
RESULTS. 70 pts were included in the study (47 men), median age
67(55-79) years; they underwent either elective (n=57, 81.4%) or
emergency (n= 13, 18.6%) surgery; 33 pts (47.1%) were submitted to
pancreatic surgery, 15 (21.4%) to intestinal resection, 13 (18.6%) to
hepato-biliary surgery, and the rest to other kind of abdominal sur-
gery; they were admitted to ICU on POD 0 for scheduled (n =52,
74,3%) or unscheduled (n= 18, 25,7%) intensive PO monitoring.
These latter were admitted because of surgical length (10, 4.9%), sep-
tic episode (4, 5.7%), intraoperative hypotension (2, 2.9%) , intraoper-
ative hemorrage (2, 2.9%).
11 pts were MDR+ pre operatively (15,7%), 4 of whom were either
Klebsiella Pneumoniae Carbapenemasis Producer or Vancomycin Re-
sistant Enterococcus (VRE) colonized and 7 pts were Extended
Spectrum Beta Lactamase (ESBL) Escherichia Coli colonized. Both ICU
and hospital LOS were significantly higher in MDR+ compared to
MDR- (16±23 vs 2±3 and 37±25 vs 22±16, respectively, p < 0.05).
Hospital mortality occured in 4 patients, all MDR+ (p< 0.001). Postop-
erative complication incidence and type did not significantly differ
between the two groups.
4 MDR+ patients (5.7%) received targeted pre-operative antibiotic
therapy compared to standard prophylaxis but this did not influence
their outcome (small number).
CONCLUSIONS. Pre-operative surveillance swab positivity correlates
with both ICU and hospital LOS and post-operative mortality, no
matter swap and surgical sites. Targeted antibiotic therapy may be
routinely used to improve patients' outcome. More studies are
needed to further investigate the possibile therapeutic options in
MDR+ patients undergoing surgery.

**A point prevalence study of ventilator associated pneumonia (VAP)
across four London ICUs**

N. Shah[1,2], J. Hadley[1,3], P. Zolfaghari[1,3], C. Hinds[1,4]
[1]Queen Mary, University of London, London, United Kingdom; [2]Queen
Elizabeth Hospital, Department of Chest Medicine, London, United
Kingdom; [3]Royal London Hospital, Intensive Care Medicine &
Anaesthesia, London, United Kingdom; [4]St Bartholomew's Hospital,
Intensive Care Medicine, London, United Kingdom
Correspondence: N. Shah
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0176

INTRODUCTION. There are few studies describing the incidence
and prevalence of VAP in the UK. This may partly be due to the
complexity of the various definitions of VAP in current use. We
describe a one-day point-prevalence study of VAP using a prag-
matic definition and a specially adapted electronic case report
form.
OBJECTIVES. To determine the point prevalence of VAP with 30-day
follow-up using an electronic data collection tool in 4 ICUs at Barts
Health NHS Trust: The Royal London (RLH-trauma/neuro/general),
St. Bartholomew's Cardiac ICU (SBH cardiac), St.Bartholomew's gen-
eral/oncology (SBH), and Whipps Cross University Hospital (WXH-
general).
METHOD. This was a multi-centre 24-hour cross-sectional observa-
tional study. Data was collected for all patients receiving Advanced
Respiratory Support over a 24-hour period on the 13 April 2016 with
30-day follow-up on the 13 May 2016. Study data was collected
using a purpose built REDCap™ (Research Electronic Data Capture)
portal hosted at Queen Mary University of London (UK). Additional
data were collected for patients with a study definition of VAP (com-
menced on antibiotics for chest sepsis 48 hours or more after initi-
ation of invasive ventilation). This audit was registered with the
clinical effectiveness unit.
RESULTS. Data was submitted for 35 patients across 4 ICUs on study
entry: mean age 54.7 years (std±18.1,17-83); male 28 (80%) and
female 7 (20%); mean ICU length of stay 18.8 days (range 1-126); dur-
ation of ventilation 17.3(std±26.6,1-126); mean FiO_2 0.4 (std±0.1,0.21-
0.90). Seven patients (20%) met the study definition for a current
VAP: mean age 60.3 years (std±19.0,34-82); mean initial APACHEII
score 21.1 (std±8.6,13-34); mean ICNARC score (5 of 7 patient data)
17.8 (std±4.0,12-22) and mean initial SOFA score (5 of 7 patient data)
7.2 (std±3.9,3-13).
30-day follow-up for those who met study definition of VAP revealed:
mean ventilator days 23.7 (±19.7,8-65); mean ICU LOS (days) 26.4
(±17.8,13-65); 2 patients (28.6%) died on ICU; 3 patients (42.9%) were
discharged from ICU; 2 patients (28.6%) remained as ICU inpatients;
mean hospital LOS (days) 38.4 (std±14.8, 21-65) and tracheostomy
was performed in 4 (57%) patients. Pathogens were identified in 6
cases (85.7%), E.coli was isolated most frequently (3/7, 42.9%); Pro-
teus spp. in 2 cases (28.6%); S.aureus (MSSA) in 2 cases (28.6%); with
single cases of Klebsiella spp., unidentified S.aureus and Candida spp.
Antibiotics for VAP included piperacillin tazobactam (4); vancomycin
(2); meropenem (2); amikacin (1) and fosfomycin (1).
CONCLUSIONS. This pilot study of an electronic data collection portal
was successfully used to determine a point prevalence of 20% (7/35)
of VAP across 3 ICUs with a varied case-mix. The methodology used
showed good feasibility to carry out a wider national VAP study to
identify the epidemiology of VAP.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0177

INTRODUCTION. Hospital acquired infections (HAI) due to gram
negative bacteria are oppose tremendous challenges in the spectrum
of critically ill patients. These infections are associated with higher
morbidity, mortality and healthcare costs. Besides Acinetobacter bau-
mannii and Pseudomonas aeruginosa, the Enterobacteriaceae family is
increasingly responsible for nosocomial infections in the recent years.
OBJECTIVES. To determine the frequency, the microbiological charac-
teristics, risk factors and outcomes of HAI due to Enterobacteriaceae
in a 6 separate beds MICU in Tunisia.
METHODS. A retrospective analysis of chart reviews of all patients
admitted more than 48H to the 6-bed tertiary MICU of Yasminette re-
gional Hospital since the inauguration of the unit on October 17th,

2016 to July 17th, 2017.Were assessed the patients' characteristics, bacteriological aspects of HAI and outcomes. Univariate and multivariate regression analyses were performed to identify factors independently associated to *Enterobacteriaceae´* HAI.

RESULTS. Of the 97 admitted patients during the 9 months of the study, 90 (92.7%) were eligible and they acquired 57 nosocomial infections. The main characteristics of the patients were : mean age, 55.9±20.6 ; male gender, 63(70%) ; SAPS II, 41.7±20.4 ; invasive mechanical ventilation, 49(50.5%) ; median mechanical ventilation duration, 5[3-17] days ; length of stay, 8[4-15.5] days ; mortality, 28(28.9%). 22(38.6%) HAI episodes were due to *Enterobacteriaceae* and they were detected in 14(15.5%) patients. The identified *Enterobacteriaceae* were responsible for 8 (36.4%) central venous catheter acquired infections (CVC-AI), 7 (31.8%) ventilator associated pneumonias (VAP) and 7 (31.8%) urinary tract infections (UTI). 2 (28.5%) VAPs, 2 (25%) CVC-AIs and 1 (14.2%) UTIs were poly-microbial (associated with *Pseudomonas aeruginosa*). 13(59.1%) of the isolated bacteria were Extended-spectrum β- lactamases (ESBL) producers and 6(27.2%) were carbapenemases producers. *Klebsiella pneumoniae* was the most frequently isolated microorganism: 40.9% (n = 9). Table 1 describes the type of nosocomial infection according to the responsible *Enterobacteriaceae*. The independent risk factors for Enterobacterial infection were acute renal failure upon admission (OR=6.23, CI95[1.06; 36.56], p=0.043) and a length of stay ≥ 12 days (OR=8.36, CI95[1.26; 55.31], p=0.028).

CONCLUSIONS. More than the third (38.6%) of nosocomial infections in our MICU are due to *Enterobacteriaceae* with a recurrent presence of *Klebsiella pneumoniae*. The alarming emergence of carbapenem-resistant strains requires improved measures of infection control and prevention.

Table 1 (abstract 0177). Type of nosocomial infection according to the responsible Enterobacteriaceae

	Central venous catheter acquired infection	Ventilator associated pneumonia	Urinary tract infection	Total
Klebsiella pneumoniae	4	1	4	9
Escherichia coli	1	3	2	6

INTRODUCTION. Healthcare-related infections are controllable and avoidable infectious diseases.

OBJECTIVES. The aim of this study is to reduce catheter associated urinary tract infection (CA-UTI) rates by carrying out a constructive training programme for the staff working in Intensive Care Units (ICU) of the Hospital.

METHODS. This study is a retrospective and prospective interventional thesis study. There are three Anesthesiology and Reanimation ICU in our hospital. The health staff of these three units consists of 62 people. There are 38 nurses, 17 assistant health personnels and 7 doctors. Constructive training interviews were conducted with all ICU staffs between 1-31 December 2016 to prevent CA-UTI. Before the constructive training programme, CA-UTI data of ICUs from 1 June to 30 November were obtained from the infection control committee (ICC) of the hospital. After the constructive training programme, the surveillance data were obtained from 1 January to 30 June and the cases were evaluated with ICC. In the hospital, National Hospital Infection Surveillance Standards are used according to CDC´s 2008 diagnostic criteria, as diagnostic criteria for health-care related infections by ICC. Data was compared before and after constructive training, statistical analysis of the study was done by SPSS version 15.0 program. A four-question survey was conducted by the staff to assess the constructive training programme. The result of this survey is also evaluated.

RESULTS. When the 6-month CA-UTI rates of the ICUs before and after the constructive training programme were compared, pre-training and post-training CA-UTI rates were 8.3 and 8.7 (p=0,837) in ICU-1 respectively; 7.0 and 8.1 (p=0,745) in ICU-2; In ICU-3 it is calculated as 7.3 and 9.9 (p=0,495). There was no statistically significant difference found between pre-training and post-training data for these three ICUs. According to the assessment questionnaire, 92% of nurses (35/38) and 88% of assistant health personnels (15/17) were positively effected from the training programme but among them, 63% of nurses and 33% of assistant health personnel were able to apply what they learned.

CONCLUSIONS. In all three ICUs, the intervention of constructive training did not significantly reduce the CA-UTI rates alone. However, the awareness of the staff about CA-UTIs were increased and also improvable, but time-consuming problems are identified. As a suggestion, the constructive training programme which aims to prevent CA-UTIs should be improved.

Clinical outcome, microbiological spectrum and antibiotic susceptibility of clinical isolates from adult intensive care unit in a tertiary care hospital in India

A. Sardar, A.M. Kumar, L. Kashyap, V. Darlong, P. Khanna
All India Institute of Medical Sciences, Anaesthesiology Pain and Critical Care, New Delhi, India
Correspondence: A. Sardar
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0179

INTRODUCTION. Incidence and prevalence of hospital acquired infections are increasing alarmingly over the years throughout the world.

OBJECTIVE. To find out microbiological spectrum, antibiotic susceptibility of the organisms prevalent in the intensive care unit (ICU) and to determine the cause of ICU mortality, clinical outcome & organ dysfunction due to nosocomial infection.

METHODS. The study was conducted in a 12 bedded mixed medical and surgical ICU of the All India Institute of medical Sciences, New Delhi, India. A cross sectional retrospective analysis were carried out based on ICU chart review of microbiological data, clinical parameters of all the patients whose clinical sample's culture came out to be positive during the ICU stay from 1st May 2014 to 30th April 2016.

RESULTS. Total 1243 patients were admitted in the specific time period. Out of which 172 (100 alive and 72 dead) patients were found to be microbiological culture positive of their clinical samples and included in the analysis. Total 207 organisms were isolated from the clinical samples. Only 17 samples had grown gram positive infection where as rest 190 samples had gram negative infection. Most common organisms were Pseudomonas, Acinetobacter, Klebsiella and E.coli. Most of the gram negative organisms were multidrug

resistant. Risk factors associated with overwhelming gram negative infections were diabetes mellitus, hypotension, cardiovascular support >7days, respiratory support >15 days, renal support >2days, haematological support >2days, pre admission placement of arterial catheter, pre admission hemodialysis therapy and immunosuppressive drugs, whereas presence of COPD was found to be associated with survival.

CONCLUSIONS. Most of the hospital acquired infections are fatal, multidrug resistant and carries poor prognosis to the patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0180

INTRODUCTION. Nosocomial infection of the central nervous system is related to neurosurgical procedures, trauma, or rarely to systemic infection[1]. Risk factors include increased drainage duration, intraventricular hemorrhage, surgical technique and CSF leak[2].
OBJECTIVES. Retrospective analysis of NBM treated in the ICU in a 2 year period.
METHODS. During a 2 year period (1/1/2016 - 31/12/2017), 15 patients, managed as NBM and treated in the ICU were identified. Lumbar puncture(LP), CSF analysis, GRAM stain, CSF cultures were performed in all patients(pts). Cellular pleocytosis was consistent with the diagnosis of NBM.
RESULTS. The analyzed sample included 15 non-immunocomprised pts (50±20y and APACHE II score 19±6): 7 had traumatic brain injury, 5 intracerebral hemorrhage, 1 hydrocephalus, 1 tumor and 1 no history of neurosurgery or trauma. 7/15 pts underwent craniectomy, 2/15 aneurysm embolization, 1/15 tumor resection. External ventricular drain(EVD) or intraventricular catheter for intracranial pressure(ICP) monitoring was inserted in 12/15pts.
NBM was diagnosed 12±6 days after ICU admission while ICP catheter/ EVD was retained for 8±4 days. All pts were febrile, 6/15 experienced new onset seizures and 2/15 developed septic shock. Meningeal enhancement or brain abscess was found on CT in 7pts(47%).
NBM was confirmed by a positive CSF culture in 5(33%)pts. In pts with positive and negative CSF cultures, there was no statistically significant difference regarding CRP (117-167mg/L p=0.51), procalcitonin (0.69-0.82ng/ml p=0.87), WBC (15.69x10^9-15.10x10^9/L p=0.80). Differences in CSF WBC (8.394-2.332/µl p=0.12), CSF RBC (34.218-31.837/µl p=0.94), CSF protein (643-250mg/dl p=0.08) and CSF/serum glucose ratio (0,38-0,49 p=0.37) between the two groups were not statistically significant. Isolated microorganisms in CSF cultures were multidrug resistant(MDR) *Klebsiella pn*. and *Acinetobacter baumanii*. In 2/15 pts the EVD/ICP catheter tip culture was positive for *Klebsiella KPC* and MDR *Acinetobacter baumanii*. One patient had a positive blood culture. All pts had previously received broad spectrum antibiotics and 13(87%) were colonized with MDR pathogens. Specific individualized therapy for NBM was administered according to overall clinical and laboratory findings of each patient and despite negative cultures. 2 pts(13%) received intraventricular antibiotics combined with intravenous therapy. Meningitis attributed mortality was 20%.
CONCLUSIONS. Neurosurgical procedure or head trauma must raise a high level of suspicion for intracranial infections. Negative CSF culture should not preclude the diagnosis, given the wide use of broad spectrum antibiotics. Additional clinical, laboratory and imaging characteristics should be co-evaluated in order to avoid treatment delays.

The unrecognized in-ICU days of TB patients without isolation in South Korea

E. Lee, J.S. Kim, H.W. Kim
The Catholic Medical Center,St. Mary's Hospital, Internal Medicine, Pulmonology, Incheon, Korea, Republic of
Correspondence: E. Lee
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0181

INTRODUCTION. Delay in dignosing Mycobacterium tuberculosis (TB) aggravates the nosocomial transmission in a tertiary care hospital, especially in ICU (intensive care unit). Backgrounds: The aim of the study is to estimate the unrecognized in-ICU days of TB patients without isolation in South Korea, using national health insurance claim data.
METHODS. Total patients who had claim data of drug susceptibility test for TB during 2014~2016, which means culture-proven tuberculosis were included. Among them, patients with admission records of ICU during infectious periods were selected, and their in-ICU days were calculated after subtracting periods of isolation. Infectious periods were defined according to the CDC's guideline for contact

investigation. The first day of infectious periods was simply defined as 3 months before doctor's suspicion of TB in patients who received the prescription for respiratory medications, which means he had respiratory symptoms, and 1 month before doctor's suspicion without prescription records of respiratory medications. The last day of infectious periods was defined as the day of first prescription of anti TB medications.

RESULTS. From 2014 to 2016, 1282 cases were identified as having ICU care records during their infectious periods. Among them, 1174 cases had records of staying ICU for at least one day without isolation. Total sum of in-ICU days without isolation were 18,584 person-days during 3 years. Among the 1174 cases of unrecognized in-ICU TB patients, 374 cases underwent bronchoscopy, and 56 cases had records of laryngoscopy during their infectious periods. There were 201 cases of endotracheal intubation, 19 cases of cardiopulmonary resuscitation, 602 cases of nebulizer treatment, 63 cases of of high flow nasal cannula oxygen therapy, and 350 cases of mechanical ventilation during infectious periods in ICU.

CONCLUSIONS. The burden of nosocomial transmission of TB in ICU is still substantial in South Korea.

Evolution of the microbial flora in patients of a Greek ICU over two decades

P. Kontou[1], I. Tsioulis[1], C. Giannaki[1], E. Sourla[1], A. Lavrentieva[1], M. Bitzani[1], I. Kioumis[2]
[1]G. Papanikolaou Hospital, A' ICU, Thessaloniki, Greece; [2]G. Papanikolaou Hospital, Pulmonology Department, Thessaloniki, Greece
Correspondence: A. Lavrentieva

INTRODUCTION. The continuously rising antimicrobial resistance in the ICU is a major problem worldwide. Although the widespread use of antibiotics appears to be the main cause, the relevant studies aren't always conclusive.

OBJECTIVES. The purpose of this study was to evaluate the change of the microbial flora and the level of antimicrobial resistance of bacteria in ICU patients in a timeframe of two decades.

METHODS. This is a retrospective study of the findings of cultures of patients in a general ICU of a tertiary hospital in Greece at the years 1995 and 2016. The cultures were from respiratory samples, blood, tips from central venous catheters, urine, cerebrospinal fluid and wound exudates. The microorganisms evaluated were staphylococci, enterococci, Enterobacteriaceae and non-fermenting Gram-negative bacilli. The antibiotics tested were oxacillin, trimethoprim-sulfamethoxazole, imipenem, ciprofloxacin, ceftazidime, cefoxitin, amikacin, gentamicin and ampicillin-sulbactam.

RESULTS. A similar number of Gram-positive and Gram-negative microbes was identified in 1995, whereas there was a clear benefit in favor of the latter in 2016, which tripled over time. In total, there was a decrease in Gram-positive isolates from 48% in 1995 to 33% in 2016 and a corresponding increase in Gram-negative isolates from 52% in 1995 to 67% in 2016. The most common Gram-positive pathogens were *Staphylococcus aureus* in 1995 and *Staphylococcus epidermidis* in 2016. The 3 most frequently isolated Gram-negative pathogens were *Acinetobacter baumannii*, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*, with a small difference in their ranking at the two time points. Finally, some microbes were isolated in 2016 (*Proteus mirabilis*, *Klebsiella oxytoca*, *Morganella morganii* and *Stenotrophomonas maltophilia*), that were not reported in 1995.

Regarding antimicrobial resistance, there was a fall in MRSA percentage in our ICU by 50% during these years. On the other hand, an increased resistance to all classes of antibiotics was noted concerning *A. baumannii* and *K. pneumoniae* in the more recent year. Interestingly, *P. aeruginosa* showed higher sensitivity to cephalosporins, quinolones and aminoglygocides but not to carbapenems. A major concern was found to be multi-drug resistant (MDR) *A. baumannii* (sensitive only to colistin and tigecycline) that appeared in 2016 in a great percentage (47% of strains). Current rates of *K. pneumoniae* carbapenemase-producing isolates (KPC) are also alarming (68% of strains).

CONCLUSIONS. The differentiation of the microbial flora in ICU patients with time is important. MRSA and other resistant Gram-positive pathogens are not the worst threat in our ICU. The urgent issue is the uncontrollable spread of MDR Gram-negative microbes, which are endemic in our ICU. Nevertheless, the development of antimicrobial resistance due to the widespread use of antibiotics isn't always a fact and is of unpredictable direction.

0183

Acinetobacter baumannii patterns and course in a tertiary-care mixed-type ICU

Y. Durmus, C. Ates, O. Mert, I. Kurt, F. Yilmaz, M. Reis, Z. Ademoglu, H. Aggul, A.S. Uyar, S. Efe, V. Inal
Trakya University Medical Faculty Research Hospital, ICU, Edirne, Turkey
Correspondence: V. Inal

INTRODUCTION. *Acinetobacter baumannii* is an increasingly common nosocomial pathogen and multidrug-resistant strains (MDR-AB) have emerged, most frequent in ICUs.

OBJECTIVES. This study was conducted to review the annual-2017 data of A. baumannii patterns and course in our University based tertiary-care mixed-type ICU, as a part of quality management implementations.

METHODS. The annual data (2017) of patients with isolated *A. baumannii* were retrospectively analyzed at respect of antibiogram/susceptibility and survival patterns.

RESULTS. The overall 445 patients, invasive mechanic ventilator (IMV) and VAP rates were 71% and 12.7%, in addition, central venous catheter (CVC) and CVC related BCI rates were 12.7% and 82% at respect. A. baumannii was isolated in 32 (7%), 24 in endotracheal and eight in central venous catheter of all. We compared A. baumannii to all-patients data as; the mean age was 65 ± 18.3 to 65 ± 16 (ns); LOS was 35.7 ± 7.5 to 8.9 ± 6 days ($p< 0.01$); IMV length 10.2 ± 3.7 to 6.5 ± 3 days ($p< 0.05$), mortality rate was 72% to 44% ($p< 0.05$), at respect. On the other hand, additional gram negatives (87%) and fungal agents (60%) were co-isolated with in A. baumannii positive patients. According to MIC data, the mean stream therapy was required colistin+carbapenem combinations. However, de novo ARF required CVVHD, determined and heralded to colistin in 68% of patients after 1.8 ± 0.6 days of treatment (KDIGO).

CONCLUSIONS. Take home messages; (1)Infections caused by A. baumannii were associated with adverse clinical outcomes, including high rates of morbidity and mortality, prolonged hospital stay, and substantial health care expenses, yet. (2)In addition, colistin-assumptive high ARF rates were also a matter of debate. (3)At last, concomitant MDROs (gr-) and occult IFIs were quite frequent, should be precluded and revised for preemptive or empiric treatments.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0184

INTRODUCTION. Infection with dengue virus is a serious emerging health threat and has commanded considerable medical and public-health concern worldwide in terms of morbidity and mortality. The platelet count is key in management of dengue fever. A relationship between blood groups and disease was first hypothesized by Kaipainen and Vuorinen during 1960, and the gene involved in ABO blood groups was discovered in 1990. We hypothesized association between distribution of ABO Rh blood groups and dengue fever and thrombocytopenia.
OBJECTIVES. The aim of study was to evaluate association between ABO Rh blood groups and dengue fever with respect to thrombocytopenia.
METHODS. Prospective observational study was performed in the ICU of tertiary care hospital with mixed population from June 2017 to Dec 2017. Serum samples were collected from patients with acute febrile illnesses. Acute dengue virus infections were confirmed serologically by enzyme linked immunosorbent assay for immunoglobulin (Ig)M/IgG (four-fold rise) and NS 1 antigen either of one. Standard hemagglutination assays were used to type the blood groups in all patients. The platelet count was done on each day for all patients. We compared ABO and Rh blood-group frequencies in dengue disease.
Statistical analysis was performed with SPSS 17 windows. Comparison between categorical data was performed using Chi Square test.
RESULTS. Results were as per table 1 and 2 given below.
CONCLUSIONS. The frequencies of each blood group in the dengue disease were consistent with those in the general Indian population EXCEPT we observed that dengue infections were higher in individuals with O positive blood group (42.8%). The severe thrombocytopenia was more common in AB blood group (62.5%). These data present further evidence for the association of the blood groups to susceptibility of dengue infection. Further studies are needed to answer why thrombocytopenia was more severe in AB blood group. Thus, from this study we propose that blood group analysis should be done in all patients with dengue fever, this will help us to predict subgroup of patients likely to develop profound thrombocytopenia which can have impact on morbidity and mortality.

Epidemiology and prognosis of ICU nosocomial ventilator-associated pneumonia

N. Foudhaili, M. Fatnassi, H. Maamouri, S. Habacha, N. Brahmi
Poison Control Center, Intensive Care Unit, Tunis, Tunisia
Correspondence: N. Foudhaili
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0185

INTRODUCTION. Ventilator-associated pneumonia (VAP) is an important cause of morbid-mortality.
OBJECTIVES. The aim of the present study was to report epidemiological aspects of VAP and to evaluate its prognosis.
METHODS. It was a 1-year prospective study from April 2015 to May 2016 including all patients undergoing mechanical ventilation for longer than 48 hours. Patients, in whom VAP was clinically suspected with positive direct examination of a blind protected specimen (BPS), were eligible.
RESULTS. Two hundred sixty eight patients were enrolled. Fifty-four VAP episodes were diagnosed in thirty four patients, which represent 1.58±0.85 episode/patient and a frequency of 12%. They were 12 males and 22 females aged of 39±19 years with a mean SOFA score of 5.2±1.8. The delay between admission and VAP suspicion was 5.9 ±2.7 days and between two VAP episodes was a 17±20 day (4-39 days). ICU acquired VAP were microbiologically documented in 32 patients (11%) : *Acinetobacter baumannii* (35%), *Pseudomonas aeruginosa* (33%), *Klebsiella pneumonia* (22%) and methicillin-resistant *Staphylococcus aureus* (7%). Multidrug resistant isolates were extended- spectrum β-lactamases (ESBL) in 10% of cases and carbapenemases in 12%. Initial antibiotherapy included imipenem and colistin according to local ecology and was revised in 33 of cases. The main complications were septic shock (28%), ARDS (24%) and second VAP episode (26%). The mean length of stay was 62.5±10 days (7-180). Favorable outcome was observed in 34 patients (63%). VAP related death in our study are the direct result of the infection , caused by *Pseudomonas aeroginosa* in 7 second VAP episodes (5%) and imipenem-resistant *Acinetobacter baumannii* in 63% of cases.
CONCLUSIONS. Morbi-mortality in nosocomial VAP is often due to respiratory or hemodynamic complications and also resistant strains of pathogens.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0186

INTRODUCTION. Ventilator-associated pneumonia (VAP) is the most frequent hospital-acquired infection among intensive care unit (ICU) patients and is a leading cause of morbidity and mortality. Therefore, early diagnosis and appropriate antibiotic treatment are essential.
OBJECTIVES. The aim of the study was to determine the rate of VAP and the change of profiles causative microorganisms in an intensive care unit (ICU) of a teaching hospital.
METHODS. An active, targeted prospective surveillance was performed by infectious disease specialists and infection control nurses in the unit. VAP was diagnosed by using the clinical criteria of the

Centers for Disease Control and Prevention. Isolated strains was identified and antibiotic resistance of species was determined by the disk diffusion method according to the The European Committee on Antimicrobial Susceptibility Testing criteria and Vitek 2 system. Fisher exact test was used for the statistical analysis.

RESULTS. Between January 2010 and December 2017, a total of 8756 patients hospitalized for 59.317 patient days in ICU and acquired 749 VAP (8.5 per 100 patients and 13.2 per 1,000 patient days). The most frequently isolated microorganisms were *Acinetobacter baumannii, Pseudomonas aeruginosa* and *Enterobacteriacea spp*. The incidence densities of infections decreased from 31.5% to 7.7 % per 1,000 device-days (p< 0,05) for VAP during the study period. It was found that an increase in the proportion of *Klebsiella spp.*isolated from VAP (from 6.0% to 13.2 %, p=0.14), and a significant decrease in the proportion of *Staphylococcus aureus* isolated from VAP(from 7,8 % to 1.8 , p=0.05).

CONCLUSIONS. In conclusion, VAP rates are decreasing in our ICU. An increasing trend of infections caused by *Klebsiella spp*. and a decrease in the proportion of *S.aureus* isolates is the remarkable findings of this study.

Sex-related differences in patients who suffered an acute coronary syndrome

A. Ubeda, I. Fernandez, R. Torcuato, A. Alvarez, A. Fregosi, P. Cobo
Hospital Punta de Europa, Intensive Care Unit, Algeciras, Spain
Correspondence: A. Ubeda

INTRODUCTION. Despite remarkable advances in the treatment of acute coronary syndrome, substantial early patient mortality remains. Individual patients reflect a combination of clinical features that influence prognosis, and these factors must be appropriately weighted to produce an accurate assessment of risk.

OBJECTIVES. To analyze the differences according to gender in patients with acute coronary syndrome (ACS) admittedto the intensive care unit (ICU) of a regional hospital using the ARIAM database.

METHODS. Retrospective analysis performed on a prospective cohort in a 12-bed ICU during 8 years (2009-2017). Demographic variables, comorbidities, risk factors, Killip, location and degree of obstruction, risk scores (TIMI, GRACE) and bleeding score (CRUSADE). Statistical analysis: categorical variables (frequencies and percentages) and numerical variables (mean and standard deviation or medians and interquartile range). Comparisons: X2 test (percentages), Student test (means) and Mann-Whitneytest (medians).Statistical significance with p< 0.05.

RESULTS. 1009 patients were included, 751 (74.43%) male, 258 (25.65) female. Most frequent risk factors: arterial hypertension (AH) (52.6%), dyslipidemia (40.3%), smoking (37.5%), diabetes mellitus (DM) (37.2%), STEMI 466 (46.2%), NSTEMI 543 (53.8%). Complications: shock 96 (9.5%), cardiac arrest 80 (7.9%). Discharge diagnosis: AMI 671 (66.5%), unstable angina 316 (31.1%). Location: inferior 288 (42.9%), anterior 235 (35%), undetermined 100 (14.9%). ICU length of stay (LOS): 4.1 ± 3.8 days. Hospital LOS: 10.5 ± 9.7 days. ICU mortality: 76 (7.5%). Hospital morality: 97 (9.6%).

Men vs. women (bivariant analysis): age (63.02 [±12.62] vs. 69.58 [± 12.60], p< .001), smoking (43.9% vs. 18.6%, p< .001), previous smoker (23.4% vs. 5.4%, p< .001), diabetes mellitus (DM) (34.4% vs. 45.3%, p=.002), arterial hypertension (AH) (48.9% vs. 63.6%, p< .001), congestive heart failure (CHF) (3.6% vs. 8.5%, p< .001), chronic obstructive pulmonary disease (COPD) (7.9% vs. 1.2%, p< .001), elevated ST (51.8% vs. 59.7%, p=.028), TIMI (2.71 [±2.05] vs. 3.30 [±2.36]), p<

.001), CRUSADE (28.11 [±15.34] vs. 44.71 [±16.35], p< .001). Body mass index (26.56 ± 4.09 vs. 27.87 ± 5.00, p< .001). ICU mortality (6.1% vs. 11.6%, p=.004), hospital mortality (8.4% vs. 13.2%, p=.024).

CONCLUSIONS. Women who suffered ACS were older and had higher prevalence of DM, AH and CHF such as higher TIMI, CRUSADE and GRACE. ICU and hospital mortality were significantly higher among women.

Trends and outcome of patients with complicated infective endocarditis in intensive care unit; a 20 years retrospective study

F. Ahmad[1], S. Cox[2], C. Soon Thim[3], E. Abdul Rahman[4], I. Zainal Abidin[1], M.A. Sadiq[5]
[1]Universiti Malaya Medical Centre, Kuala Lumpur, Malaysia; [2]Healthcare Partners, Cardiology, Brisbane, Australia; [3]Putrajaya Hospital, Kuala Lumpur, Malaysia; [4]Universiti Teknologi Mara, Selangor, Malaysia; [5]Sultan Qaboos University, Muscat, Oman
Correspondence: F. Ahmad

INTRODUCTION. Despite improvement of diagnosis and treatment, the mortality for patients for complicated infective endocarditis (IE) is still high. Unfortunately, data about IE-patients with the need for Intensive Care Unit treatment are sparse.

OBJECTIVES. This study investigates predictors of mortality and the short term, intermediate and long term outcome in patients with complicated IE admitted to MICU/CCU for medical treatment.

METHODS. A single - centre retrospective analysis was conducted among patients with complicated infective endocarditis that fulfilled the modified Duke Criteria requiring admission to MICU between 1998 and 2017. All patients undergo both transthoracic echocardiography (TTE) within 3 days on presentation to the hospital and then followed by transesophageal echocardiography (TOE) within 3 days prior to transfer to MICU or on the day of transfer itself.

RESULTS. 110 patients, with a mean age of 59.7 ± 4.1 years, were diagnosed with complicated IE, in which, 76 (69%) of them were male. IE survivors were defined as patients who survived after being discharged from MICU and at 6 months follow up with a documented diagnosis of IE. A total of 51 survivors from total patients of 110 were identified. 104 patients required inotropic support and 94 patients developed multi-organ failure. 42% of the patients developed mobitz type II heart block or complete heart block. 23 patients of the mobitz type II heart block progressed to complete heart block requiring temporary/ permanent pacemaker. Microbiology laboratory investigation showed 93% of the patients grew gram-positive cocci in their blood cultures. Surgical intervention was conducted in 54% of the patients and the remaining was medically treated. Biomarkers of acute infection, APACHE II as well as echocardiographic findings were analyzed. Using multivariate analysis, patients who developed acute kidney injury prior transfer to ICU (OR 9 95% CI 1.18-23.00, P=0.03) or echocardiographic evidence of vegetation size > 15mm (OR 7 95% CI 1.09-17.77 P = 0.03) were identified as predictors for in-patient death.

CONCLUSIONS. In contrast to general IE populations, infectious agents and the type of infected impaired valve are not the main predictors of survival in critically ill IE patients. Our study concludes that markers for severity of illness (scores and organ failure) as well as echocardiographic findings of vegetations size >15 mm are independent risk factors for poor prognosis and mortality.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0189

OBJECTIVES. To analyze the diagnostic process of acute heart failure (AHF) in the Spanish Intensive Care Units (ICU) and its impact on mortality.

METHODS. Multicenter prospective observational study that included patients older than 18 years admitted to the ICU for more than 24 hours between April and June 2017. Demographic, physiological and clinical variables, including complementary explorations of those who suffered AHF during their ICU stay were collected.

Comparisons were made among the different subgroups of patients according to the timing of AHF: AHF as main reason for admission vs. complication during ICU stay (Adm-AHF Vs Com-AHF) or first episode of AHF vs. exacerbation of chronic heart failure (AHFnew Vs CHFex). Statistical analysis was made using ANOVA or chi-square test as appropriate. The multivariate study was performed by Cox regression for survival analysis and logistic regression. Values of p ≤ 0.05 were considered statically significant.

RESULTS. We analyzed 587 patients with AHF admitted in 32 ICUs. In 98.6% of patients a chest x-ray was performed and in 98.8% an EKG. In all the patients, at least a blood sample test was extracted, the 78% included troponin and 37.5% natriuretic peptide concentrations. In the 24.6% of the episodes an invasive or minimally invasivehemodynamic monitoring system was used (5.4% pulmonary artery catheter, 4.9% transpulmonary thermodilution, 14.3% other systems) In the 81.2% of patients an echocardiography (ECHO) was performed: 61.1% during the first 24h, 10.1% between the 24-48h and 8.5% > 48h after the diagnosis. In 91.2% of ECHOs, the LVEF data was reported, and showed a 57.9% of systolic dysfunction (LVEF < 50%). Diastolic function were reported in the 17% of ECHOs, with an incidence of diastolic dysfunction of 29.1%. Right ventricular function was reported in the 52.8% of ECHOs, with a 43.8% of right ventricular dysfunction. A significant delay in the diagnosis of AHF was observed in the 9.3% of the episodes. The existence of delay was associated with an 30.8% (p = 0.015) and 46.2% (p = 0.007) absolute risk increase in mortality in the Com-AHFnew and in Com-AHFexarcebation subgroups respectively.

CONCLUSIONS. In patients with AHF, ECHO is the most used advanced monitoring system. Diastolic function and right ventricle function are reported in less than half of the ECHO. Natriuretic peptides are underused. The diagnostic delay of AHF when it appears as a complication in patients admitted to the ICU for another reason, is related to a significant increase in mortality.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0190

INTRODUCTION. Despite remarkable advances in the treatment of acute coronary syndrome, substantial early patient mortality remains. Individual patients reflect a combination of clinical features that influence prognosis, and these factors must be appropriately weighted to produce an accurate assessment of risk.

OBJECTIVES. To analyze the factors related to the develpment of shock in patients who suffered acute coronary syndrome (ACS) and were admitted to the intensive care unit (ICU) of a regional hospital using the ARIAM database.

METHODS. Retrospective analysis performed on a prospective cohort in a 12-bed ICU during 8 years (2009-2017). Demographic variables, comorbidities, risk factors, Killip, location and degree of obstruction, risk scores (TIMI, GRACE) and bleeding score (CRUSADE). Statistical analysis: categorical variables (frequencies and percentages) and numerical variables (mean and standard deviation or medians and interquartile range). Comparisons: X2 test (percentages), Student test (means) and Mann-Whitney test (medians). *Multiple logistic regression.* Statistical significance with p< 0.05.

RESULTS. 1009 patients were included, 751 (74.4%) male. 96 patients (9.51%) suffered shock during their ICU stay. Those who suffered shock: Univariable *logistic regresion*: age (OR 1.04, CI 95% [1.02-1.06], p< .001), diabetes mellitus (OR 1.63, CI 95% [1.07-2.49], p=0.023), previous ACS (OR 1.89, CI 95% [1.13-3.16], p=0.015), congestive heart failure (OR 8.85, CI 95% [4.79-16-34], p< .001), chronic renal failure (OR 2.06, CI 95% [1.04-4.09], p=0.039), Killip II (OR 13.25, CI 95% [4.4-39.83], p< .001), Killip III (OR 91.48, CI 95% [32.51-257.44], p< .001), rescue percutaneous coronary intervention (OR 2.84, CI 95% [1.15-6.98], p=0.23), anterior vs. inferior acute myocardial infarction (OR 2.27, CI 95% [1.45-3.55], p< .001), left main coronary artery (OR 7.22, CI 95% [1.48-35.17], p=.014), TIMI (OR 1.55, CI 95% [1.41-1.70], p< .001), GRACE (OR 1.04, CI 95% [1.03-1.05], p< .001), ICU LOS (OR 1.13, CI 95% [1.08-1.18], p< .001), ICU mortality (OR 47.69, CI 95% [26.78-84.95], p< .001), hospital mortality (OR 39.46, CI 95% [23.27-66.91], p< .001). Multivariable regresion model: Killip II (OR 19.66, CI 95% [4.40-87.86], p< .001), Killip III (OR 191.16, CI 95% [44.38-823.46], p< .001), Q infarction (OR 3.44, CI 95% [1.55-7.61], p=.002). AUROC 0.92 (CI 95% 0.89-0.95).

CONCLUSIONS. Q infarction and Killip II-III were predictive factors for shock in patients admitted to ICU who suffered from ACS.

A retrospective observational cohort study of patients admitted to a mixed medical and surgical intensive care unit in the United Kingdom with atrial fibrillation: incidence, risk factors and treatment efficacy

A. Hampden-Martin[1], N. Miller[1], B. Johnston[1,2], I. Welters[1,2]
[1]University of Liverpool, Institute of Ageing and Chronic Disease, Liverpool, United Kingdom; [2]Royal Liverpool and Broadgreen University Hospital Trust, Intensive Care Department, Liverpool, United Kingdom
Correspondence: B. Johnston
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0191

INTRODUCTION. Atrial Fibrillation (AF) is the most common arrhythmia in ICU.[1] New onset AF (NoAF) is estimated to occur in 5-15% of patients.[1] Development of atrial fibrillation is associated with increased length of hospital stay, increased ICU length of stay and increased mortality.[1] It has been suggested that NoAF is likely to have a separate aetiology and respond differently to treatment compared to chronic AF. It remains unclear what risk factors are associated with new onset AF and the most effective management of NoAF in ICU patients.[1]

OBJECTIVES.

1. To determine the incidence and risk factors associated with NoAF
2. Assess the efficacy of first and second line anti-arrhythmic agents used in NoAF
3. Assess outcomes associated with NoAF

METHODS. A retrospective observational cohort study was conducted at a large mixed medical and surgical intensive care unit in Northwest England. Patients admitted to ICU that developed AF during their admission were enrolled in the study. Data was extracted retrospectively from daily ICU nursing sheets, online patient notes system and online patient investigation system. Demographic data and co-morbidities were recorded. Data regarding first and second line treatment was recorded. First and second line anti-arrhythmic were assessed for efficacy. Outcomes included, mortality, length of ICU stay, length of organ support, length of hospital stay.

RESULTS. 1185 patients were admitted to ICU of which 115 had AF during their admission. 42% had permanent AF, 46% had NoAF and 11% had paroxysmal AF. Patients with permanent AF compared to NoAF were older (75 vs 67) and had more hypertension (70 vs 53), cerebrovascular disease (35 vs 14.3), structural heart disease (62.5 vs 36), diabetes (40 vs 12) and chronic kidney disease (25 vs 8). Patients with NoAF had higher CRP, white cell count and lactate. Amiodarone was the most commonly used anti-arrhythmic, followed by beta blockers then digoxin in NoAF. Digoxin was the most commonly used anti-arrhythmic in permanent AF. Patients with NoAF had longer length of ICU stay (13d vs 6d), longer hospital stay (21d vs 16d). Amiodarone more often achieved heart rate control compared to beta blockade (64 vs 58).

CONCLUSIONS. In our study the overall incidence of AF was 6% of all ICU admissions. In keeping with previous studies, we have shown that NoAF is associated with increased inflammatory markers and sepsis.[1] Permanent AF is more associated with chronic medical co-morbidity and structural heart disease. Amiodarone was more effective compared to beta blockers for the management of acute AF. AF leads to worse outcomes for patients admitted to ICU.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0192

INTRODUCTION. Recent studies have shown a mixed results on the accuracy of combining copeptin with different cardiac troponin assays for rapid rule out of acute myocardial infarction (AMI).

OBJECTIVES. We aimed to perform a systematic review and meta-analysis to evaluate the diagnostic accuracy of copeptin in conjunction with different troponin assays for early rule-out of AMI.

METHODS. Primary studies evaluating the diagnostic accuracy for copeptin with conventional or high sensitivity troponin assays in patients with symptoms suggestive of AMI were eligible for inclusion. Eligible studies were identified by searching PubMed and EMBASE from inception to March 2018. QUADAS-II was used to appraise the quality of included studies. A random-effect bivariate model and a hierarchical summary receiver operating curve were used to summarize the performance characteristics of different combination of copeptin and troponin assays.

RESULTS. A total of 31 studies consisting of 15,661 patients were included for final analysis. The sensitivity for early rule out AMI was similar for combining coopetin with conventional troponin T assay (summary sens: 0.90; 95%CI: 0.78-0.96) or troponin I assay (summary sens: 0.90; 95%CI: 0.84-0.94). There was no significant increase in sensitivity when combining copeptin with high sensitivity troponin T assay (summary sens: 0.92; 95%CI: 0.86-0.96) or high sensitivity troponin I (summary sens: 0.92; 95%CI: 0.86-0.96).

For all combinations, the summary specificity estimates were between o.63 to 0.67.

CONCLUSION. In conclusion, combining copeptin with conventional troponin assays could achieve a comparable sensitivity and negative likelihood ratio to combining copeptin with high sensitivity troponin assay for early exclusion of AMI.

Effect of diabetes mellitus on heart rate variability and blood pressure variability in patients with acute ischemic stroke

E. Hasen
Faculty of Medicine, Minia University, Neurology, Minia, Egypt
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0193

BACKGROUND. Diabetes mellitus is frequently characterized by autonomic nervous system (ANS) dysfunction. Analysis of heart rate variability (HRV) has become a popular noninvasive tool for assessing the activities of ANS.

OBJECTIVES. We aimed to evaluate possible changes of heart rate variability (HRV) and blood pressure variability (BPV) parameters in acute ischemic stroke patients with diabetes mellitus.

SUBJECT AND METHODS. 15 diabetic and 15 non-diabetic patients with first-ever acute ischemic stroke were studied. All patients were subjected to Brain C-T scan, assessment of stroke severity by the National Institute of Health Stroke Scale (NIHSS). Heart rate and blood pressure variability were evaluated by 24 hour monitoring for electrocardiogram (ECG) and blood pressure. The ANS activity was quantified by means of frequency and time domain analysis of R-R interval variability in electrocardiogram. Systolic and diastolic blood pressure variability parameters were measured.

RESULTS. In diabetic group, both sympathetic and parasympathetic parameters were significantly reduced. Diurnal variability of the sympathetic tone was with higher sympathetic level in the morning. The diurnal changes of the BPV parameters were higher in diabetic group especially the systolic parameters.

CONCLUSION. In diabetic patients, HRV parameters were reduced as well as the daily variability of the sympathetic fluxes which was predominant in the late night (at 2 am). There were more changes in the blood pressure levels especially the systolic blood pressure parameters. This highlights the importance of considering these alterations in diabetic patients.

INTRODUCTION. Despite remarkable advances in the treatment of acute coronary syndrome, substantial early patient mortality remains. Individual patient risk factors reflect a combination of clinical features that influence prognosis, and these factors must be appropriately weighted to produce an accurate assessment of risk.

OBJECTIVES. To analyze the factors related to mortality of patients who suffered an acute coronary syndrom (ACS) and were admitted to the ICU of a regional hospital using the ARIAM database.

METHODS. Retrospective analysis performed on a prospective cohort in a 12-bed ICU during 8 years (2009-2017). Demographic variables, comorbidities, risk factors, Killip, location and degree of obstruction, risk scores (TIMI, GRACE) and bleeding score (CRUSADE). Statistical analysis: categorical variables (frequencies and percentages) and numerical variables (mean and standard deviation or medians and interquartile range). Comparisons: X2 test (percentages), Student test (means) and Mann-Whitney test (medians). *Multiple logistic regression.* Statistical significance with p< 0.05.

RESULTS. 1009 patients were included, 74.4% male. Global mortality 7.5%. Those who died: female (39.5% vs. 24.4%, p=.004), age (72.13 ±11.47 vs. 64.09 ± 12.86; p< .001), no risk factors (10.5% vs. 4.5%, p=.020), smoking (25% vs.38.5%, p=.020), dyslipidemia (25% vs. 41.6%, p=.005), previous ACS (27.6% vs. 13.4%, p=.001), known coronary artery lesión (21.1% vs. 11%, p=.009), *cardiac insufficiency* (23.7% vs. 3.3%, p< .001), cerebrovascular accident (11.8% vs. 5.9%, p=.041), chronic obstructive pulmonary desease (11.8% vs. 5.7%, p=.031), chronic renal failure (14.5% vs. 5.8%, p=.003), shock as a complication (69.7% vs. 4.6%, p< .001), cardiac arrest (52.6% vs. 4.3%, p< .001), anterior acute myocardial infarction (52.1% vs. 33.1%, p=.001), TIMI (4.84 ± 2.66 vs. 2.70 ± 2.02; p< .001). *Multiple logistic regression*: female (OR 2.27, 95%CI [1.09-4.74] p=.029), age (OR 1.05, 95%CI [1.01-1.08] p=.005), Killip III (OR 3.70, 95%CI [1.27-10.81] p=.017), Killip IV (OR 5.98, 95%CI [1.25-28.46] p=.034), shock as a complication (OR 31.16, 95%CI [12.78-76.02] p< .001), cardiac arrest (OR 23.68, 95%CI [10.25-54.66] p< .001), ICU length of stay (OR 0.93, 95%CI [0.88-0.99] p=.002). AUROC 0.95 (95%CI 0.92-0.98).

CONCLUSIONS. Age, female sex, Killip III, IV and complications such as shock and cardiac arrest were statistically related to mortality in patients who suffered an ACS.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0195

INTRODUCTION. Admission blood glucose (BG) level is a predictor of mortality in critically ill patients with various conditions. However, limited data are available in this relationship in critically ill patients with cardiovascular diseases according to their diabetic state.

OBJECTIVES. We sought to investigate the association between baseline BG level and clinical outcomes in critically ill patients with various cardiovascular diseases admitted to cardiac intensive care unit (CICU) and whether prognostic role of admission BG level may differ according to the presence or absence of diabetic mellitus.

METHODS. A total of 1780 patients (595 diabetic patients) who admitted cardiac intensive care unit (CICU) were enrolled from a single center registry. Admission BG level was defined as their maximal serum glucose level within 24 hours of admission. Patients were divided by their admission BG level; Group 1 < 7.8 mmol/L, Group 2 7.8 - 10.9 mmol/L, Group 3 11.0 - 16.5 mmol/L, Group 4 > 16.5 mmol/L.

RESULTS. One hundred and five patients died in CICU (62 non-diabetic patients [5.2%] and 43 diabetic patients [7.9%], p = 0.105). CICU mortality rate increased with admission BG (1.7%, 4.8 %, 10.3%, and 18.8% from Group 1 to Group 4, p < 0.0001). In non-diabetic patients, hypertension, mechanical ventilator, continuous renal

replacement therapy, APACHE II score and admission BG level (Group 1 versus Group 3, hazard ratio [HR] 3.31, 96% confidence interval [CI] 1.47 - 7.44, p = 0.004; Group 1 versus Group 4, HR 6.56, 95% CI 2.76 - 15.58, p < 0.0001) significantly influenced CICU mortality. However, in diabetic patients, continuous renal replacement therapy and APACHE II score influenced on CICU mortality, but not admission BG level.

CONCLUSIONS. Admission BG level was associated with an increased CICU mortality in critically ill non-diabetic patients admitted to CICU but not diabetic patients.

Advanced age as a risk factor for postoperative bleeding in the intensive care unit after left ventricular assist device implantation

R. Sakaguchi, R. Abe, A. Matsumoto, Y. Horiguchi, A. Tanaka, A. Uchiyama, Y. Fujino
Osaka University, Anesthesiology and Intensive Care Medicine, Suita, Japan
Correspondence: R. Sakaguchi
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0196

INTRODUCTION. Left ventricular assist device (LVAD) is a treatment of choice for patients with end stage heart failure (1). Shortage of donors is a serious problem in Japan. LVAD plays a pivotal role for patients waiting for heart transplantation. However, post-operative bleeding after LVAD implantation is a common adverse event (2). Few reports are available on risk factors of early postoperative bleeding in the intensive care unit (ICU).

OBJECTIVES. The aim of our study was to investigate the incidence and risk factors of early postoperative bleeding in the ICU.

METHODS. A retrospective medical review was performed on 91 patients who underwent continuous flow type of LVAD (CF-LVAD) implantation from January 2012 to June 2016 at Osaka University Hospital. Patients under 18 years of age were excluded. In this study, postoperative bleeding was defined as bleeding that needed surgical intervention and cerebral hemorrhage in the ICU. Univariate and multivariate analysis were performed to clarify the risk factors.

RESULTS. The rate of postoperative bleeding was 26% (24 of 91 patients); 14 (58%) of the bleeding events occurred within 4 days postoperatively and the main site was the thorax (70.1%). Compared with patients without postoperative bleeding, those with postoperative bleeding had longer ICU stay [23 days (interquartile range, 14-33 days) vs. 8 days (interquartile range, 4-16 days), p< 0.01] and shorter duration of ventilator-free days within 28 days postoperatively (10 days [interquartile range, 0-22 days] vs. 25 days [interquartile range, 18-27 days], p < 0.01). Univariate analyses showed that advanced age, re-sternotomy, total bilirubin, and longer operation time were significantly associated with postoperative bleeding. Multivariate analysis of the preoperative factors showed that advanced age was associated with postoperative bleeding (odds ratio: 1.05, 95% CI: 1.0-1.1).

CONCLUSIONS. Advanced age was the risk factor for early postoperative bleeding after LVAD implantation in the ICU. Older patients warrant careful monitoring after operation.

Atrial fibrillation incidence and prophylaxis adherence post cardiac surgery

H. Burns, N. Velev, M. Ahmed
St Georges Hospital, CTICU, London, United Kingdom
Correspondence: H. Burns
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0197

INTRODUCTION. Post- operative Atrial Fibrillation (AF) is common post cardiac surgery, with an incidence of 33% post Coronary Artery Bypass Graft (CABG) surgery, higher post valve surgery. There is clear guidance from National Institute of Clinical Excellence (NICE) for the prophylaxis and management of perioperative AF.
"In patients undergoing cardiothoracic surgery reduce the risk of postoperative atrial fibrillation by offering 1 of the following: Amiodarone or beta blocker"
OBJECTIVES. To review our incidence of AF, post cardiac surgery and adherence to prophylaxis guidance.
METHODS. Retrospective review of all patients who had cardiac surgery and were discharged from our Cardiothoracic Intensive Care Unit (CTICU) from 01/03/2017 to 30/06/2017. We included all patients that had Cardiac Surgery which involved either a CABG and/or valve Surgery. Basic demographic data was collected. The patient CTICU charts, online notes, electronic results and online prescriptions were interrogated to identify those with documented AF. Data was collected regarding the strategies for the prevention and management of AF following up from CTICU to ward to clinic.
RESULTS. Data was collected from 296 patients who had cardiac surgery over 4 months. Pre-existing AF was present in 49 patients (16.5%). Amongst the 247 patients with no history of AF, 76 (30%) had an episode of AF during their admission, peak onset on day 2-3 post op. Incidence of AF amongst patients having a CABG, single Valve Surgery or combined procedures was 25%, 46% and 35% respectively.
Beta blocker prophylaxis was poor across all patients, and when comparing new onset AF with no AF, there was a statistical significance on Day 2.
Noradrenaline peak doses (mcg/kg/min) were different on Day 1 in those developing AF 0.034 vs. 0.021 (p=0.021). Those that developed AF were more likely to be paced post operatively 48% vs. 31% (p=0.002).
Patients who were paced were much less likely to be given beta blockers on Day 1 (p=0.0011) and Day 2 (p=0.000021). For management of AF 60 patients (79%) were treated with amiodarone during their inpatient stay. Three patients (4%) remained in AF on 6 week follow up.
CONCLUSIONS. Our incidence of Post-operative AF was similar to previous studies. Adherence to perioperative beta blocker prophylaxis was poor immediately post surgery. Patients who develop AF were more likely to have had valve surgery, have high noradrenaline levels and be paced on day 1. Those on noradrenaline are more likely not to be given prophylaxis early and develop AF. This has helped inform guidance within our department which stipulate introducing beta blockade on day 1 post surgery, which is not dependent on noradrenaline dose and will aim to reduce of incidence of post-operative AF and the potential long term sequelae of long-term AF.

Presence of atrial fibrillation in patients with acute myocardial infarction undergoing percutaneous coronary intervention predicts contrast-induced nephropathy

J. Wi
Severance Hospital, Yonsei University College of Medicine, Cardiology, Seoul, Korea, Republic of
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0198

PURPOSE. Atrial fibrillation (AF) is known as one of factors that negatively influence kidney function. Contrast-induced nephropathy (CIN) is associated with poor clinical outcomes in patients with acute myocardial infarction (AMI) undergoing percutaneous coronary intervention (PCI). We investigated whether AF could predict CIN in AMI patients treated with PCI.
METHODS. We analyzed clinical data from 1041 AMI patients treated with PCI. CIN was defined as an increase in serum creatinine level (>25% or >0.5 mg/dL) within 48 hours after PCI. AF was divided into AF with prior history or new-onset AF developed during AMI without previous history.
RESULTS. Atrial fibrillation was observed in 70 patients (6.7%) and CIN in 148 patients (14.2%). Patients with AF exhibited higher incidence of CIN than those without AF (31.4 vs. 13.0%, p < 0.001). Multivariate analysis showed that AF was the second most significant independent predictor of CIN [odds ratio (OR) 3.48, 95% confidence interval (CI) 1.69 - 7.15, p = 0.001], following impaired renal function (serum creatinine level >1.5 mg/dL) at baseline (OR 3.50, 95% CI 1.89 - 6.49, p < 0.001). Each new-onset AF (OR 3.94, 95% CI 1.55 - 9.99, p = 0.004) and AF with prior history (OR 2.98, 95% CI 1.04 - 8.57, p = 0.043) was also a significant predictor of CIN, compared to non-AF group. Left ventricular systolic dysfunction (ejection fraction < 40%, OR 2.01, 95% CI 1.25 - 3.23, p = 0.004), age >75 years (OR 1.97, 95% CI 1.16 - 3.34, p = 0.012), contrast volume >300 mL (OR 1.89, 95% CI 1.13 - 3.17, p = 0.015), diabetes (OR 1.83, 95% CI 1.17 - 2.88, p = 0.009), female gender (OR 1.71, 95% CI 1.09 - 2.70, p = 0.020) were other clinical predictors of CIN. Variables including heart rate, LV filling pressure (E/E`), low body mass index (< 24 kg/m2), anemia, hypertension, and multi-vessel disease were not statistically significant in multivariate analysis, although significant in univariate analysis.
CONCLUSION. Presence of AF predicts CIN in patients with AMI undergoing PCI, regardless of pre-existing AF or new-onset AF.

High sensitive troponin T predicts myocardial ischemia and mortality in medical-surgical ICU

G. Kotnik[1], M. Mežnar[1,2], G. Voga[1,2], M. Golmajer[3], M. Podbregar[1,4]
[1]University of Ljubljana, Medical Faculty, Ljubljana, Slovenia; [2]General and Teaching Hospital Celje, Department for Internal Intensive Care, Celje, Slovenia; [3]General and Teaching Hospital Celje, Department for Anesthesiology, Intensive Care and Pain Treatment, Celje, Slovenia; [4]UMC Ljubljana, Clinical Department of Cardiology, Ljubljana, Slovenia
Correspondence: G. Kotnik
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0199

INTRODUCTION. Elevated cardiac troponin (cTn) level is detected in up-to 84% of critically ill and is negative predictor of survival. (1,2,3) cTn alone is not sufficient for diagnosis of myocardial ischemia or

myocardial infarction and must be interpreted along with other diagnostic procedures (i.e. ECG, echocardiography, angiography). (1,2)

OBJECTIVES. High sensitive cTn (cTn-hs) enables detection of more patients at risk for myocardial ischemia, it has high prognostic value for cardiac events in patients with renal failure and shortens the time to diagnosis by almost 3 hours. A protocol-guided cTn-hs with admission echocardiography was compared to retrospective cohort of critically ill to assess the prognostic value and outcome of patients.

METHODS. In this prospective, observational study, 100 consecutive patients, hospitalized in a level 3 medical-surgical ICU at General and Teaching Hospital Celje in 2017 for more than 48 hours, were enrolled. 12-lead ECG and cTn-hs (Elecsys® Troponin T high sensitive, Roche Diagnostics; 99th percentile upper reference limit: 14 ng/L) for detecting myocardial ischemia were screened at admission, twice daily for the first week and then weekly until discharge/death. An echocardiographic exam was also performed at admission and during acute events. At events indicating the presence of myocardial ischemia (hypotension, acute heart failure, chest pain...) ECG, cTn-hs and echo were repeated. Myocardial ischemia was diagnosed according to Third universal definition of myocardial infarction. Results were available to the medical team for further therapeutic decisions. The prospective group was compared to case-matched retrospective group treated in 2016.

RESULTS. In the prospective group, 95% patients had at least one elevated cTn-hs level, 21% had myocardial ischemia, 74% had elevated cTn-hs only. All patients with myocardial ischemia in the prospective group had cTn-hs >100 ng/L. Maximal level cTn-hs, but not admission level, was associated with ICU mortality (ROC: AUC 0.80, p< 0.01, cut-off 150ng/L, sensitivity 80.0% specificity 72.2%). More patients with myocardial ischemia were detected in prospective compared to retrospective study (21/100 vs. 5/100, p=0.006). ICU-mortality mortality was lower in protocol base population (10/100 vs 27/100, p=0.01).

CONCLUSION. Elevated cTn-hs is detected in majority of ICU-patients. cTn-hs >100ng/L indicates myocardial ischemia. Maximal level of cTn-hs predicts ICU-mortality. It is possible to detect more patients with myocardial ischemia with protocol based approach.

LOS and mortality evolution in the acute myocardial infarction in a polyvalent ICU across 15 years

J. Ruiz, M. Pujol, B. Sánchez, S. Quintana, J. Trenado
Hospital Universitario Mutua de Terrassa, Terrassa. Barcelona, Spain
Correspondence: J. Ruiz

OBJECTIVE. To analyze the in Hospital and ICU (intensive care unit) LOS (long of stay) and mortality in patients affected by acute myocardial infarction (AMI) attended in a polyvalent ICU of a university hospital.

METHOD. Unicentric, observational and descriptive study between January 2000 and June 2015. Three study periods were established. The first period covered from January 2000 to December 2004. The second period covered from January 2005 to May 2009 (Start of Hemodynamic Service in the hospital). The last period covered from June 2009 to June 2015 (involves the implementation of the Infarct Code in Catalonia).

STATISTICS. Qualitative variables are expressed as percentages and compared using the X2-test; quantitative ones are expressed as means and standard deviations (± S.D), and analyzed using Student´s t-test. Analysis of variance (ANOVA) was performed for intergroup comparison The level of significance was placed at p < 0.05. The statistical analysis was performed using specific software (IBM SPSS Statistics for Window s, Version 19.0. Armonk, NY: IBM Corp).

RESULTS. 11445 patients were included, 1645 (14.4%) presented an AMI as the main diagnosis. The severity of these patients measured by the MPM 0 scales, MPM 24, SAPS 2 and APACHE III were respectively 15.16 (14.37-15.95), 10.35 (9.70-11.00), 26.64 (25.97-27.31) and 39.29 (38.10-40.49) with no inter-period differences observed. The age of the patients remains stable over the years without inter-period differences 64.14 years (63.51-64.76).

A decrease was observed in both ICU LOS 3.04 days (2.84-3.24), 2.40 days (1.94-2.86) and 1.51 days (1.32-1.69) (ANOVA 422, 05 p < 0.001) and in HOSPITAL LOS 14.04 days (13.29-14.78), 12.59 days (11.34-13.85) 5.66 days (5.01-6) , 30) (ANOVA 25484, 45 P < 0.001) respectively throughout the three periods.

Mortality in the same periods also decreased. ICU mortality 6.79% (4.67-8.91), 4.86% (2.53-7.20) and 2.98% (1.78-4.19) (ANOVA 4649.18) p = 0.005) in the three periods. Hospital mortality 9.17% (6.74-11.61), 8.21% (5.23-11.19), 4.54% (3.07-6.01) (ANOVA 7662.75 p = 0.002) in the three periods.

CONCLUSIONS. Related to the improvement in the treatment of AMI, both, mortality and LOS in ICU and HOSPITAL have decreased over the past 15 years without change in other aspects such as age or severity of patients.

Correspondence: A. Omar

INTRODUCTION. Defining the intensive care unit (ICU) outcome predictors after cardiac surgery remains an optimum goal. [1] Left main coronary artery (LMCA) disease is a disease of the main coronary branch that gives more than 80% of blood supply to the left ventricle, it carries high mortality without surgical intervention; [2] however the influence of LMCA surgery on morbidity ICU measures needs to be explored.

OBJECTIVES. To determine whether LMCA is a risk factor for prolonged ICU stay as a primary outcome and whether LMCA is definitive risk factor for early morbidity.

METHODS. Retrospective descriptive study with purposive sampling analyzing 398 patients underwent isolated coronary artery bypass

surgeries (CABG). Patients were divided into 2 groups those with LMCA disease as group 1 (75 patients) and those with coronary artery disease requiring surgery but without LMCA disease as group 2 (324 patients) then we did correlations with ICU outcome parameters including ICU stay length, post-operative atrial fibrillation, acute kidney injury, re-exploration, perioperative myocardial infarction, post operative bleeding and early mortality.

RESULTS. Patients with LMS had significantly higher diabetes prevalence (43.3% vs 29%, p=0.001). However, we did not find a statistical significant difference regarding ICU stay, or other morbidity and mortality outcome measures

CONCLUSIONS. Diabetes was more prevalent in patients with LMS. The latter group showed similar outcome as those without LMS in this study; these findings may help in guiding decision making for future practice and stratifying the patients care.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0202

INTRODUCTION. The mean arterial pressure (MAP) is routinely monitored in intensive care unit (ICU) as a hemodynimic parameter for assessing tissue perfusion. The relationship between circadian MAP variation and mortality in critically ill patients remains unclear.

OBJECTIVE. The purpose of this study was to investigate the influence of circadian MAP variation on ICU mortality and long term prognosis.

METHODS. This retrospective cohort study was performed in all adult ICUs using the Multiparameter Intelligent Monitoring in Intensive Care II (MIMIC II) database with authorised access. All patients with complete MAP recordings at the first 24 hours in ICU and complete data of their age, gender, ethnicity, first SOFA score, first SAPS-I score, vasoactive and sedative medications, major comorbidities such as congestive heart failure, hypertension, diabetes and delirium were recruited for analysis. Participants were excluded if they had: multiple ICU admissions, diagnosis of shock, ICU stay of < 1 day. The circadian variation of MAP was calculated as mean night time MAP/mean day time MAP according to our previous publications. Then the patients were divided into 2 groups based on the value of circadian MAP variation: group A (≤1) and group B (>1). The associations of circadian MAP variation and ICU mortality, hospital mortality, 30-day mortality and 1-year mortality were evaluated in multivariable logistic regression models and cox proportional hazards models. Two sensitivity analyses were performed on those with or without receiving vasoactive medications, and with first SOFA score ≤ 8 or > 8.

RESULTS. A total of 7,492 patients were eventually included. The median age of the population was 65 years, and 61% were male. Patients in group B (n=2584) had higher ICU mortality than those in group A (n=4908; odds ratio [OR], 1.37; 95% confidence interval [CI], 1.16-1.61; P< 0.001). Following multivariable adjustments, the circadian variation of MAP >1 was significantly associated with ICU mortality (odds ratio [OR], 1.29; 95% confidence interval [CI], 1.09-1.54; P=0.004) and hospital mortality (odds ratio [OR], 1.33; 95% confidence interval [CI], 1.14-1.56; P< 0.001), which was also found in the subgroups regardless of the use of vasoactive medications or first SOFA scores. During the follow-up observation, the survival analysis revealed that patients with MAP variation >1 had higher 30-day mortality (hazard ratio [HR], 1.22; 95% confidence interval [CI], 1.07-1.40; P=0.003) and 1-year mortality (hazard ratio [HR], 1.19; 95% confidence interval [CI], 1.06-1.32; P=0.002) after adjustment for multiple variables.

CONCLUSION. The circadian MAP variation may associate with ICU mortality, hospital mortality, 30-d and 1-year mortality in critically ill patients.

Autonomic system evaluation in critically ill patient and its relation with ICU mortality

C. Hernandez Cardenas, L.F. Jurado Camacho, L. Goytia
Instituto Nacional de Enfermedades Respiratorias, Unidad de Cuidados Intensivos Respiratorios, Tlalplan, Mexico
Correspondence: C. Hernandez Cardenas
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0203

INTRODUCTION. Human organism has a complex system of physiologic interactions; disease-driven compromise of this mechanisms significantly reduces the ability for adaptation and survival. The application of non-lineal dynamic system analysis in prognosis of critically ill septic patient is considerably unexplored. We hypothesized that the heart rate viability (HRV) has a pivotal role in the mortality of the critically ill.

OBJECTIVES. Define the relationship between HRV measured within the first day of ICU and mortality in critically ill mechanical-ventilated subjects.

METHODS. Prospective cohort in a pulmonary academic hospital admitted to the respiratory intensive care unit with invasive mechanical ventilation. Finapres Medical Systems|Finometer was used to measure RR intervals; HRV, its standard deviation (SDNN), asymmetry index and Poincaré plots SD2/SD1 were used to evaluate the Autonomous Nervous System (ANS) within the first 24 hours of R-ICU admittance. ROC curves were used to infer the ability to predict death before RICU discharge.

RESULTS. Patients included (115) had mean (±SD) age and SOFA score of 46 (±10) and 7.1 (±3.7) respectively; there is a significant statistical relation between HRV, SDNN and Poincaré plot with mortality before RICU discharge (p=.003). We found similar AU ROC for SDNN, HRV and SOFA (AU ROC=0.7).

CONCLUSIONS. We found significant relation between HRV, SDNN and mortality; both having a similar area under the ROC with SOFA score (0.7); Poincaré plot appears to have predictive value for mortality in the RICU Patient. We are currently working to explore the predictive value of HRV analysis and mortality at R-CU discharge

Outcome of NIV in critical care setting: 5-year experience from a tertiary care center

M. Esteves Brandão[1], S. Xavier Pires[2], A.P. Dias[3], N. Barros[3], F. Esteves[3]
[1]Centro Hospitalar de Trás-os-Montes e Alto Douro, Respiratory Medicine, Lordelo, Vila Real, Portugal; [2]Hospital da Senhora da Oliveira, Guimarães EPE, Internal Medicine, Guimarães, Portugal; [3]Centro Hospitalar de Trás-os-Montes e Alto Douro, Intensive Care Medicine, Vila Real, Portugal
Correspondence: M. Esteves Brandão
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0204

INTRODUCTION. Non-invasive ventilation (NIV) it is strongly recommended in the management of acute respiratory failure (ARF) due to COPD exacerbation and cardiogenic pulmonary oedema[1]. However there is a lower certainty of evidence for its safety and effectiveness in other specific clinical settings.
OBJECTIVE. To describe the use and outcomes of NIV in adults presenting with ARF to an Intensive Care Unit (ICU) of a tertiary hospital.
METHODS. Retrospective cohort study including all adult ICU admissions for $\geq$ 24 hours from 1 January 2010 to 31 December 2015. Demographic data, admitting diagnosis, severity of illness (APACHE II, SAPS II and SOFA), duration of mechanical ventilation (MV), intubation rate, mortality rate and ICU length-of-stay (ICU-LOS) were recorded. Logistic regression was performed to identify predictors of adverse outcome (defined as need for endotracheal intubation or death).
RESULTS. Among 3.384 subjects admitted to ICU during the study period, 810 (57.8% male; mean age 68 ± 14 years) received NIV as the initial ventilatory support for the treatment of ARF. The most frequent admitting diagnosis was pneumonia (25.8%), followed by post-operative respiratory failure (15.3%).Baseline mean PaO2/FiO2 ratio was 207.6 ± 113.1 mmHg and mean APACHE II was 20.1 ± 7.9.Three hundred and four patients (37.5%) had sepsis and 311 (38.4%) evolved to septic shock. The mean duration of MV was 7±6 days and the mean ICU-LOS was 9±8 days. Orotracheal intubation rate was 46.7% and in-ICU mortality rate was 7.2% (composite adverse outcome in 53.9% of admissions). Patients who avoided intubation had significantly (p < 0.001) shorter ICU-LOS and lower mechanical ventilation duration (p< 0.001) but no different in-ICU mortality rate. NIV failure rates varied significantly across ARF etiologies with lower rates in COPD exacerbation (38.5%)

and cardiogenic pulmonary oedema (36.5%) and higher rates in ARF in immunocompromised patient (52%), pneumonia (60.3%), and post-operative respiratory failure (63.7%). In multivariate analysis, APACHE II (p=0.04, OR 0.94, 95%CI 0.88-1.0), SAPS II (p< 0.001, OR 1.07, 95%CI 1.04-1.11) and SOFA (p< 0.001, OR 1.29, 95%CI 1.16-1.44) scores at admission, the occurrence of ARDS (p=0.04, OR 1.87, 95%CI 1.02-3.42) and nosocomial infection (p< 0.001, OR 3.08, 95%CI 1.79-5.31) were independent predictors of NIV failure.
CONCLUSIONS. Even in highly monitored setting like ICU, significant NIV failure rates can be observed in critically-ill patients with ARF caused by conditions other than COPD exacerbation and cardiogenic pulmonary oedema. APACHE II, SAPS II and SOFA scores at admission were independent predictors of NIV failure and can be useful in patient selection. Odds for NIV failure was three times higher in the presence of nosocomial infection.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0205

INTRODUCTION. AECOPD are a leading cause of admissions in ICU. Significant heterogeneity of clinical presentation and disease progression exists defining phenotypes of AE/COPD and classified according to aetiology, inflammatory biomarkers, clinical manifestation, comorbidity and the frequency of exacerbations.
OBJECTIVES. To identify independent risk factors of ICU mortality in a cohort of AE/COPD admitted to ICU.
METHODS. It is a retrospective study including consecutive patients admitted for AE/COPD in a 9-bed Tunisian medical ICU going from 2008 to 2017. Baseline characteristics were collected on admission. Univariate and multivariate analyses were performed comparing patients according to their vital status.
RESULTS. During the study period, 1090 episodes fulfilled criteria for COPD exacerbation. Patients characteristics on admission were: median age, 68[61-76] years old; sex ratio, 5/1; Sleep obstructive apnea syndrome, 74(6.8%); obesity, 165(15.1%); mMRC score $\geq$ III, 459(42.1%); severe acute respiratory failure, 630(57.8%); shock, 290(26.6%); SAPSII, 31[24-40]; pH, 7.31[7.25-7.37]; PaCO2, 61[49-76] mmHg; PaO2, 89[59-168]mmHg; PaO2/FiO2, 230[180-273]mmHg; initial NIV, 368(33.8%); success rate, 199(54%); intubation delay, 2[1-4]days; mechanical ventilation duration, 5[2-10] days; tracheostomy, 88(8.1%); VAP occurrence, 180(16.5%); length of stay, 8[5-14]days; mortality rate 433(39.7%).
Univariate then multivariate logistic regression analyses identified the following factors as independently associated to ICU mortality: age (OR=1.033, 95%CI, [1.019-1,048]; p=0.0001), obesity (OR=0.46, 95%CI, [0.28-0.75]; p=0.002), shock on admission (OR=1.66, 95%CI, [1.18-2.33]; p=0.003), NIV success (OR=0.048, 95%CI, [0.022-0.108]; p=0.0001), mechanical ventilation duration (OR=1.18, 95%CI, [1.14-1.23]; p=0.0001), VAP occurrence (OR=34.7, 95%CI, [17.4-69.1]; p=0.0001).
CONCLUSION. The present study confirmed underlying comorbidities, severity on ICU admission, prolonged mechanical ventilation and ventilator acquired pneumonia to be independently associated to ICU mortality in AE/COPD patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0206

INTRODUCTION. Between October 2016 and November 2017, an outbreak of Extensively Drug-Resistant (XDR) bacteria occurred in our surgical Intensive Care Unit (ICU). A specific organization was implemented to avoid cross-transmission, including restriction of ICU admission/discharge, cohorting of the colonized/infected patients (pts) and dedicated nursing staff (DNS) [1].

OBJECTIVES. The aim of this study was to assess the consequences of these procedures in terms of bed-days unavailability [2] and to estimate their financial impact.

METHODS. This retrospective monocentric study compared the total number of ICU admissions (TNA) and mean ICU length of stay (LS) in 2017 to the activity reported in 2016 before the outbreak. The attributable cost of bed-days unavailability was estimated as follows: (number of beds unavailable x number of days)/(ICU LS to December, 2017 x Average income (in euros) for the treated cases balanced to end of December, 2017). Number of XDR-positive pts and specific procedures implemented for their management were collected by the Hygiene Operational Team. TNA and ICU LS were collected by the Medical Information Department.

RESULTS. On a routine basis in our 20 beds ICU, the nursing staff consists of 44 nurses (N) and nurse-assistants (NA). The N/pts and NA/pts ratios are respectively 1/2.5 and 1/4 pts. From January to December 2017, 747 pts were admitted in ICU, including 19 XDR-positive pts (NDM-producing *Enterobacteriaceae* (NDM-E): 16 pts for 19 stays representing 470 days of ICU stay; OXA-48-producing *Enterobacteriaceae* (OXA-E): 3 pts for 3 stays representing 23 days of ICU stay). The overall ICU LS was 6.1 days in 2017 versus (vs) 6.5 days in 2016. For NDM-E and OXA-E, ICU LS was 25 and 8 days respectively. The total number of unavailable bed-days in 2017 was 547. Total attributable cost of bed unavailability was € 1 870 229. Nursing staff was reinforced for 165 days (NA and N for respectively 164 and 1 days). The TNA dropped dramatically in 2017 (366 vs 450 in 2016). The cost calculation based on bed-unavailability days under-estimated the financial burden of this outbreak, as it did not include costs linked to staff reinforcement, loss of income due to iterative interruptions of admissions, decreased bed occupancy, temporary cessation of the transplantation program, decreased surgical activities, increased ICU LS in ICU linked to temporary suspension of contact patients and XDR-positive patients transfers.

CONCLUSIONS. Management of an XDR outbreak in ICU is associated with a significant number of bed-days unavailability and with a huge financial burden for the Unit and the Institution. Costs linked to prolongation of hospital stay of colonized pts, staff reinforcement, and decreased TNA have to be added to this direct cost calculation.

Correspondence: M.D. Pola-Gallego-de-Guzmán

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0207

INTRODUCTION. In recent years, the number of patients older than 80 years admitted to the Intensive Care Unit (ICU) has increased exponentially.

OBJECTIVES: To analyze the characteristics of patients with age over 80 years admitted in ICU of Spain.

METHODS. Multicentric prospective observational study in the ICU of 7 Spanish hospitals (Carlos Haya in Malaga, Cabra (Córdoba), Jaén, Burgos, Arnau Vilanova in Valencia, Clinic of Zaragoza, Ronda).

Data were expressed as the mean and standard deviation for quantitative variables and percentages for qualitative variables. For the comparison of two means we used the Student´s t-test and the chi- squared test was used to compare proportions. Statistically significant differences p < 0.05.

RESULTS. N=2008 patients. 181 (9%) were over 80 years. 57 patients (3%) were between 85-90 years old and only 4 patients older than 90 years.

The type of pathology of patients with more than 80 years: 62% were medical patients and 38% surgical.

Of the medical patients, acute coronary syndrome (20% of all patients, 12% with ST-elevation myocardial infarction - STEMI), arrhythmias, especially bradycardias related to the need or surveillance of pacemaker (17% of the total), 5% for sepsis and a 4% for cardiac or respiratory arrest. 38% were surgical patients, of them 10% only for central venous catheterization, and 7% for emergency surgery. The most frequent surgeries were cardiac and maxillofacial surgery.

Previous functional situation (normal, self-sufficient but dysfunction and not self-sufficient): 50%, 36% and 14% respectively.

The SAPS-3 at admission was 53.83 ±12.71 points and the mortality was 23%, with mortality in the ICU of 14%. At admission, 26% required mechanical ventilation, with mortality of ventilated patients of 40% and non-ventilated patients of 17% (p = 0.001).

CONCLUSIONS. Of the patients admitted to the ICU, 9% are older than 80 years, the majority are self-sufficient. Rhythm disorders and ischemic heart disease are the most frequent causes. Mortality is higher than 20%, and mortality was specially high in patients required mechanical ventilation at admission.

Factors related to delayed ICU admission from emergency department

M. Aitavaara[1,2], J. Liisanantti[1,2], P. Ohtonen[3], T. Ala-Kokko[1,2]

[1]Oulu University Hospital, Department of Anesthesiology, Division of Intensive Care Medicine, Oulu, Finland; [2]Oulu University Medical Research Center, Research Group of Intensive Care Medicine, Oulu, Finland; [3]Oulu University Hospital, Department of Operative Care, Oulu, Finland

Correspondence: M. Aitavaara

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0208

INTRODUCTION. The delays in patient transfer from emergency department (ED) to Intensive care unit (ICU) are known to be linked in several adverse events including prolonged ICU stay and hospital mortality (1,2,3,7,9). The factors associated to delayed ICU admission include shortage of ICU beds (4,6) organisational factors (5), ED overcrowding (2,8) and patient related factors including sepsis as admission diagnosis (2).

OBJECTIVES. Aim for this study was to examine ED related factors associated to prolonged ED stay.

METHODS. The study population consisted of every adult patient admitted from ED to ICU between May 31, 2016 and March 19, 2017 in Oulu University hospital. The total number of patients was 479.

RESULTS. The majority of the patients (380, 79.3%) were admitted within three hours of hospital admission. The median ED length of stay (LOS) was 92 [25th- 75th PCT 60-162] minutes. In the multivariate analysis, OR for delayed EDLOS was higher, if patient had GCS above 9, thrombocytes less than 100 x 10^9, absence of pre-arrival notification, arrival time during office hours, use of vasoactive medication or use of radiological examinations. (Table 1).

CONCLUSIONS. In conclusion, OR for delayed EDLOS was higher, if there were absence of pre-arrival notification, use of vasoactive medication, arrival time during office hours (between 8am and 4pm), GCS 9 or more, low thrombocytes or use of radiological examinations.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0209

INTRODUCTION. Readmission in ICU results in increased consumption of medical resources, costs and increased mortality. So in resource limited countries like India it is important to decrease health care costs and have to utilize the available resources wisely.

OBJECTIVES. To identify patients at risk for ICU readmission, to know readmission rate , reasons for readmission, average length of stay in ICU and mortality after readmission during period from Jan 1st 2015 to June 30 Th 2017.
Readmission episodes with in 72 hrs were analyzed for risk factors, cause of readmission, length of stay and mortality.

RESULTS. Total 3290 patients admitted in ICU during study period. Total patients transferred out (2472), discharged (246), 47patients readmitted in ICU. Readmission rate in ICU 1.90%. Males constitutes 72.3 % (34/47), females constitute 27.65 % (13/47). Mean and standard deviation for age of readmitted patients is 52.77 (+/-14.98) Out of all readmitted patients 72.3% (34/47) patients are < 60 yrs age group.27.6% (13/47) are > 60 years age group. Majority of patients are in decade of 50-60 years age group (19/47). 63.82 % (30/47) of readmitted patients had associated co-morbidity. 59.57 % (28/47) patients readmitted within 24 hours, 25.53 % (12/47) patients admitted between 24-48 hrs. 14.89 % (7/47) patients admitted after 48 hrs.
Primary diagnoses are analysed. Neurotrauma 51.06%(24/47), oncology 10.6% (5/47), hepato biliary system 8.5% (4/47), postop 6.38% (3/47), respiratory 4.25% (2/47), others 8.5% (4/47).
Causes of readmission were due to respiratory system 34.04% (16/47), neurological 31.83% (13/47), cardiac 23.40% (11/47), GI causes 4.2% (2/47), and Renal causes 4.2% (2/47) and Drug reaction 2.1% (1/47).
Mortality rate for readmission patients was 27.65% (13/47). Main causes for death in readmitted patients were cardio pulmonary 46.15% (6/13), neurologic 38.46% (5/13), gastric 7.69% (1/13) and renal 7.69% (1/13).Average length of stay for our icu readmitted patients (6.79 days).

CONCLUSIONS. Readmission rate of our ICU was 1.9%. Mortality rate of readmitted patients compared with non readmitted patients was not statistically significant (27.64% vs21.05%) p value calculated was 0.35 by chi square test.
The probable reason for our promising readmission(1.9% Vs 5-6%) as compared to standard bench mark was due toMortality rate of readmitted patients was more than mortality rate of shifted out patients (27.64% vs21.05%) p value calculated was 0.35 by chi square test.That means higher mortality rate in readmitted patients is not stastically significant. increased length of stay (6.63 days Vs 4.5days).

Retrospective study of use of glucometrics to compare glucose control in medical and surgical intensive care units

S. Dixit[1], K. Khatib[2]
[1]Apka Clinic, Pune, India; [2]SKN Medical College, Medicine, Pune, India
Correspondence: S. Dixit
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0210

INTRODUCTION. Glucometrics (defined as the analysis of blood glucose data) can be used as a quality indicator of glycemic control in a

patient care unit of the hospital. Metrics generated are utilized to compare the quality of care provided to patients and different units of the hospitals can be compared. We studied the use of glucometrics to compare the glucose control metrics in the medical (MICU) and surgical (SICU) Intensive Care Unit of our hospital over one month.

METHODS: Indoor records of all patients admitted to MICU and SICU of our hospital from 1st July 2017 to 31st July 2017 were evaluated. Data regarding blood glucose level (BSL), its timing, its relation to feeding, as well as insulin dose and type given at that time, along with patient characteristics were noted. All this data was entered into a spreadsheet and then analyzed to generate metrics. A Glucometrics Report was prepared for the period of assessment. The glucometrics data was compared between the ICUs.

RESULTS. A total of 700 BSLs were studied. Of these 325 were in MICU and 275 were in SICU. The mean BSL in MICU and SICU was160 mg/dl and 145 mg/dl (p=0.45) and the Median BSL was 180 mg/dl and 166 mg/dl (p=0.75).

1.5% and 2% of BSL were in the hypoglycemic range (BSL< 70mg/dl) in MICU and SICU respectively (p=0.865). 56% and 54% of BSL were in the acceptable range (BSL in 100-180mg/dl range) in MICU and SICU respectively (p=0.65).

When patients were taken as unit of analysis, 15 and 12 % (p=0.35) of patients had hypoglycemia and 25 and 30 % (p=0.44) of patients had extreme hyperglycemia (BSL>300mg/dl) in MICU and SICU respectively.

CONCLUSIONS. There was no statistical difference in the BSL control in the two ICUs over the period of study. Glucometrics can be used to compare glycemic control between units of hospitals and hence can be used for quality assessment and benchmarking of ICU units.

Patient selection and attendance/non-attendance at critical care rehabilitation clinic

E. Morino, L. Ma, M. Allen, M. Dabliz
Kingston Hospital NHS Foundation Trust, Critical Care, Kingston-upon-Thames, United Kingdom
Correspondence: E. Morino
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0211

INTRODUCTION. Large investments are made during a patient's stay on critical care and their care can only be sustained with good quality care following discharge. Rehabilitating patients discharged from a critical care setting has been recommended by the National Institute for Health and Clinical Excellence (NICE) in 2009 (Clinical Guidance 83)[1]. Non-attendance at these clinics may negatively impact the health of this often vulnerable patient group.

OBJECTIVES. Our aims were to review our patient selection methods and processes leading to invitation to our newly-developed multi-disciplinary intensive care rehabilitation clinic over a 6-month period between October 2017 to March 2018. Our purpose was to analyse the frequency and reasons for non-attendance in order to devise strategies to reduce 'Did Not Attend' (DNA) rates in the future.

METHODS. Our study took place at Kingston Hospital, Surrey, UK. We retrospectively reviewed the cohort of patients for selection to our clinic based on length of stay in critical care, discharge destination and time since discharge. We reviewed their suitability for invitation to clinic via electronic medical records and contact via general

practitioners. We recorded attendance/non-attendance rates and reasons for the latter if these were known if patients informed us prior to clinic or via telephone conversation.

RESULTS. When developing the clinic, it was decided that patient would be selected for invitation to clinic if they had been on critical care for longer than 5 days and discharged from hospital. In total, we identified 57 patients eligible for invitation to clinic. Of these, 14 patients (25%) were deemed unsuitable. There were 3 deaths (5%), 2 moved out of area on discharge (4%), and 9 patients (16%) had moved to a nursing home or were too unwell or were hospitalised at the time of the clinic appointment. 43 patients were invited to clinic with a DNA rate of 13 (30%). Reasons given for non-attendance were unknown (41%), did not feel they needed to attend (23%), frailty (12%), transport (12%), and language (12%).

CONCLUSIONS. Non-attendance at clinic appointments is a multi-factorial problem. In our study it appeared that a significant proportion of patients eligible for invitation to rehabilitation clinic after discharge home were unsuitable due to worsening ill health and frailty. The DNA rate was considerable, and caused by many reasons. Strategies to reduce DNAs in the future may rely on increasing awareness and understanding of the purposes of critical care rehabilitation via leaflets/posters/communication from outreach teams prior to discharge home/social media, as well as administrative processes including electronic text reminders, phone-calls to confirm attendance prior to clinic date, and auditing patient feedback.

Measurement and analysis of noise levels in ICU

G. Vasileiadou[1], V. Vasilopoulos[2], C. Giannaki[1], C. Sevastiadis[2], G. Papanikolaou[2], I. Rodini[1], M. Bitzani[1]
[1]General Hospital G.Papanicolaou Thessaloniki, A ICU, Thessaloniki, Greece; [2]Aristotle University of Thessaloniki, School of Electrical and Computer Engineering, Thessaloniki, Greece
Correspondence: G. Vasileiadou
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0212

INTRODUCTION. Good professional care includes the establishment of an appropriate surrounding environment that promotes rest, sleep and wellbeing that probably contribute to better outcomes. Noise levels exert an important impact on the establishment of such a physical environment. According to World Health Organization (WHO) the recommended Equivalent Continuous Sound Level (L_{Aeq}) in hospitals should not exceed 30 dBA while maximum noise levels (L_{AFmax}) during the night should not exceed 40 dBA . However, it is not clear whether these recommendations can be applied in the high tech environment of an ICU .

OBJECTIVES. The aim of the study was the assessment of noise in a general ICU of a tertiary hospital on a 24hour basis, during weekdays.

METHODS. The measurements were conducted in a big 10- bed area (223m^2). The equipment used was: a class 1NTi XL2 sound level meter and an acoustic analyzer with a class 2 microphone (Type M4260) . The microphone was placed in 4 different, discrete positions, about 2 meters above the floor and 50 cm away from the patient's head. The installation took place 5 days prior to the commecement of actual data collection.Data collection ran over 28 consecutive days. The measurement and data analysis procedures strictly followed the International Standard (ISO1996-1, ISO1996-2) guidelines.

RESULTS. The spatial average of the Continuous Equivalent Sound Pressure (L_{Aeq}) in the 10-bed area room was 63.5 dBA, with maxima reaching 97.5 dBA (table 1).

There was no significant difference between nurse shifts or between the week days concerning the LA_{eq} (table 2,3).The night shift is less noisy compared to the morning one because the medical and nurse personnel is less and fewer interventions are performed.The main

source of noise was staff activity, especially during urgent events, followed by the alarms of the multimodal monitoring used in ICUs, while the impact of the air-conditioning system noise was very low.

CONCLUSIONS. The noise levels within the ICU do not conform to the acceptable range defined by WHO.The results of this study are similar to the findings of other studies and underline the necessity to implement measures aiming to reduce noise caused by personnel and instrumentation in the ICU.Reduction of sound levels to the recommended level of 45 dBA is a desirable target.

Correspondence: C. Lorencio
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0213

OBJECTIVE. To measure the economic impact of sepsis in Catalonia during the years 2015-2016

MATERIALS AND METHODS. The CatSalut morbidity database was used, this database integrates exhaustive information of the resident population in Catalonia. Sepsis cases in Catalonia (54.671) between the years 2015 and 2016 were identified through the methodology described by Angus [Crit Care Med 2011; 29: 1303-101] and the economic costs of these cases was analyzed.

RESULTS. The average cost per patient during the first year since the diagnosis of sepsis was €15,334. In addition, we observed that during the year prior to the sepsis diagnose, patients showed an increase in the average annual health expenditure (€ 6,738 ppy). These costs were especially at the expense of an increase in hospital admissions, emergency consults, pharmacy expenditure and non-urgent medical transport use and took place predominantly during the 3 months prior to the sepsis diagnose.

The average cost per patient during the 2nd year after the sepsis episode continues to be higher (€ 7,411 ppy) than the global average patient cost (€ 968 ppy). These costs involve hospital admission expenses, use of healthcare resources, pharmacy consumption, urgent consultations and the use of non-urgent medical transport.

CONCLUSIONS. Sepsis represents an important economic cost for Catalan Health, not only during the active episode of the disease, but also in the months before the diagnosis and up to two years after the diagnosis. Any intervention to improve the detection, diagnosis or treatment of sepsis could directly affect the economic impact of this pathology.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0214

Introduction

Supplementary oxygen is frequent in management of critically ill patients with supra-normal values of partial arterial pressure in oxygen (PaO2) being frequently achieved. However, some studies have demonstrated deleterious effects of hyperoxia in critically ill patients presenting brain injury, cardiac arrest, acute distress respiratory syndrome and/or septic shock[1-3]. These studies focused on 48 first hours of admission.

Objectives

Our objective was to evaluate the impact of hyperoxia exposure at any moment in ICU stay on ICU mortality and on overall survival.

Methods

It was an observational, retrospective, and single-centre study conducted in the department of critical care of George Pompidou European Hospital, in Paris. All patients admitted in ICU between November and December 2017 were included. Hyperoxia was defined as PaO2 >100 mmHg. Outcomes were compared between patients presenting at least one hyperoxia episode and patients who did not. A multivariate analysis was performed to assess factors associated with ICU mortality.

Results

130 patients, median age 68 years [57-79], were included. Median SAPS II was 45 [35-56]. 83 patients (64%) had mechanical ventilation during their stay during a median time of 5 days [2-11.5]. The median time of ICU stay was 4 days [2-10]. 1.450 arterial blood gas (ABG) were assessed with a median number of AGB for each stay of 4 [2-13]. Eighty patients (62%) presented at least one episode of hyperoxia.

During their ICU stay, 35 patients died (27%). Overall survival was significantly lower in patients that presented at least one episode hyperoxia during ICU stay, p=0.0047 (Figure). In univariate analysis, maximal PaO2 and time of hyperoxia exposure are significantly higher in the deceased group.

In multivariate analysis including age, sex, SAPS II and admission for respiratory cause, to have at least one hyperoxia episode during ICU stay was independent risk factor of ICU mortality, OR=5.18, $_{95}$CI=[1.53-21.71], p=0.013 (Table).

Conclusion

Presenting at least one hyperoxia episode at any moment of ICU stay decreased overall survival and is an independent risk factor of ICU mortality regardless the severity of the patients or the cause of ICU admission.

INTRODUCTION. The elderly are a growing population among patients admitted to Intensive Care Units (ICU) in the industrialized world, who will most probably influence in a capital way on the future development of the critical medicine. To delve in the features and prognosis of these patients will provide reliable information to help the clinicians manage the ICU resources properly and offer an adjusted care to older patients.

OBJECTIVES. To describe characteristics and clinical course of patients over 65 years old admitted to Spanish ICU during the period from 2013 to 2016. To identify factors related to in-ICU mortality.

METHODS. Data gathered from a prospective multicentric registry (ENVIN-HELICS) that compiles information from every region in Spain. Variables regarding demographics, comorbidities, clinical course and applied devices were studied. Multivariate analysis was employed to determine factors related to in-ICU mortality. Predictive power of the model measured by the AUC. Categorical variables are expressed as percentages; for continuous variables mean value and standard deviation (SD) are provided.

RESULTS. 37,172 patients over 65 years old were registered, 62.5% males and 8.0% over 85 years old. 80.0% of the patients had comorbidities: diabetes was the most frequent one (32.6%), followed by malignancies (18.0%). The mean value of the APACHE II scale was 11.9 points (SD 8.9 points). Pre-ICU length of stay (LOS) was 3.3 days (SD 10.0 days) and mean ICU LOS 6.3 days (SD 9.4 days). In 8.6% of the patients multidrug resistant pathogens (MRP) were isolated, more frequently acquired before ICU admission (OR 1.97; IC95% 1.63-2.38). The most frequent in-ICU acquired infections were catheter related urinary tract infections (2.3%). 4,260 patients died in ICU (11.5%). The variables that showed association to mortality were: to be admitted for a non-surgical pathology (OR 1.44; IC95% 1.19-1.74), pre-ICU LOS over 7 days (OR 1.30; IC95% 1.09-1.58); chronic kidney disease (OR 1.22; IC95% 1.04-1.44), previous immunosuppression (OR 1.74; IC95% 1.39-2.19); use of renal replacement therapies (OR 4.56; IC95% 3.73-5.58), artificial nutrition (enteral OR 1.33; IC95% 1.10-1.61 and parenteral OR 1.27; IC95% 1.03-1.57), arterial, central venous and urinary catheter insertion (OR 1.40; IC95% 1.22-1.62, OR 3.60; IC95% 2.89-4.48 and OR 3.04; IC95% 2.25-4.10 respectively); and among in-ICU acquired infections, ventilator associated pneumonia (OR 2,44; IC95% 1.76-3.40) and secondary bacteremia (OR 2.20; IC95% 1.43-3.40). The predictive power of the model was adequate, AUC 0.82 (IC95% 0.80-0.83).

CONCLUSIONS. Characteristics and clinical course of the elderly admitted in ICU are described. MRP are more frequently acquired pre-ICU. In-ICU mortality was affected by various factors such as comorbidities, previous clinical course or in-ICU acquired infections. The predictive model obtained out of the sum of prognosis factors had an adequate discriminatory power.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0216

INTRODUCTION. Despite improved survival of critically ill cancer patients hematopoietic stem cell transplantation (HSCT) patients remain a subgroup with poor prognosis. Consequently, ICU management is still seriously debated. ICU structure and organization is known to affect patient outcome and quality of critical care in general ICU but data on implementing specialized oncological ICU structures are lacking.

OBJECTIVES. We therefore aimed to elucidate the effect of implementing an intensivist lead multidisciplinary care team in the highly-specialized field of critically ill HSCT patients on ICU survival.

METHODS. We compared ICU mortality of HSCT patients admitted to the ICU in 2011/2012 (before an intensivist model was established) with those in the years 2013/2014 and 2015/2016 (after the model was established). Organizational change implemented in 2012 consisted of high intensity staffing according to the Leapfrog model and daily rounds between intensivist and hematologist. We allowed for 1

year of transition (2012) to implement the changes required. In 2015, a respiratory therapist was added to secure ventilation and weaning protocol adherence. We assessed the effect of staffing on ICU outcome by accounting for patient and illness-related confounders using multivariate logistic regression analysis.

RESULTS. A total of 182 patients were included. In 2011/2012 (n=43) overall ICU, hospital, 6 months and 1 year - survival was 20.9%, 20.9%, 18.6% and 9.3%. In patients with IMV (83.7%) ICU, hospital, 6 months and 1 year - survival was 8.3%, 8.3%, 5.5% and 2.7%. In 2013/2014 (n=71) overall ICU, hospital, 6 months and 1 year - survival increased to 32.4%, 31.0%, 31.0% and 26.8%. In patients with IMV (61.9%) ICU, hospital, 6 months and 1 year - survival increased to 18.2%, 18.2%, 18.2% and 15.9%. In 2015/2016 (n=68) overall ICU, hospital, 6 months and 1 year - survival further increased to 51.4%, 42.6%, 32.4% and 30.9% while IMV patients (66.2%) ICU, hospital, 6 months and 1 year - survival increased to 31.1%, 24.4%, 17.8% and 17.8%. The following variables were associated with ICU survival; CRRT (OR 0.12 [95%CI 0.01-0.34]; p< 0.01), IMV (OR 0.03 [95%CI 0.01-0.10], p< 0.01) and study period (p=0.04; 2011/2012, OR 1; 2013/2014, OR 1.28 [95%CI 0.4-4.07], p=0.68; 2015/2016, OR 3.6 [95%CI 1.17-11.1], p=0.03).

CONCLUSION. Implementing a specialized intensivist lead multidisciplinary critical care team significantly improves ICU and long-term survival of hematopoietic stem cell transplantation patients.

INTRODUCTION. Critically ill patients in intensive care units (ICUs) are exposed to stressful conditions and experience discomfort from multiple sources with potential short-term and long-term consequences, such as various degrees of anxiety and/or depression or post-traumatic stress disorder (PTSD), which may affect their quality of life and lead to increasing healthcare utilization.

OBJECTIVES. The aim of this study was to assess the impact of the implementation of a tailored multicomponent program (TMCP) for discomfort reduction on the occurrence of post-traumatic stress disorder (PTSD) 12 months after ICU discharge.

METHODS. After carrying out the IPREA3 study (a multicenter, cluster-randomized, two-arm parallel, controlled study involving 34 French adult ICUs to assess the efficacy of our TMCP for discomfort reduction in the ICU), we conducted, in 30 of the 34 ICUs, the AQVAR study consisting of 1-year follow-up of the patients already included in IPREA3. The TMCP consisted of assessment of ICU-related self-perceived discomforts by using the IPREA questionnaire, immediate and monthly feedback to healthcare teams, and tailored site-targeted measures under control of a duo of local champions.The main objectives of the AQVAR study were to assess anxiety and depressive symptoms and PTSD using resp. the Hospital Anxiety and Depression Scale (HAD-S) and the Impact of Event Scale-revised (IES-R). Based on a design of a case-control study, the cases were patients hospitalized in the ICUs which implemented the TMCP and the controls were patients hospitalized in the ICUs which did not implement the TMCP. HAD-S and IES-R were administered either by telephone or returned by patients after mailing. Sociodemographic data, clinical data related to the ICU stay, discomfort´s levels assessed the day of ICU discharge, life situation (home/care center) were collected at 12 months after ICU discharge, in addition to IES-R and HAD-S.

RESULTS. From the 617 eligible cases and 847 eligible controls, 344 cases and 475 controls were included. A total of 6.1% of the cases and 12.0 % of the controls presented certain symptoms of PTSD at 12 months (*p*=0.004). After adjustment for age, gender, IPREA score, McCabe score, use of invasive devices and considering anxiety-depression symptoms at 12 months, cases are less likely to have PTSD symptoms than controls.

CONCLUSIONS. A tailored multicomponent program for discomfort reduction in the ICU may significantly reduce the incidence of PTSD assessed at 12 months. Diffusion of such a program should be enhanced in the ICUs paving the way for a new strategy in care management.

INTRODUCTION. Predicting weaning outcome from mechanical ventilation in multiple trauma patients is very important. The rapid shallow breathing index (RR/TV) is one of most widely used index to predict weaning outcome.As diaphragm plays a fundamental role in generating TV ,substitution of Tv with diaphragmatic displacement measuring by ultrasonography and calculate the ratio between respiratory rate and diaphragmatic displacement could predict weaning outcome.

OBJECTIVES. The aim of this study was showing the ability of D-RSBI to predict weaning outcome in multiple trauma patients .

METHODS. In this study fifty patients in the trauma intensive care unit who required mechanical ventilation over 48 hrs and met the criteria for weaning were assessed. Patients with a history of diaphragmatic disseases before trauma or cervical cord injury were excluded. During weaning, each hemidiaphragm was evaluated by M-mode ultrasonography using the liver and spleen as windows with the patient in supine position.

RESULTS. Most of the patients 26(52%) were successfully weaned from mechanical ventilation and 24(48%) were failed. Right D-RSBI and Left D-RSBI were successfully predict weaning outcome with pvalue (right=0.007) and (left=0.02). The cut of point for RD-RSBI is 22.2250 rr/min/cmn with sensitivity 87% ans specifity 93%. The cut of point for LD-RSBI is 18.97 rr/min/cm with sensitivity 87.5% and specifity 89%.

CONCLUSIONS. This study shows that, the assessment of D-RSBI by ultrasonography may predict weaning outcom in multiple trauma patients

INTRODUCTION. Sensitivity of chest radiograph(CXR) is as low as 49% especially in ICU patients taken in supine position. Lung ultrasound (LUS) has a number of advantages in the intensive care unit (ICU). For example, it can be used in real time at the bedside, radiation-free, and it more accurately defines the causes of undifferentiated opacities on CXR. In mechanically ventilated patients, it has been found that lung ultrasound (LUS) is more accurate than chest radiograph (CXR) in diagnosing and distinguishing different types of consolidations and dynamic air-bronchograms(DAB) has good sensitivity and specificity (>90%) to diagnose pneumonia.
OBJECTIVES. We aimed to investigate the agreement of chest radiograph and LUS when concomitantly performed in the evaluation of pleural effusion and pneumonia and pneumonia under the pleural effusion at the same site which can be happen frequently in ICU patients and can be hardly detected with CXR.
METHODS. The presence of pleural effusion, signs of pulmonary congestion and/or consolidation was evaluated on the CXR by an independent expert pulmonologist. Bedside LUS was performed in the same day with CXR while patients in the supine position by the experienced intensivists. The Vividq(GE) ultrasound system and linear and phase array probes were used for the data collection. The LUS exam was required to identify the lung sliding, lung point, A-lines, B-lines, consolidation/atelectasis and pleural effusion, dynamic and static air bronchograms associated with a pleural effusion. The lung consolidation accompanied by an dynamic air bronchogram was accepted as main feature of pneumonia on LUS. Kappa statistics were used for agreement analysis.
RESULTS. The study included 57 cases that admitted to ICU with in one year period. According to CXR there were pneumothoracis in 2 patients but LUS and thorax CT were not confirm this finding. There were poor aggrement between LUS and CXR(less than moderate(Kappa:0.39, p 0.001) in the comparison of pleural effusion and there were no aggrement in the comparison of pneumonia(kappa: 0.21,p: 0.09). Agreement was better in patients with COPD (kappa>0.5,p< 0.05). CXR underestimated bilateral pleural effusions (9% versus 25%). 17% of patients had DAB+Pleural effusion in the left side and 21% of them had on the right side with LUS but CXR detected only 8% of them in both side.

CONCLUSIONS. These results suggest that in the suspicion of pleural effusion and concomitant pneumonia which is very frequent in ICU patients, LUS is better than CXR to detect them.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0220

INTRODUCTION. The muscle loss described in the critical patient has been related to a poor prognosis. This process is conventionally identified through biochemical parameters. The muscle reserves can reflect the body protein reserve, muscle ultrasound has a strong correlation with magnetic resonance (r = 0.91, p < 0.001). The depletion of myofibers can be assessed the Heckmatt scale (Table 1). There may be a correlation between muscle loss and protein decrease reflected in nutritional assessment.
OBJECTIVE. The goal of this study was to determine the correlation of the sonographic measurement of the anterior muscles of the thigh with the conventional biochemical parameters to assess the nutritional status in the ICU.
METHODS. This longitudinal, prospective, observational study, was conducted at the Intensive Care Unit, Centro Médico Nacional del Bajío UMAE 1, in León Guanajuato, between December 2017 to March 2018. Patients were admitted over 18 years with medical, traumatic and surgical diagnoses, who received enteral diet in the first 24 hrs after admission, with a minimum protein intake of 0.8mg / kg / day. Nitrogen Balance, Prealbumin, Albumin and simultaneously sonographic parameters at the level of the Rectus Femoris (RF) and Vastus intermedius (VI) (Muscle wasting percentage, AP diameter, Lateral diameter and Cross sectional area and Muscular Ecogenicity) were measured at their admission and 7 later days. We excluded patients with any pathology that affects the muscular area to evaluate or amputation of pelvic limbs. Statistical analysis was performed using MDCalcX version 18.
RESULTS. We included 8 patients, mean age of 36 years, Female Gender: 37.5% Male: 62.5%. 50% with normal Body Mass Index, 37.5% with overweight and 12.5% with Obesity grade I. The average protein intake per early enteral diet was 1.28 gr / kg /day. The mean APACHE II and SOFA were 18 and 10 points respectively; The most frequent diagnosis was of traumatic origin (62.5%). We found a significant difference between the biochemical and sonographic values between days 0 and 7 (Table 2). A correlation test was performed for the most significant parameters (cumulative nitrogen balance and the cross-sectional area VI, however, was not positive (r = 0.14) (Figure 1), whereas the Heckmatt scale on day 0 had an average and on day 7 of 2.8 , showing deterioration in the quality of the myofibrils throughout the stay in the ICU.
CONCLUSION. Although biochemical parameters such as the nitrogen balance is used to assess the nutritional status of critical patients, there is no positive correlation with muscle sonographic assessment.

INTRODUCTION. Many instruments have been developed to evaluate hospital mortality, but less attention has been paid to the long-term functional status and quality of life (QOL) of traumatic brain injury (TBI) patients.

OBJECTIVES. To study the QOL in two follow-up period between 1 year and 3-4 years and the related variables in TBI admitted to the intensive care unit at the University Clinical Hospital (Malaga) between 2004 to 2008.

METHODS. Prospective cohort study of all TBI admitted to the Carlos Haya Hospital (Málaga) between 2004-2008.

Data were expressed as the mean and standard desviation for quantitative variables and percentages for qualitative variables.

We used ANOVA and Newman Keuls test to compare means, Pearson coefficient for correlation and linear regression for multivariate analysis. Statistically significant differences $p < 0.05$.

RESULTS. 531 patients. Mean age 40.35±19.75 years, APACHE-II 17.94±6.97, admission GCS 7.53±3.83 points. Computerized tomography (CT) on admission by Marshall score was: diffuse injury type I (10.4%), type II (28.1%), type III (24.5%), type IV (8.3%), mass evacuated (22.6%), mass not evacuated (6.2%). Hospital mortality 28.6%. 171 patients died at first year (32.2%) (6.6% missing) and at 4 years 175 died (33%) (16.2% missing). Imputation with statistical techniques the 86 patients were classified as alive. Normal functional status or with dysfunction but self-sufficient: 1st year 65.3% of the 325 patients alive and 3-4 years: 75.76% of the 264 alive and followed.

The evaluation of the QOL was performed by PAECC (Project for the Epidemiological Analysis of Critical Care Patients) questionnaire (0 points: normal QOL, 29 points: worst score). Mean score at first year follow-up (n = 324) 9.44±8.73 points, indicating high deterioration in QOL. At 3-4 years 6.77±7.70 points (n=238). An improvement in QOL was observed between 3-4 years (-2.39±3.71 points, N=238) (p< 0.001).

The evolution of QOL between 1 and 3-4 years is associated with age ((r=0.235, p< 0.001), age < 35 years have greater improvement (-3.07± 3.58 vs -1.16± 3.64 points, p< 0.001), with QOL 1º year ((r = -0.378, p < 0.001) ≤ 1 point present lower improvement than the rest (-0.16± 0.37 vs -315± 4.02 points, p< 0.001), stay in ICU (r = - 0.245, p< 0.001), admission GCS (r = 0.252, p< 0.001), days of mechanical ventilation (r = -0.239, p< 0.001) and admission TC.

Multivariate analysis by multiple regression found association between the QOL evolution with the quality of life at 1ºyear and age. If only variables evaluated during hospitalization are included, the model included: age, stay in ICU and CT at admission by Marshall scale.

CONCLUSIONS. Approximately 75% of TBI that survive are self-sufficient at three years. Between 1st and 3rd year, QOL modifies favorably, being higher in young people and with worst QOL 1º year.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0222

INTRODUCTION. The traumatic brain injury (TBI) requires critical management of the patient in an intensive manner to avoid secondary damage to the trauma. The use of continuous sedation, strict control of mean arterial pressure (MAP), and the definitive airway are important interventions used in this population. Hemodynamic monitoring offers valuable information on cardiovascular performance in the critically ill. The literature points to neuromuscular electrostimulation (NMES) as an alternative to intensive care unit-acquired weakness (ICU-AW) combat, with positive results in critically ill patients, but there is a need to evaluate the safety of this intervention.

OBJECTIVES. The present study aimed to verify the hemodynamic safety of a NMES protocol in patients with TBI.

METHODS. We performed an experimental prospective trial in the trauma intensive care unit (ICU). It was included traumatic brain injury patients, aged from 18 to 65 years, in the first day or until 72 hours of mechanical ventilation. Electrical stimulation was applied daily in the muscles: quadriceps, tibialis anterior, gastrocnemius and hamstrings for 14 days. The protocol (pulse width of 400 μs, frequency of 100 Hz, rise and fall times of 1 second each, 5 second flow time and rest time of 25 seconds) lasted 25 minutes in the anterior (quadriceps and tibialis anterior) muscles and 25 minutes in the posterior ones (hamstrings and gastrocnemius). Hemodynamic variables were assessed before and immediately after the end of each NMES session. Mean arterial pressure (MAP) was measured in invasive arterial line and heart rate (HR), using a five-lead electrocardiogram.
RESULTS. We enrolled 18 patients totaling 226 interventions and 109 were finished 14 days of follow up. 266 predicted sessions, 52% were lost due to hemodynamic instability, deaths, ICU discharge and protocol discontinuity. There were no statistically significant differences between MAP (P = 0.81) and HR (p = 0.63); pre and post intervention
CONCLUSION. Considering the findings of this study, we can say that NMES is safe for this population because not producing variations in MAP and HR.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0223

INTRODUCTION. Tracheostomy is an operative procedure frequently utilized in acute brain injury (ABI) patients admitted to the Intensive Care Unit (ICU). This maneuver is associated with several complications (1).
OBJECTIVES. To analyze complications associated with tracheostomy during the ICU stay in patients with acute brain injury (ABI). In particular, to evaluate: 1) acute intraoperative problems, 2) perioperative respiratory, hemodynamic and cerebral effects and 3) postoperative complications during ICU stay.
METHODS. A prospective single-center observational study was performed from January to December 2017 including all ICU patients with acute brain injury undergoing tracheostomy.
RESULTS. n the study period, 515 patients were admitted to our ICU (50% with ABI). We enrolled 104 patients [69 (66%) males]. The main diagnosis was traumatic brain injury [35 (33%)]. Median Glasgow Coma Scale (GCS) score at ICU admission was 7 (IQR 5-9). All tracheostomies were performed at the bedside by ICU physicians [surgical technique in 88 (85%) cases and percutaneous technique in 16 (15 %) cases]. Tracheostomy was performed on average 5 day (± 2.8) after ICU admission. The mean duration of the procedure was 22 (± 10.7) minutes. Intracranial pressure (ICP) monitoring was performed in 62 (60%) patients. Acute intraoperative problems requiring interventions were: increase in arterial blood pressure (ABP) [71 (68%)], increase in ICP [5 (5%)], simultaneous increase in ABP and ICP [14 (14%)] and surgical site bleeding [1 (1%)] requiring maxillo-facial surgeon intervention. Postoperative complications were: stoma bleeding [8 (8%)] (not needing surgery), stoma infection [8 (8%)] and cannula

obstruction [1 (1%)] (needing urgent change without clinical consequences). Perioperative respiratory, hemodynamic and cerebral effects were reported in Table 1. Ninety-eight (94%) patients were discharged alive from ICU [median GCS 10 (IQR 8-11)]. Mean length of stay in ICU was 21.5 (± 10.8). Tracheostomy was present at discharge in 89 (85%) patients.
CONCLUSIONS. Tracheostomy seems to be a safe procedure in ABI patients. However, some complications (mainly intraoperative), requiring a rapid and appropriate management, may be present.

INTRODUCTION. Mannitol and hypertonic saline (HTS) are commonly used for the treatment of elevated intracranial pressure (ICP) in patients with traumatic brain injury (TBI). However, their effects on mortality and neurological outcome are unclear.
OBJECTIVES. To study the effect of mannitol and HTS during the first three days on mortality in TBI patients treated in the intensive care unit.
METHODS. We studied patients included in the Erythropoietin in TBI (EPO-TBI) trial, excluding patients who died before day three. We included the amount of mannitol and HTS administered during the first three days. Severity of TBI was categorized according to the International Mission for Prognosis and Analysis of Clinical Trials (IMPACT) model. Cox regression analysis was used to predict time to death beyond day three until discharge from the ICU.

RESULTS. Out of 600 survivals at day three, 76 (13%) later died and 264 (44%) died or survived with poor neurological recovery. Patients who died received on average 67 ml (95% confidence interval [CI] 20-114 ml) of mannitol and those who survived received 18 ml (95% CI 10-26 ml) (p=0.006). The corresponding figures of patients with poor outcome were 18 ml (95% CI 7-29 ml) and 34 ml (95% 18-51 ml) (p=0.04). Patients who died received 277 ml (95% CI 156-399 ml) of HTS and survivors received 226 ml (95% CI 170-282 ml) (p=0.06). Patients who survived with poor outcome received 258 ml (187-329 ml) compared to 207 ml (136-278 ml) in those with good outcome (p=0.44). Independent predictors of time to mortality were proportion of hours of ICP higher than 20 mmHg during the first two days (per 100%) (HR 6.7 95% CI 2.9-15.6, p< 0.001), IMPACT TBI severity (per 10% increase of risk of poor outcome) (HR 1.3 95% 1.2-1.5, p< 0.001), APACHE II score (per point) (HR 1.07 95% CI 1.03- 1.1, p=0.001) and amount of administered mannitol (per 100 ml increase) (HR 1.2 95% CI 1.0-1.4, p=0.02). The administered amount of HTS was not associated with mortality (HR 1.0 95% 1.0-1.001, p=0.21)

CONCLUSIONS. The amount of administered mannitol during the first two days was independently associated with to survival beyond day three when controlling for several factors of TBI severity. The role of mannitol in moderate to severe TBI should be studied further.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0225

INTRODUCTION. Last-tier treatments benefit on traumatic Intracranial Hypertension remains unclear. Recent randomised controlled trial suggest that there is a significant impact on survival in surgical versus medical therapy.[1]

OBJECTIVES. Characterization of the population, aged 18 years to 75 years, diagnosed with traumatic brain injury and refractory elevated intracranial pressure, submitted to last-tier intervention (secondary decompressive craniectomy vs. barbiturate coma) admitted to an intensive care unit, of a tertiary hospital, between 2011 and 2017.

METHODS. Retrospective, descriptive and inferential trial of 37 patients, evaluating: age; sex; Glasgow Come Scale (GCS), paO2; pupillary symmetry and hypotension at admission; time to Intracranial pressure monitoring, start and duration of last-tier treatment, ventilatory support, length of stay in ICU, in-hospital mortality, and systematic analysis of primary clinical outcome at 6 months using the Extended Glasgow Outcome Scale (GOS-E). Secondary outcomes were also evaluated, namely imaging pattern of ICP elevation, duration of barbiturate coma, extracranial lesions and duration of intracranial hypertension.

RESULTS. A total of 37 patients, 81,1% male, with mean age of 43.6 years (+/- 15.6). GCS on admission to the emergency room was similar in both groups. The time to the last-tier intervention was higher in the surgical group (137h 6min vs. 69h 34min). The Barbiturate coma patients had longer length of stay in the ICU (18days 6h vs.

14days 16h). In-hospital mortality rates were 19% in the medical group and 18% in the surgical group. At 6 months, the GOS-E in surgical group vs. barbiturate coma were: 25% vs. 47,1 % death; vegetative state, 35% versus 17,6%; moderate disability, 15% versus 17,6%; and good recovery, 20% versus 11,8%, respectively.

CONCLUSIONS. Despite the better prognosis associated with surgical therapy, with lower mortality rates at 6 months, there was a negative impact on the functional status and unfavorable neurological results compared to medical therapy.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0226

OBJECTIVES. To assess whether implementation of antibiotic impregnated (AI) external ventricular drains (EVD) catheters, instead of the ordinary silastic ones, can eliminate the burden of prophylactic catheter exchange for the critically ill patients of general ICUs.

METHODS. A retrospective cohort study of all the EVD cases that were treated in the general ICU of a regional tertiary hospital in Greece during the decade 2006 - 2016. Comparisons and statistical analyses were performed between two groups of patients (with AI-EVDs or common EVDs) and two groups of EVD catheters (AI-EVDs versus ordinary ones). Data collected from 49 patients (median age 67 years), 81 EVD catheters (AI = 43,ordinary =38) and 1080 days of drainage. The analysis referred mainly to duration of catheterization, in relation to confirmed ventricular assosiated infections (VAI), catheter colonizations, predisposing to VAI factors, handling and catheter exchange protocols, clinical and laboratory findings and patients' outcome.

RESULTS. We found that median duration of catheterization with AI-EVD catheters was more than double the duration with ordinary ones, 17 and 7.5 days respectively, p < .0001, with the rate of colonization being unaffected (p = .4). In addition, per 1000 days of EVD the colonization rate for the ordinary catheters was threefold the AI catheters one (OR = 0.65). The accumulative median level of white blood cell count in CSF samples was significantly higher for the ordinary catheters (p < .05) whereas number of EVD manipulations varied inversely (median number 7 for AI and 3 for ordinary catheters, p < .001). Our colonization (and confirmed VAI) flora, for both types of catheters, was resistant Gram (-) bacilli and median per patient, EVD duration was 17 days.

CONCLUSIONS. Antibiotic impregnated EVD catheters seem to last much longer than ordinary silastic ones in general ICU settings, by means of colonization, hence they do not require a predetermined exchange protocol. They are also more resistant, colonization-wise, to increased number of manipulations. The mechanism of their efficacy towards Gram (-) bacteria needs to be investigated further with clinical and laboratory studies.

OBJECTIVE. To verify if physiotherapy care (PTc) provided within 24 h/day for Trauma patients in the Intensive Care Unit (ICU) reduces the length of stay, mechanical ventilation (MV) support and mortality compared to a physiotherapy care provided within 18 h/day.

METHODS. A longitudinal study was designed to assess differences between first three months of the year (2016) hospital where patients were given physiotherapy care for 18 h/day and last 3 months of 2016 with 24 h/day. We considered the following as outcome measurements: clinical diagnosis, Acute Physiology and Chronic Health disease Classification System II (APACHE II), ICU and mechanical ventilation length of stay and survival. T test of student was made to compare differences between two groups.

RESULTS. 118 patients were enrolled in this study (70% male, age 45 ± 16 years, APACHE II 18 (15-23). Patients admitted during 24h/day of PTc showed a lower length of stay in ICU (17 ± 3.1 days X 21.1 ± 3.9 days respectively, p = 0.03) and mortality rate (71% versus 79% respectively, p =0.04). No difference was found for APACHE II score (p = 0.8) and MV length of stay (11.5 ± 3.4 X 13.5 ± 3.3 days, p > 0.05) between two groups.

CONCLUSION. The presence of a PTc contributes decisively to reduce number of hospitalization days and mortality of ICU trauma patients.

Glycemic variability in patients admitted to the ICU due to TBI and its relationship with morbidity and mortality

J.F. Martínez Carmona, F.A. Hijano Muñoz, E. Lopez Luque, J.M. Mora Ordoñez, M. Delgado Amaya, G. Quesada
H. R. U de Málaga, Intensive Care, Málaga, Spain

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0228

INTRODUCTION. Critical patients, diabetic or not, present glycaemic alteration, due to an increase in glucose production (glycogenolysis / gluconeogenesis), as well as the presence of insulin resistance. Dysglicemia leads to an increase in morbidity and mortality. Glycemic variability has been shown to be an independent risk factor for mortality in critically ill patients.

OBJETIVES. The main objective of the study is to assess the glycemic variability in patients admitted to the ICU by TBI, assessing the possible relationship with mortality and morbidity.

MATERIAL AND METHODS. We studied a sample of 17 patients admitted to the ICU due to TBI. It is a retrospective study, we analyzed the glycemic controls during admission to the ICU, with at least 4 determinations per day of glycemia. The following variables are collected: age, sex, diabetes mellitus, APACHE II, SOFA, stay in ICU and hospital, mortality in ICU and hospital.

RESULTS. In our sample, 82.4% were male, and only 29.4% were diabetic. The average stay was 13.94 days. The ICU mortality was 17.6%. We did not find significant differences in glycemic variability between diabetic and non-diabetic patients. When we analyze the Standard Deviation (SD) of the standard deviation of glycemic variability during admission to the ICU, we observe a statistically significant relationship with mortality, using Chi2 test (p 0.02), as well as a linear relationship using the Coefficient of Pearson correlation (p 0.019). We found a cut-off SD in 20.13 (Sensitivity 66.7% and Specificity 85.7%). We found a relationship between APACHE II on admission and SD glycemic, but without statistical relationship (p 007).

CONCLUSIONS. Glycemic variability in critically ill patients is an independent risk factor for mortality. Strict control of blood glucose levels has proven to be detrimental to the patient. In our sample, patients with Standard Deviation below 20.13 presented higher survival in ICU, as well as lower in-hospital mortality.

RESULTS. NO_2^- levels, as an indicator for tissue NO production, were consistently elevated in the ipsilateral hemisphere (1.3 fold ipsi- vs. contralateral). Nitrotyrosine formation was increased in the ipsilateral hemisphere, in particular in areas of hematoma and tissue injury.

CONCLUSIONS. This study revealed increased rate of NO synthesis in ipsilateral specimens accompanied by increased oxidative and nitrosative stress in a porcine resuscitated model of ASDH. These data suggest that inhibition of NO production or ROS/RNS scavenging can help to attenuate TBI-induced neuro-inflammation.

INTRODUCTION. Traumatic brain injury (TBI) is characterized by increased intracranial pressure (ICP) associated with hypoxia, microvascular collapse, ischemia, blood-brain barrier (BBB) dysfunction, and swelling (1,2). Over 40% of all TBI cases develop an acute subdural hematoma (ASDH) resulting from rupture of the bridging veins (3,4). We recently showed in septic shock that reduced tissue expression of the H_2S-producing enzyme cystathionine-γ-lyase (CSE) was associated with kidney vascular barrier dysrupture (5) and impaired coronary artery integrity and left ventricular dysfunction (6). Exogenous H_2S was protective in TBI (7), but little is known on the role of CSE in TBI.

OBJECTIVES. To study brain CSE expression after long-term, resuscitated porcine ASDH-induced TBI.

METHODS. Anesthetized mechanically ventilated pigs (n=9) were surgically instrumented for bilateral multimodal brain monitoring, ASDH was induced by injection of 20mL blood into the subdural space at the left parietal cortex. TBI management was performed according to TBI guidelines for up to 54h (8). Post mortem cortical brain samples were analysed by immunohistochemistry for CSE and albumin expression as a marker of vascular leakage. All arteries in frontal cortex samples of the injured (ASDH) and non-injured (neurosurgical instrumentation for monitoring alone) were analysed using a scale from 0-3, averaged and then expressed as fold increase injured.

RESULTS. ASDH caused a several-fold higher CSE expression than the neurosurgical instrumentation alone (100(40;100) vs. 8(7;50)·10^6 densitometric units). Vascular expression of CSE was present in the media as expected and increased 1.5-fold in the injured region. The increased CSE expression coincided with higher tissue albumin extravasation.

CONCLUSION. In a long-term, resuscitated porcine model of ASDH-induced TBI CSE was upregulated as a response to injury, more than likely as an adaptive stress mechanism. The non-injured hemisphere, although instrumented, showed little albumin extravasation and reduction of CSE expression.

INTRODUCTION. Subarachnoid hemorrhage (SAH) is a devastating form of stroke. The patients present approximately a 50% mortality rate, mostly occurring before hospital admission, and another 30% have permanent disability. Cerebral vasospasm (CVS) is a major complication in these patients and may lead to delayed cerebral ischemia (DCI). The improvement of outcome is limited by the reversal of arterial narrowing and improvement of perfusion. Several agents and endovascular therapy have been used in patients with SAH with consistent benefit in relieving vasospasm. Milrinone is an inotropic and vasodilatory drug proven safe for use in the treatment of cerebral vasospasm.

OBJECTIVES. We aimed to review the success rate of aggressive management with milrinone for severe and refractory CVS used in our center from 2013 to 2018.

METHODS. A total of 11 patients who received milrinone treatment for CVS following SAH between 2013 and 2018 were included in the study. Refractory vasospasm was defined as patients with CVS refractory to therapies requiring ≥3 endovascular interventions. Overall, 8 patients meet criteria for refractory CVS. WFNS, Fisher, APACHE II e SAPS II score were assessed. The protocol management of these patients included nimodipine and control of arterial blood pressure according to autoregulation evaluation, decrease of blood viscosity and normal body temperature.

RESULTS. All patients had aneurysmal subarachnoid hemorrhage. The median WFNS was IV (min: I, Max: V), Fisher: 4 (min: 3, Max: 4), APACHE II: 14 (min: 7, max: 24) and SAPS II score: 27 (min: 8, max: 52). Nimodipine was given to all patients (11) and daily transcranial Doppler was performed. When severe vasospasm occured (3 men and 5 women), an endovascular intervention was made with verapamil (25) or milrinone (2) intra-arterial injection. Afterwards, an IV perfusion of milrinone was added (15 days, min: 9, Max: 18) and a progressive reduction of CVS was observed.

CONCLUSIONS. A combination therapy including milrinone seems to be a useful approach as a rescue therapy to avoid DCI related to hypoperfusion secondary to severe refractory vasospasm.

INTRODUCTION. Acute subdural hematoma (ASDH) assumes major importance in traumatic brain injury (TBI), in particular in the elderly and/or vascular co-morbid patient (1). Increased levels of reactive oxygen and nitrogen species (ROS/RNS) are reported to promote TBI-related neuro-inflammation (2). In TBI, enhanced formation of nitric oxide (NO) may lead to peroxynitrite production due to reaction with the superoxide anion (O^{2-}), thus aggravating oxidative and nitrosative stress (3,4). Peroxynitrite is capable of protein nitrosylation of tyrosine residues, thus leading to nitrotyrosine formation (3).

OBJECTIVES. The aim of this experiment was to investigate cerebral nitrosative stress in a resuscitated porcine model of ASDH.

METHODS. Anesthetized, mechanically ventilated and surgically instrumented pigs underwent ASDH (trepanation above the left parietal cortex and subdural injection of 20 ml of blood). Resuscitation was performed according to the guidelines of TBI management (5) and comprised fluid and catecholamine administration to maintain mean arterial pressure at pre-ASDH levels and cerebral perfusion pressure >75 mmHg. Fifty four hours after ASDH induction, animals were sacrificed and the brains were harvested. Tissue nitrite (NO_2^-) levels were assessed on homogenized ipsi- and contralateral specimens using a chemiluminescent assay (N=5). Immunohistochemistry for nitrotyrosine was performed on formalin-fixed cortical paraffin sections (N=7).

INTRODUCTION. In 1959 Lundberg presented a system to monitor ICP continuously which is used worldwide and regarded as gold standard. The zero reference point for the external pressure gauge has to use anatomical structures on the head. These structures vary according to the literature and may cause deviation from the true ICP values at different head positions.
OBJECTIVES. We wanted to evaluate some of the set ups for placing the zero reference point of the ICP device and their relation to Midbrain, Monroe and brain surface by looking at 3D MRI scans.
METHODS. Patients with MRI scanning's, intact cranial cavity and no space occupying lesions or hydrocephalus at the Neuroradiologic Dept. of Lund, was selected. Length and height for the brain were measured. Different structures, Monroe, Meatus, Orbit and Midbrain were identified (Fig 1) and distance between them measured. The pictures were placed like the patients were lying supine, with 45^0 head elevations (Fig 2), upright and 45^0 on the side (Fig 3). The skin to Midbrain and Monroe were measured at the same positions of the head. All values are presented as Mean $\pm$ SD. Distance in mm is converted to mmHg by multiplying with 0,074.
RESULTS. MR scanning's from 10 females 40 $\pm$ 10, 10 males 42 $\pm$ 9 were examined. A zero point at meatus was ideal when the patients was supine with no head elevation, resulting in a minor deviation from Midbrain of -1 to + 0,5 mmHg. Elevating the head overestimates the ICP by up to 6 mmHg. Head on the side, the glabella results in an ideal Midbrain zero point, but if turned 45^0 an underestimation up to 6 mmHg was found. Monroe was situated at a point 39 to 56 mm up from the mid-OM line. This point follows head elevation, but cannot be used when the head is turned.The highest point of the head deviated from Midbrain by maximum1,8 mmHg, depending on the position of the head, if the ICP reading was corrected by adding 6 mmHg. The shortest distance is to vertex and the longest from midpoint to the frontal skin resulting in a difference of 2 to 3 mmHg when the head is repositioned from lying to upright. Monroe is, compared to Midbrain situated $\approx$ 12 mm in front, and $\approx$ 25 mm below Midbrain, making the skin to Monroe distance more equal in all clinical positions of the head. If the ICP reading at the highest point of the head is corrected by adding 6,3 mmHg, the deviation from Monroe would be $\leq$ 0,9 mmHg.
CONCLUSIONS. ICP pressure device placed at Meatus and nose tip-glabella are well defined structures and represent Midbrain ICP when the head is strict supine or strict on the side, but in all other positions they result in an up to 6 mmHg deviation up and down from ideal values. The highest point on the head underestimates the ICP at Midbrain as well as Monroe, but this underestimation is fairly constant and can be corrected providing the most exact ICP under all clinical head positions.

INTRODUCTION. Little is known about the predictive value of early systemic lactate and glucose levels in patients after severe traumatic brain injury (TBI), in particular in relation to in-hospital mortality. The role of lactate in the ischemic brain is topic for debate since there is growing evidence for a neuroprotective role.[1,2,3,4]

OBJECTIVES. In this study we evaluated the association of arterial lactate and glucose levels in the acute phase after severe TBI in relation with in-hospital mortality. We investigated the predictive value of arterial lactate and glucose levels in patients with severe TBI from the Emergency Department (ED) to the first 48 hours (h) after hospital admission (HA).

METHODS. This study is a retrospective analysis of an observational follow-up study of 298 patients (age ≥16 years) with severe TBI admitted to the Intensive Care Unit (ICU) of the University Medical Center Groningen (UMCG) in the period of 2000-2014. Median age at injury was 34.0 years (interquartile range (IQR) 21.0-54.0) and Glasgow Coma Scale at admission 6 (IQR 5-7). Outcome was defined as in-hospital mortality.

RESULTS. The in-hospital mortality was 30%. From the ED to 48h after HA mean ±SD glucose was 7.2 ± 1.7 and lactate was 1.6 ± 1.1. Concerning in-hospital mortality, a significant difference from ED to 48h after HA was present respectively for survivors (mean ±SD glucose 7.0 ± 1.5 and lactate 1.5 ± 1.0) and for non-survivors (mean ±SD glucose 7.7 ± 2.1 and lactate 1.9 ± 1.2), (both p< 0.001) (see figure 1).

CONCLUSIONS. Both the arterial glucose and lactate course in patients with severe traumatic brain injury showed an increase from the Emergency Department to the first 48 hours after hospital admission. This data suggests that dysregulation from the glycometabolism in the early phase after injury are valuable predictors for in-hospital mortality.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0234

INTRODUCTION. Traumatic brain injury (TBI) is a common cause of morbidity and mortality worldwide. Neuromonitoring have improved considerably in recent years in TBI patients. Brain tissue oxygenation (pBtO$_2$) is an important variable in TBI patients treatment.

OBJECTIVES. The main goal is to examine whether clinical scales (Glasgow Coma Scale [GCS], Injury Severity Score [ISS], radiographic scales based on admission computed tomography (Marshall), Intra Cranial Pressure [ICP], pBtO$_2$ and pBtO$_2$/paO$_2$ ratio are associated with clinical outcome after severe TBI.

METHODS. This is prospective observational study with institutional review board approval. TBI patients with a GCS ≤8 were identified on admission. GCS, ISS, Marshall score, ICP, pBtO$_2$ and pBtO$_2$/paO$_2$ ratio during first 24 hours were recorded. Patient outcome was determined as favorable (patient had no, little, or moderate disability) or unfavorable (patient died, or was in a vegetative state or had severe disability) using the Glasgow Outcome Scale by medical record review at 6 months after TBI. We considered an ordinal analysis with proportional odds methodology. A logistic regression model was used to calculate the 95% CI for the odds of unfavorable outcome.

RESULTS. Over a 4-year period, 44 patients were entered into the study. The mean age was 48 ±28.4 years, ISS was 27.7±10.7, and GCS was 5.2±3.4. At 6 months, 8 (18.18%) patients had died, and 28 (63.63%) had a favorable outcome. Favorable outcome consistently demonstrated higher pBtO$_2$/paO$_2$ ratio compared with non-survivors including age as a covariate (p < 0.001). Factors associated with unfavorable outcome (univariate analysis): ISS>50 (OR 1.47, CI 1.22-1.68), Marshall ≥ 3 (OR 1.88, CI 1.44-2.20), ICP > 20 mmHg (OR 2.88, CI 2.52-3.24), GCS < 5 (OR 2.11, CI 1.94-2.30), PtiO2 < 23 mmHg (OR 2.16, CI 2.05-2.27) and pBtO$_2$/paO$_2$ ratio < 0.2 (OR 3.88, CI 3.48-4.27).

CONCLUSIONS. The first 24 hours of pBtO$_2$/paO$_2$ ratio < 0.2 predicts mortality and outcome. When pBtO$_2$/paO$_2$ ratio remains below 0.2 in the first 24 hours of monitoring, mortality and unfavorable outcome is increased. This study challenges the brain oxygenation threshold of 23 mm Hg that has been used conventionally and delineates a time for monitoring pBtO$_2$/paO$_2$ ratio that is predictive of outcome.

INTRODUCTION. Early Brain Injury is believed to be a major component of poor outcomes after aneurysmal subarachnoid haemorrhage (aSAH), leading to delayed cerebral ischemia (DCI) . The underlying mechanisms, however, are poorly understood and probably include complex interactions between the immunologic and inflammatory systems. Leucocyte profiles, in the form of various ratios, are

considered to reflect immune function and have been associated with outcome in numerous pathologies, including admission neutrophil to lymphocyte (NLR) and platelet to lymphocyte (PLR) ratios in subarachnoid hemorrhage.

OBJECTIVES. To explore the association of other components of the leucocyte profiles to outcome in subarachnoid patients and validate NLR and PLR association with unfavorable outcome.

METHODS. We retrospectively reviewed 100 consecutive aSAH patients admitted to the Centre Hospitalier Universitaire de Montréal from February 2011 to June 2014. We selected 50 patients treated with endovascular approach and 50 with a surgical approach to control for its potential effect on immuno-inflammatory indices. Clinical, radiological, laboratory and follow-up data were extracted from patient records. Functional outcome was assessed using the modified Rankin scale with a good neurological outcome defined as a score of 0-3. Logistic regression was used to measure the association between NLR, monocyte to lymphocytes ratio (MLR), eosinophil to lymphocytes ratio and PLR at admission, day 5 and day 10 with odds of poor outcomes.

RESULTS. Included patients had a mean age of 57 years with 30% presenting as poor grades (WFNS ≥ 4). Mean follow-up was 16 months. After adjustment for age, poor neurological grade at admission and the presence of IVH, the results are as follows: 1) at admission, there is no association between leucocyte profiles and outcome 2) at day 5, higher NLR and higher MLR are associated with lower odds of poor outcomes (OR 0.88 [0.78, 0.96] and 0.34 [0.11, 0.98] respectively) and 3) at day 10, there is no association between leucocyte profiles and outcome. It is worth noting that there was no difference in inflammatory parameters between treatment approaches.

CONCLUSIONS. Our data does not support the association between admission PLR or NLR with outcome, contrary to a previously published report. The immunological signal emerging from the leucocyte profiles suggests a potential role of neutrophils and monocytes at a later time point in aSAH patient outcomes. The positive association with good prognosis implies that the phenotype of these cells might be important to the patient natural inflammatory history. The discrepancy with a previous study underscores the limitations of retrospective data and the urgency of prospective and comprehensive immunomonitoring in SAH patients to unravel the contribution of immune cells in the complex events leading to DCI.

INTRODUCTION: Traumatic brain injury (TBI) is a leading cause of morbidity and mortality worldwide (1). Extra-cranial lesions needing emergency surgery, especially if associated with hemorrhage, worsen further the outcome of TBI (2).

OBJECTIVES: To survey acute phase management practices in polytrauma patients with severe TBI. The main endpoints of the survey were the evaluation of: a) intracranial pressure (ICP) monitoring during extracranial emergency surgery (EES), b) hemodynamic management without ICP monitoring during EES c) coagulation management, and d) utilization of simultaneous multisystem surgery (SMS).

METHODS: A questionnaire including 24 items was available on the World Society of Emergency Surgery (WSES) website (https://docs.google.com/forms/d/1Y7-L1ZNJWllb9e4ea9QQkGqQZYZ2Byr2-uNcHXZl4nxl/edit) between December 2017 and February 2017. The survey was endorsed and promoted by WSES and restricted to emergency surgeons.

RESULTS: Respondents (RSP) were 122 [70 (57%) from Europe]; mainly working in a Level I Trauma Center [66 (54%)]. ICP probes were inserted mostly by neurosurgeons [117 (96%)]. ICP monitoring was utilized in 10-30% of patients, at risk of intracranial hypertension undergoing EES, by the majority of respondents [35 (29%)]. Few respondents utilized an ICP monitoring protocol in this setting [48 (39%)]. However, 102 (84%) respondents considered ICP monitoring during EES important, very important or mandatory. Hemodynamic and coagulation management issues are reported in Table 1. SMS was performed in 5-19% of patients, needing both an emergency neurosurgical operation and EES, by the majority of respondents [49 (40%)]. Few respondents have a protocol for SMS [33 (27%)]. Nevertheless, 112 (92%) respondents considered the ability to perform SMS important, very important or mandatory. In polytrauma patients with ICP monitoring and intracranial hypertension, extra-cranial pressures (such as intrathoracic pressure and abdominal pressure) were monitored by the majority of respondents [93 (76%)].

CONCLUSIONS: A great variability in practices during the acute phase management of severe TBI patients with polytrauma was identified in this survey. These findings may be helpful to define future investigations in this topic and for educational purposes.

INTRODUCTION. SAH is a complex neurovascular syndrome with high disability and mortality. Pour outcomes are usually secondary to early brain injury or delayed cerebral ischemia (DCI). Recent clinical

data suggest that cerebral hypoxia may occur despite normal levels of ICP and CPP in poor grade SAH. Therefore the use of multimodal neuromonitoring, including PtiO2 in an early reversible state may be a good practice to improve management and prognosis.

OBJECTIVES. To investigate the utility of PtiO2 monitoring in detecting cerebral hypoxic events and the relation between them, the outcome and the development of DCI.

METHODS. This observational study evaluated 19 ICU patients after severe SAH with Hunt- Hess grade 4 or with secondary deterioration to this grade. Monitoring of ICP, CPP, $P_{ti}O_2$ was performed. Patients were divided in non-survivor and survivor group. The second group was further divided in infraction and non-infraction group. Critical values of $P_{ti}O_2 \leq$ 15mmHg, CPP≤70mmHg and ICP>20mmHg were derived from data sets for different time intervals (first 24h, 48h and >48h). We investigated the relation between pts outcome and the appearance and duration of hypoxic events.

RESULTS. 19pts were enrolled, mean age 51.52 (± 9.8), mean APACHE II 17.15 (± 5.5). In 14 pts an external ventricular drain was inserted. Survivor pts were 11 (57.89%) and non survivor 8 (42.1%). 5 pts developed DCI (45.4%). Critical $P_{ti}O_2$ on first 24h was detected in 14pts (73.6%), but this frequency was decreased later. After 48h brain hypoxia was detected in 10pts (52.6%). Long lasting and persistent low $P_{ti}O_2$ was detected in 9pts (48.3%). Among these pts only 4 were associated with low CPP (21.05%). In the survivor group low $P_{ti}O_2$ in first 24h was detected in 9pts (81.8%), but in only 3 of them (27%) after 48h. In non-survivor this proportion was 5 (62.5%) and 7 (87.5%) respectively . Moreover, persistent brain hypoxia was detected in 1 survivor (9%) and 7 non-survivor (87.5%). From the DCI group all pts developed long-lasting brain hypoxia mostly after 48h.

CONCLUSIONS. Monitoring of PtiO2 provides additional information in detection of cerebral hypoxic events. Therefore the use of multimodal monitoring may be a good complement to ICP/ CPP monitoring to detect cerebral oxygen in an early reversible state and to guide therapy, in order to improve outcome.

REFERENCE(S)

2. The Critical Care Management of poor-grade subarachnoid haemorrhage, AL de Oliviera Manoel et al. Crit Care 2016; 20:21

registered in the Japan Primary Registries Network (UMIN000025313). After written informed consent was obtained, patients of age >18 who underwent elective colon resections were enrolled from January to December 2017. Patients with end-stage kidney disease were excluded. Blood samples were collected just before surgery and on postoperative day (POD) 1, 2, 3, 4, and 6. Infectious complications were diagnosed by surgeons who were not involved in this study. Statistical analyses were performed with two-way RM ANOVA followed by Bonferroni's multiple comparison test. Predictive performance was assessed by the area under the ROC curves. A p value < 0.05 was accepted as significant.

RESULTS. A total of 114 patients were examined, and 27 patients (23.7%) developed infectious complications: 11 anastomotic leaks, 13 intra-abdominal infections, and 3 wound infections. The median interval between surgery and the diagnosis of infection was 5 days. The changes in biomarkers are shown in the Figure. CRP and PCT markedly increased from POD1 to POD3 and then gradually decreased toward POD6 in both groups, but the trends of the decrease in the infected group were blunt, compared with those in the non-infected group. On the other hand, presepsin did not show major changes just after surgery, but it increased on POD4 and POD6, when the complications occurred. ROC analysis to predict infectious complications revealed that the best accuracy was obtained on POD 6 for all biomarkers. The cut-off values, sensitivities, specificities and AUCs on POD6 are shown in the Table. CRP showed excellent predictability and presepsin showed good predictability. However, the cut-off values of all biomarkers were relatively lower than expected.

CONCLUSIONS. The trends of change in presepsin following colorectal surgeries were distinct from those of CRP and PCT. Monitoring the presepsin trends after colorectal surgeries could be helpful to detect postoperative infectious complications.

INTRODUCTION. Infectious complications remain a major clinical problem in colorectal surgery, contributing to prolonged hospital stays, additional costs and significant postoperative mortality. Presepsin has been reported to be a useful marker to diagnose sepsis, similar or superior to C-reactive protein (CRP) and procalcitonin (PCT),[1] and plasma presepsin concentrations are associated with the severity of sepsis and its outcome.[2]

OBJECTIVES. The aim of this study was to assess the diagnostic value of presepsin in the early detection of infectious complications after elective colorectal surgery, compared with CRP and PCT.

METHODS. This study was a prospective observational study. The protocol was approved by our university ethics committee and

The impact of goal-directed fluid therapy during major abdominal surgery on postoperative oxygenation and extravascular lung water

A. Hasanin, K. Hussein, I. Farouk, S. Abdelraouf, H. Ezzat

Cairo University, Anesthesia and Critical Care Medicine, Cairo, Egypt

Correspondence: A. Hasanin

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0239

INTRODUCTION. Proper fluid management during major abdominal surgery is essential for good patient outcome. Goal-directed fluid therapy (GDFT) was previously investigated during major abdominal surgery; however, its impact on extravascular lung water (EVLW) was not evaluated.

OBJECTIVES. To investigate the impact of GDFT during major abdominal operations on postoperative EVLW.

METHODS. We recruited 120 patients undergoing major abdominal operations in Cairo University hospital in a randomized controlled trial. Patients were divided into GDFT group (n=60) and control group (n=60). In the control group, fluids were infused at a rate of 6 mL/Kg/hour; whilst, in GDFT group, fluids were infused at a rate of 2 mL/Kg/hour. Fluid boluses were administered in GDFT group to optimize stroke volume variation (measured by electrical cardiometry) less than 10%. In both groups, mean arterial pressure (MAP) of 65 mmHg or more was targeted. Both groups were compared in demographic data, hemodynamic variables (MAP and heart rate), infused fluids, and post-operative P/F ratio. lung ultrasound score (LUS) was evaluated using 12-region lung ultrasound technique.

RESULTS. One-hundred and twenty patients were available for final analysis with mean age of 49±13 years. Seventy-four (62%) of our patients were males. Mean surgical duration was 4.5±0.7 hours. MAP and heart rate were comparable between both study groups; however, GDFT group received less fluids compared to control group {1350(1125-1700) mL versus 3000(2500-3475) mL, P< 0.001}. Post-operative LUS was lower in GDFT compared to the control group {2(0-4) versus 4(3-6)} mL, P< 0.001}. P/F ratio was slightly higher in the GDFT group compared to the control group (368 ±37 versus 353±39 P=0.04). The number of patients who showed significant postoperative increase in LUS was higher in the control group {52(87%) patients versus 31(52%) patients, P< 0.001}.

CONCLUSIONS. Using GDFT in major abdominal surgery was associated with less total fluid intake, lower EVLW, and slightly higher P/F ratio without compromising patient hemodynamics.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0240

INTRODUCTION. Although there is a scoring system predicting prognosis of patients with intestinal perforation, the existing system was established too long ago and many new prognostic factors have been reported since then.

OBJECTIVES. The aims of this study are to investigate the risk factors for in-hospital mortality after surgery for intestinal perforation and evaluate the effect of lactate level on in-hospital mortality.

METHODS. Among the patients (≥ 18 years) who underwent surgery for intestinal perforation from 2013 to 2017, only those patients whose lactate levels were checked before surgery and within 12 hours after surgery were retrospectively analyzed. We evaluated risk factors for in-hospital mortality after surgery for intestinal perforation using univariable and multivariable analyses.

RESULTS. A total of 105 patients were enrolled and 17 patients (16.2%) died before discharge. There were no significant differences in Charlson Comorbidity Index score (5.8 vs. 4.7, P = 0.114), preoperative C-reactive protein level (14.3 vs. 16.9, P = 0.468), proportion of emergency surgery (82.4% vs. 72.0%, P =1.000), and proportion of large bowel as perforation site (35.3% vs. 54.5%, P = 0.146). The patients in the mortality group had higher preoperative maximum lactate level (6.3 vs. 3.4, P = 0.036), higher proportion of dirty and fecal contaminated ascites (94.1% vs. 68.2%, P = 0.036), lower albumin level (2.5 vs. 2.9, P =0.022), and lower delta lactate level between pre and postoperative check (-1.6 vs. -0.2, P = 0.026) than the patients who survived after the surgery. Multivariable analyses revealed that the preoperative maximum lactate level (OR 1.272, 95% CI 1.094~1.479, P = 0.002) and delta lactate level (OR 0.732, 95% CI 0.576~0.942, P = 0.015) had significant effects on the in-hospital mortality after surgery for intestinal perforation.

CONCLUSIONS. Preoperative maximum lactate level and delta lactate level between pre and postoperative period were predictive risk factors for the in-hospital mortality after surgery for intestinal perforation.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0241

INTRODUCTION. Between 200 and 300 patients per year currently receive extracorporeal membrane oxygenation (ECMO) at our tertiary referral service. A proportion of these patients develop indications for emergency laparotomy which might have previously been considered a futile undertaking in this potentially more unstable population in multiple organ failure, however it is now regarded as a feasible treatment strategy in our institution. There is no other comparable service in the United Kingdom and a paucity of literature on the subject[1].

OBJECTIVES. The study objectives were to evaluate our current service, identify the indications and outcomes of emergency laparotomy in this population and inform future service planning with regards to the co-location of ECMO services in general surgical centres.

METHODS. A single-centre, retrospective, observational cohort study of adult patients admitted to a university teaching hospital severe respiratory failure service between December 2011 and January 2017.

RESULTS. Of 355 patients established on ECMO, 13 patients required emergency laparotomy, 11 on veno-venous and 2 on veno-arterial circuits. Mean time from cannulation to surgical referral was 5.23 days, 11 of 13 for increasing abdominal distension, 4 with rising lactate and 2 for rising noradrenaline requirements. Mean lactate

immediately pre-operatively was 7.62 with 3 patients having a normal lactate. 11 of 13 had pre-operative CT scanning with features of bowel ischaemia the most common feature. P-POSSUM over-predicted mortality, with group predicted mortality 83.38% (SD 14.64), versus actual mortality 69.2%, weighted mortality ratio 0.83. Most patients required a bowel resection (53.8%) and similar number had planned re-look laparotomy or laparostomy (61.5%). Operative mortality was 0% but 6 patients required an emergency change of ECMO circuit post-operatively. Hospital mortality for ECMO patients not requiring laparotomy was 25.1% and 69.2% for those undergoing emergency laparotomy (*p*=0.001).

There was no significant difference in age, SOFA score on admission, days on ECMO or total Length of Stay on ICU between groups.

CONCLUSIONS. Emergency laparotomy can be successfully undertaken in patients on ECMO with 30% surviving to hospital discharge. Emergency requirement for ECMO circuit change is a post-operative risk. Traditional methods of diagnosis and risk assessment such as CT scans, lactate levels and P-POSSUM scoring, are not wholly applicable in this niche population and the decision to operate is best made on the clinical judgement of the intensive care and general surgical teams. There is a substantial need for general surgical speciality input into patients on ECMO and this should be recognised as one of the requirements of the service.

Intraoperative positive end-expiratory pressure setting guided by esophageal pressure measurement during laparoscopic gynecologic surgery: a pilot study

A. Piriyapatsom, S. Phetkampang
Faculty of Medicine Siriraj Hospital Mahidol University, Department of Anesthesiology, Bangkok, Thailand
Correspondence: A. Piriyapatsom
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0242

INTRODUCTION. Setting of positive end-expiratory pressure (PEEP) has an important role in respiratory management during laparoscopic surgery. However, there is no consensus on the optimal PEEP level or the best method to set PEEP during laparoscopic surgery.

OBJECTIVE. To investigate whether setting of PEEP guided by measurement of esophageal pressure would affect oxygenation and compliance of respiratory system (C_{rs}) during laparoscopic surgery.

METHODS. Ten patients undergoing laparoscopic gynecologic surgery were randomly divided into the intervention and the control groups. In the intervention group, PEEP was set according to esophageal pressure measured to maintain transpulmonary pressure during expiration ($P_{TP, exp}$) between 0 and 5 cm H_2O. In the control group, PEEP was constantly set at 5 cm H_2O. Gas exchange, lung mechanics, and hemodynamic parameters were recorded after induction and intubation (T0) and at 15 and 60 minutes after gas insufflation (T1 and T2, respectively) and data were analyzed.

RESULTS. There were no significant differences regarding age, BMI, ASA physical status, anesthetic time, insufflation time, and intraabdominal pressure applied during gas insufflation between two groups. During gas insufflation, plateau pressure (P_{plat}), PEEP and $P_{TP, exp}$ were significantly higher in the intervention group compared to the control group (P_{plat}; T1, 26.0±2.0 vs. 19.0±1.6 cm H_2O, p< 0.001; T2, 26.8±1.3 vs. 19.0±0.7 cm H_2O, p< 0.001; PEEP; T1, 13.4±2.3 vs. 5.0 ±0.0 cm H_2O, p=0.001; T2, 13.2±2.2 vs. 5.0±0.0 cm H_2O, p< 0.001; and $P_{TP, exp}$; T1, 0.3±2.4 vs. -6.2±5.3 cm H_2O, p=0.04; T2, 1.0±2.1 vs. -6.7±5.1 cm H_2O, p=0.03). PaO_2/FiO_2 ratio and C_{rs} were decreased from T0 but these change did not reach statistical significance neither within group nor between groups (change in PaO_2/FiO_2 ratio; T1, -24.2±23.2 in the intervention group vs. -64.3±74.6 in the control group; T2, -34.1±34.1 vs. -19.2±69.0 and change in C_{rs}; T1, -12.0±9.3 vs. -21.4±2.9 mL/cm H_2O; T2, -15.2±6.2 vs. -21.6±6.1 mL/cm H_2O).

There were no significant changes in hemodynamic parameters during gas insufflation neither within group nor between groups. There was one patient in the control group required oxygen supplement after discharge from the recovery room.

CONCLUSIONS. This pilot study showed that PEEP setting guided by measurement of esophageal pressure during laparoscopic surgery was feasible. However, a larger number of subjects may be required to investigate any potential benefits on oxygenation or Crs.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0243

INTRODUCTION. In select patients with peritoneal carcinomatosis, cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) is an optional treatment to improve survival. The procedure is lengthy and involves extensive surgical debulking, needing aggressive resuscitation with fluids required intraoperatively due to blood losses and fluid shifts. Several complications are described in postoperative as acute renal failure, hypovolemia and electrolytes disorders.

OBJECTIVES. to determine the electrolytes disorders and kidney complications during intensive care unit (ICU) stay after CRS and HIPEC.

METHODS. prospective observational study during 5 years. All patients admitted to ICU postoperatively after CRS and HIPEC therapy. Data recorded were age, sex, type of cancer, severity at ICU admission (APACHE II and SOFA scores), laboratory data (creatinine and electrolytes), volume of diuresis and ICU mortality.

We defined normal range in plasma of potassium as 3.5- 5 mmol/l, magnesium as 1.5-2.3 mg/dl, sodium as 135-145 mmol/l and phosphorus as 2.4-5.1 mgr/dl. Acute kidney injury (AKI) as increase of serum creatinine x1.5 from baseline (serum creatinine at hospital admission). Polyuria as diuresis >3 ml/kgr/h.

Qualitative variables are described as number and percentages, quantitative variables with normal distribution as mean ± S.D. and compared with chi-square test, quantitative variables with non-normal distribution as median (interquartile range).

RESULTS. we included 73 patients. 40 (55%) were males. Mean age was 60.3±9.9 years. (86%) had a digestive cancer (52% colorectal, 44% gastric cancer). Mean APACHE II and SOFA scores at ICU admission were 9.6±4.2 and 2 (1-3), respectively. 53 patients (73%) developed electrolytes disorders. 19(26.0%) had hyponatremia, 2 (2.7%) hypernatremia, 28 (38.4%) hypokalemia, 1 (1.4%) hyperkalemia, 21 (28.8%) hypomagnesemia, 5 (6.8%) hypermagnesemia and 19 (26.0%) hypophosphatemia. Only 1 patient with hypomagnesemia suffers a hemodynamically stable ventricular tachycardia, treated with intravenous magnesium.

4 (5,5%) patients had AKI. 20 (27,4%) had polyuria.

ICU mortality was 1.36%. There were not a statistically significant difference in ICU mortality between patients without this complications and patients who suffers electrolytes disorders (1.9% vs. 0.0%, p=1.00), polyuria (1.9% vs. 0.0%, p=1.00) or AKI (4.4% vs. 0.0%, p=1.00).

CONCLUSIONS. Electrolytes disorders are frequent in patients in inmediate postoperative after CRS and HIPEC), most of them are asyntomatic. The development of kidney damage in these patients is rare and not related to mortality.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0244

INTRODUCTION. Extreme digestive oncology surgery (EDOS) is considered when 2 or more solid organs and/or the peritoneum are totally or partially removed as a cancer treatment. Due to the risks of the surgery, its indications are very restrictive and only skilled facilities can provide a reasonable benefit-to-risk ratio.
OBJECTIVES.

(a) To identify clinical variables associated to mortality.
(b) To develop a predictive model for hospital mortality.

METHODS. We conducted a retrospective study that include all patients

(a) older than 18 years old,
(b) undergoing EDOS and
(c) admitted to the intensive care unit (ICU) of the Hospital Universitario HM Sanchinarro during the period 1/01/14 to 10/31/16.

Day 0 was the day of ICU admission. All data are expressed as means (±SD) or proportions. Alive vs death patients at hospital discharge were compared. The proportions and qualitative data were compared using the Chisquare test and quantitative data using the unpaired Student's t test for normally distributed variables or the Kruskal-Wallis test. The maximum logistic regression model include all variables with a *p* value < 0.1 in the univariate analysis. P values less than 0.05 were considered significant. The discriminatory capability of the model calculated using the area under receiver operation curve (AUROC).
RESULTS. There were 164 consecutive patients admitted to the ICU after an EDOS. The following variables recorded the day 0 were: age 63±11 y.o., male 106, Charlson comorbidity index 6.31±2.2; Nutritional Risk Screening 2002 (NRS-2002) 4.02±0.88 and APACHE-II punctuation 11.2±4.4; length of ICU stayed 6±10 and days undergoing invasive mechanical ventilation 6±9. Site of the cancer: esophagus (n=8), gastric (n=11), yeyuneum-ileon (n=3); colon-rectal (n= 91); pancreas (n=38); liver (n=5), gallbladder and bile duct (n=8). Cancer stage: stage II (26), stage III (56) and stage IV (82). Hospital mortality n=22 (13.4%). The maximum logistic

regression model for hospital mortality included: NRS-2002, APACHE II, Charlson score, invasive mechanical ventilation at ICU admission, and Easter Cooperative Oncology Group Scale - Performance Status (ECOG-PS). Variables associated to mortality were: Charlson comorbidity index (OR 1.37; IC 95% 1.07; 1.80; p 0.012), APACHE II (OR 1.13; IC 95% 1.01; 1.27; p 0.032) and NRS-2002 (OR 1.98; IC95% 1.10; 3.72; p 0.02). The AUROC for the regression model was 0.79 (95% CI: 0.67-0.92) and for the APACHE II at day 0 was 0.66 (95% CI: 0.51-0.81). The difference was statistically significant (DeLong test p < 0.01)
CONCLUSIONS. In this wide cohort of patients undergoing and EDOS the mortality was acceptable. Type and stage of the cancer does not seem to influence hospital outcome. The predictive model we have developed predicted the outcome better than the APACHE II score. Future studies should validate this new tool.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0245

INTRODUCTION. Emergency surgery in elderly patients (> 80 years) is associated with high mortality rates. Various scoring systems may be valuable to predict mortality and morbidity rates. It has lately been suggested that the Norton Score (NS) could be used to indirectly quantify frailty, thus, it may be employed to predict surgical patients outcome.
OBJECTIVES. We hypothesized that NS could be a useful tool for identifying high risk patients prior to emergency/urgent surgeries.
METHODS. A retrospective study was conducted in the Department of Surgery at Kaplan Medical Center, Rehovot, Israel. Inclusion criteria were: age ≥ 50 years, American Society of Anesthesiologists (ASA) physical status score ≥ 3 and urgent/emergency laparotomy (no trauma surgery).
Four hundred patients who underwent emergency/ urgency surgeries were identified, of which 150 (37.5%) matched the inclusion criteria.
RESULTS. Our study included 150 patients, ASA 3-5, who underwent emergent/urgent laparotomy not for trauma, from 1.1.2011 through 31.1.2013. Age was 77 ± 9,7 years. Mortality rate at 1 month was 44% (66 patients) and at 1 year was 54.7% (82 patients). A higher ASA score was significantly associated with mortality (p< 0,001). Survivors had lower frailty scores and presented significantly higher pre-operative NS (Modified Frailty Index 2.45 vs 3.06, p< 0,05; NS 16.09 vs 12.94, p< 0,01). Preoperative NS was the most significant variable that predicted poor patient prognosis (OR,0,84; 95% CI, 0.73-0.96). In addition, for ASA 3 and ASA 4 patient independence showed positive correlation with survival (p< 0.001).
CONCLUSIONS. Norton Score can be a very useful and quick tool to evaluate surgical risk in emergency surgery. Our study supports the use of NS in the perioperative evaluation prior to emergency surgery.

Effects of perioperative high inspired oxygen fraction on surgical site infection in the patients with gastrointestinal surgery

A. Kumasaka, T. Hayasaka, N. Momose, M. Ogura, M. Yoshioka, M. Kudo
Nihonkai General Hospital, Anesthesiology, Sakatashi, Yamagata, Japan

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0246

INTRODUCTION. Surgical Site Infection (SSI) in the general surgical population is serious health issue[1)].

There is evidence that optimized blood flow to the surgical incision decreases SSI rates through avoidance of hypothermia, hypoxia and decreased perfusion[2)].

In the WHO surgical site infection prevention guidelines, use of high fractions of inspired oxygen concentration (FiO_2) during the perioperative period is recommended to reduce SSI. Because additional oxygen contribute less to arterial oxygen content of blood and high FiO_2 has been reported to cause atelectasis[3)] and pulmonary toxicity[4)], use of high FiO_2 is still controversial.

OBJECTIVES. The aim of this study is to assess whether the use of high FiO_2 perioperatively reduce the SSI, and to investigate postoperative complications.

METHODS. 586 patients older than 18 years who were undergoing elective and emergency operation of gastrointestinal surgery were included. Patients who were hemodynamically unstable and had an American Society of Anesthesiology physical status 4 or 5 were excluded.

We compared patients who were supplied high FiO_2 with patients who were supplied lower inspired oxygen. Patients with the use of high FiO_2 were given 80% of oxygen during surgery and 6 hours after the surgery.

Surgical site infection within 30 days after surgery was determined by clinical assessment.

As the secondary outcome, respiratory complications and mortality were determined.

RESULTS. The overall incidence of SSI was 23.4%. The incidence of infection in the group with high FiO_2 had tendency to lower than the group with the patients with conventional treatment. (17% vs. 24%; P=0.09)

There were no significant differences between the groups in the postoperative complications.

CONCLUSIONS. Administration of high perioperative FiO_2 for the patients with gastrointestinal surgery might have some effect to reduce the risk of SSI.

The frequencies of pulmonary complications were not significantly different by the FiO_2.

Prevalence and risk factors of preoperative sarcopenia and malnutrition in elderly cancerous patients

O. Chaiwat, W. Muangpaisan
Siriraj Hospital Mahidol University, Bangkok, Thailand
Correspondence: O. Chaiwat
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0247

INTRODUCTION. The aging population is associated with an increasing prevalence of frailty and comorbidities. In combination with the diagnosis of cancer, the incidence of perioperative adverse outcomes is considerably increased. Sarcopenia and malnutrition have been reported as the major risk factors for adverse outcomes during perioperative period[1]

OBJECTIVES. To identify the prevalence of sarcopenia and malnutrition in preoperative elderly cancerous patients who scheduled to have elective surgeries at Siriraj Preanesthesia Assessment Center (SiPAC) and to determine the risk factors and outcomes of sarcopenia patients

METHODS. The assessment of sarcopenia according to the Asia working group for sarcopenia[2] and malnutrition by the Mini Nutrition Assessment -Short Form[3] were performed at SiPAC. The inclusion criteria were the patients aged over 60 years old and had the diagnosis of cancer that required surgery

RESULTS. 226 patients were enrolled. Sarcopenia was found in 71 patients (31%). 31 patients (13%) were diagnosed presarcopenia. The incidence of malnutrition was 3-times lesser (9.3%). Older age [adjusted odd ratio (AOR) 1.14, CI (1.08-1.20)], lower scores of preoperative Barthel index [AOR 0.94, CI (0.91-0.98)] and malnutrition [AOR 5.01, CI (2.54-9.88)] were identified as independent risk factors for sarcopenia. Barthel index scores was significantly lower (p value = 0.01) and mortality rate was significantly higher (p value = 0.01) at 3 months after discharge from the hospital in sarcopenia patients compared to non-sarcopenia patients

CONCLUSIONS. The incidence of sarcopenia was high in preoperative elderly cancerous patients. Older age, impaired functional status and malnutrition were the risk factors for preoperative sarcopenia in this population

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0248

INTRODUCTION. Significant numbers of patients present postoperative cognitive decline after non-cardiac surgery. Postoperative cognitive dysfunction (POCD) has a tendency to improve over a certain period of time, but some patients suffer from permanent cognitive impairment. Adequate intraoperative cerebral oxygen supply is one of the inciting causes for postoperative cognitive disturbances. Prone position, used during spinal neurosurgery, causes important physiological changes in a human body and can lead to impaired brain oxygen supply. Regional cerebral oxygen saturation monitoring devices are non-invasive and provide continuous, real time monitoring of brain tissue oxygenation.

OBJECTIVES.

1. To identify regional cerebral oxygen saturation (rScO2) intraoperative parameters in patients undergoing spinal neurosurgery in prone position.
2. To evaluate intraoperative rScO2 relationship with POCD.
3. To evaluate POCD in patients undergoing spinal neurosurgery in prone position but not receiving intraoperative rScO2 monitoring (control group).

METHODS. 48 patients were scheduled for spinal neurosurgery in prone position. In the study group (n=38) rScO2 was intraoperatively continuously monitored using INVOS 4100 NIRS device. The control group (n=10) didn't receive intraoperative rScO2 monitoring. All patients received standard general anaesthesia. During the surgery every 5 min in both groups MAP, HR, SpO2, EtCO2 was fixed. We also fixed intraoperative blood loss, duration of the operation. Cognitive function was assessed in both groups using Montreal - Cognitive Assessment (MoCA) scale before surgery and 2 days after. MoCA scores range between 0-30. 26 or over is considered to be normal.

RESULTS. We didn't observe any significant changes in our calculated medium rScO2 intraoperative values. During the whole surgery when patients were lying supine rScO2 was 72±9%, in prone position rScO2 was 73± 9%. We didn't observe differences in medium MoCA scores when comparing study and control group. MoCA score before surgery in study group was 24±3 points and 23±4 points in control group. MoCA 2 days after the surgery was 25 ±3 points in study group, 23±3 points in control group.

In our study group 1 patient showed POCD-from MoCA 27 points before surgery to MoCA 23 points after the surgery. We didn't observe any significant changes in other patients' measurements that would differ from average in the study group.

In control group in 6 from 10 patients we observed MoCA score decrease for 1-2 points after the surgery.

CONCLUSIONS. No significant changes were observed in medium MoCA scores between patients who intraoperatively received non-invasive cerebral oxygen saturation monitoring and patients who did not receive it.

Intraoperative regional cerebral oxygen saturation monitoring can help to obviate cerebral desaturation that can lead to postoperative cognitive decline.

INTRODUCTION. Pleiotrophin (PTN) is one of nerve growth factors, which particularly promotes neurite growth. PTN is higher expressed in dorsal root ganglions and the dorsal horn of the spinal cord in a neuropathic pain model involving with improvement of allodynia and nerve recovery. Further, gene mutation of PTN reportedly affects nociceptive transmission and opioid sensitivity in the spinal cord. However, clinical significance of PTN has not yet been investigated.

OBJECTIVES. We examined the relationship between polymorphism of PTN and individual variation of cancer pain severity.

METHODS. Patients with cancer pain (n=89) and patients with postoperative pain after laparotomy (n=57) participated. Regarding 53 single nucleotide polymorphisms (SNPs) in the PTN gene, each patient-group was categorized into into three sub-groups, major allele homozygosity (mAajor), heterozygosity (hetero), and minor allele homozygosity (mInor). We analyzed associations among respective SNPs and pain intensity, and opioid consumptions (translating into intravenous fentanyl-equivalent dosages: mcg/kg/day). We used non-parametric comparison tests and corrections if necessary.

RESULTS. One of SNPs of the PTN gene (rs11764598) was associated with cancer pain; mAjor demonstrated significantly stronger pain intensity than other groups (mAjor 6.3+/-1.7, hetero 4.6+/-1.4, mInor 3.0+/-0.7; K-W test, p< 0.0001). There was no defference in opioid consumptions among three sub-groups of cancer pain. No patients which had mInor SNPs in postoperative pain patients, and no difference in both pain intensity and opioid consumptions between mAjor and hetero sub-groups.

CONCLUSIONS. PTN is known to have relationships with nociceptive transmission and opioid analgesia, and cancer pain severity followed these in the present study. On the other hand, postoperative pain is considered as nociceptive pain, but postoperative pain did not demonstrate such relationships. PTN contributes to recovery from a neuropathic pain condition. Different pathophysiological mechanisms of cancer pain group and postoperative pain in the present patient groups might affect the findings because many cancer pain patients suffered from neuropathic cancer pain.

Frequency of occurrence of arterial hypotension in anesthesia, including alpha2-adrenoagonists in neurooncological patients

M. Rumiantceva, R. Nazarov, A. Kondratiev
Russian Polenov Neurosurgical Institute, Saint Petersburg, Russian Federation
Correspondence: M. Rumiantceva
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0251

INTRODUCTION. An integral part of neuroregulatory systems of the brain stem are opioid and adrenergic antinociceptive systems. The use of anesthesia, including a combined effect on opioid and adrenergic antinociceptive systems, creates favorable conditions for performing operations on brain tumors. Arterial hypotension is the most common side effect of alpha2-adrenoagonists.

OBJECTIVE. Frequency of use of vasopressors with anesthesia, including alpha2-adrenoagonists in neurosurgical operations.

METHODS. The study included 118 patients (mean age 50.5±13.6) who underwent planned surgical treatment at the RNHI named after prof. A.L.Polenov about brain tumors (supratentorial localization - 25% and subtentorial - 75%).

In all patients induction of anesthesia included: muscle relaxants (pipecuronium 0.1mg/kg or rocuronium 0.6mg/kg), hypnotics (propofol 2mg/kg), opioid analgetic (fentanyl 4.8±0.6mcg/kg) + alpha2-adrenoagonist (clonidine or dexmedetomidine). Maintenance of anesthesia: hypnotic (propofol 4.5±0.9mg/kg/h), opioid analgetic (fentanyl 1.3±0.4mcg/ kg/h) + alpha2-adrenoagonist (clonidine or dexmedetomidine).

All patients were divided into three groups, depending on the alpha2-adrenoagonist used and its dosage. In group I (26 patients) induction of anesthesia: clonidine 1.5±0.4mcg/kg; maintenance of anesthesia: clonidine 0.4±0.15mcg/kg/h. In group II (58 patients) induction of anesthesia: dexmedetomidine 1.5±0.4mcg/kg; maintenance of anesthesia: dexmedetomidine 0.4±0.2mcg/kg/h. In group III (34 patients) induction of anesthesia: dexmedetomidine 0.7±0.1mcg/kg; maintenance of anesthesia: dexmedetomidine 0.2±0.1 mcg/kg/h. All three groups are statistically comparable by sex, age, initial blood pressure, initial heart rate, position on the operating table and localization of the brain tumor.

RESULTS. In group I, 5 patients (19%) had arterial hypotension, which required the use of vasopressors (mezaton). Two out of five patients immediately after induction of anesthesia, and in three patients after shrinkage on the operating table (operations in the sitting position). In two out of five cases, the use of vasopressors was required before the end of the operation. In group II only one patient (1.7%) had arterial hypotension. Arterial hypotension was noted after shrinkage on the operating table (operation in the sitting position), the need for the use of a vasopressor was short-lived. In group III, 3 patients (9%) had arterial hypotension. In all three cases, vasopressors were used after shrinkage on the operating table. In two of the three cases, the need remained until the tumor was removed. In one of three cases, the application was short-lived.

CONCLUSIONS. The combined use of opioid analgesic and alpha2-adrenoagonist mutually reduces the frequency of side effects and at the same time creates optimal conditions for performing neurosurgical operations. When using dexmedetomidine, arterial hypotension is much less common than with clonidine.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0252

INTRODUCTION. Gastrointestinal endoscopy is gradually expanding the diagnostic capacity and therapeutic field of the gastroenterologist. Appropriate patient tolerance is essential to successfully complete a safe endoscopic procedure and subsequent follow-up. Key aspects of proper sedation include selection of the optimal sedative and continuous monitoring of the patient during the procedure. Traditional sedation is performed using intravenous benzodiazepines such as midazolam (gamma-aminobutyric acid [GABA] agonists) and short-acting opiates, resulting in moderate sedation. Recently, the use of alternative sedatives such as propofol (phenolic derivative) and dexmedetomidine (selective alpha-2 agonist) has increased.

OBJECTIVES. We compared the safety of sedatives (Midazolam, propofol, and dexmedetomidine) for use during gastrointestinal endoscopic procedures.

METHODS. We searched for all relevant randomized controlled trials published until September 2017, and examined the incidence of adverse events (desaturation, bradycardia, and hypotension) according to the type of sedative used during gastrointestinal endoscopy. A network meta-analysis was performed using the Review Manager 5 and R packages.

RESULTS. Fifty-four studies and 7,057 patients were included in this network meta-analysis. The risks of desaturation when using propofol and propofol with midazolam were 2.56 and 3.46 times higher than that of dexmedetomidine (odds ratio [OR], 2.56; 95% confidence interval [CI], 1.14-5.74 vs. OR, 3.46; 95% CI, 1.47-8.12, respectively). In terms of hemodynamics, the risks of bradycardia using midazolam and propofol were 0.22 times and 0.25 times lower than when using dexmedetomidine (OR, 0.22; 95% CI, 0.10-0.50 vs. OR, 0.25; 95% CI, 0.11-0.59, respectively). Hypotension was more common when using propofol and propofol with midazolam than when using midazolam (OR, 2.40; 95% CI, 1.95-2.95 vs. OR, 2.35; 95% CI, 1.63-3.38, respectively).

CONCLUSIONS. Our network meta-analysis provided a better understanding of the comparative safety of sedatives used during gastrointestinal endoscopy. Dexmedetomidine had less of a respiratory depression effect and increased the risk of bradycardia compared to other sedatives. Patients who received dexmedetomidine had a similar risk of development of hypotension compared to midazolam, and propofol use was twice as likely to cause hypotension as midazolam in gastrointestinal endoscopy.

Effect of transfusion ratio on mortality in patients undergoing massive transfusion during cytoreductive surgery: a retrospective cohort study

S. Pawar[1], K. Deshpande[1], D. Morris[2]

[1]St George Hospital, Intensive Care, Sydney, Australia; [2]St George Hospital, Liver Surgery, Sydney, Australia

Correspondence: S. Pawar

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0253

INTRODUCTION. The evidence suggests favorable effects of blood transfusion with high plasma and platelet to RBC ratios on the outcomes of patients receiving MT. Our local massive transfusion (MT) protocol recommends that red blood cells (RBC), plasma (FFP), and platelets should be administered in 1:1:1 ratio. The adherence to the recommendation, and its impact on the clinical outcome f peritonectomy patients has not been described.

OBJECTIVES.

1. To describe characteristics and outcomes of patients undergoing peritonectomy with heated intraperitoneal chemotherapy (HIPEC) who received MT.
2. To determine the ratios of blood products transfused and to evaluate the predictors of mortality.

METHODS. This was a retrospective cohort study involving patients who received MT during peritonectomy from January 2009 to December 2017 at St George Hospital. Data on patient demographics, diagnosis, surgery, blood products transfused, length of stay, morbidity and mortality were collected from peritonectomy database. Appropriate descriptive statistics were used to describe patients' baseline characteristics. The distribution of patient characteristics and clinical outcome were compared using chi-square test or fisher exact test for categorical parameters, and independent t-test, non-parametric Wilcoxon test, and Mann-Whitney U test for continuous variables. A multiple logistic regression analysis was performed to determine predictors of mortality.

RESULTS. Out of 896 patients a total of 338 (38%) patients (mean age 55.8±12.7 years, 43.2% males, were included in the analysis. Of the 338 patients who underwent surgery 126 (37.3%) were diagnosed with appendicular carcinoma, 22.5% with colorectal cancer, 20.7% with DPAM and mesothelioma and ovarian cancer constituted 8% and 5.9% each. No patient received transfusion with blood products using the RBC: FFP: Platelets ratio of 1:1:1. Compliance with 1:1 ratio of FFP: RBC and Platelets: RBC was 70.5 % and 6.5% respectively. The overall hospital mortality rates 3.9 %, while 46.1 % patients died during 8 years follow up. Patients who received FFP: RBC ratio > 1 had survival benefit of 2.5 years with hazard ratio of 0.62. On multivariate analysis, ratio FFP: RBC transfusion > 1, was an independent predictor of decreased mortality, while completeness of cytoreduction score (CC2/3), diagnosis of ovarian Ca were independent predictors of increased mortality.

CONCLUSIONS. The compliance with the recommended 1:1:1 ratio of blood products was poor. There was significant survival benefit with more FFP transfusion compared to packed red blood cells. Large multicenter randomized controlled trial is warranted to confirm the benefit of higher FFP and Platelet ratios during massive transfusion.

Do statins help prevent VTE in haemorrhagic stroke during the acute period?

K. Jo
Bucheon St. Mary's Hospital, The Catholic University of Korea, Neurosurgery, Bucheon, Korea, Republic of
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0254

INTRODUCTION. Venous thromboembolism (VTE) is a common disease affecting more than one per 1000 persons each year. Patients with stroke have a relatively high risk of VTE because of immobility and increased prothrombotic activity. Statins represent a mainstay in the prevention of arterial events. However, two recent meta-analyses suggested that statins may also reduce the incidence of VTE by 10-20%. The ability to decrease tissue factor expression offers a biological rational for statin's anti-thrombotic effect. These studies showed that statin medication for more than 3 months helps prevent VTE.

OBJECTIVES. The effect of statins on venous thromboembolism (VTE) especially pulmonary embolism (PE) is debatable. This study investigated whether statin medication can decrease the occurrence of VTE in patients with haemorrhagic stroke during the acute period.

METHODS. This is a retrospective study of patients with haemorrhagic stroke between March 2011 and December 2013. Patients with newly diagnosed haemorrhagic stroke were observed during 6 weeks of hospitalisation. Occurrence determined using Doppler ultrasound and computed angiography was used to assess risk factors of VTE in patients with haemorrhagic stroke during the acute period. The difference and incidence of the VTE among acute haemorrhagic stroke was analysed in patients who did not receive no statin medication, who received statin medication after the current haemorrhagic stroke, and who received statin medication after previous haemorrhagic stroke.

RESULTS. Among 98 patients, 9 (9.2%) patients representing 3 from each group had VTE (6 for deep vein thrombosis and 3 for PE) during the follow-up. Each incidence of VTE was 6.4%, 13.6%, and 10.3% in patients who did not receive statins, who received statin medication after the current haemorrhagic stroke, and who received statin medication after previous haemorrhagic stroke, respectively (p>0.05).

CONCLUSIONS. Average dose of statin use was not associated with a reduced risk of VTE in patients with haemorrhagic stroke, especially in the acute period.

Clinical impact of the use of procalcitonin-based algorithms for duration of antibiotic treatment in critical adult patients: a meta analysis of randomized clinical trials

A. Gutiérrez-Pizarraya[1], M.C. León-García[2], R. de Juan-Idígoras[2], J. Garnacho-Montero[1]
[1]Hospital Virgen Macarena, Intensive Care Unit, Seville, Spain; [2]Hospital Virgen Macarena, Seville, Spain
Correspondence: J. Garnacho-Montero
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0255

OBJECTIVES. To assess the impact on 28-day mortality and ICU stay as well as antimicrobial therapy duration of a strategy based on an algorithm based on the sequential measurement of procalcitonin compared to usual clinical practice.

METHODS. Two independent reviewers performed a systematic search in PubMed, Embase, ISI Web of Knowledge, BioMed Central, ScienceDirect and the Cochrane Central Register of Controlled Trials. Eligible studies had to be clinical trials comparing a procalcitonin-

guided antimicrobial therapy strategy with the standard of care in patients with sepsis admitted to the ICU. The search was restricted to articles in English and published before December 31th, 2017. Studies in the pediatric population were excluded. Heterogeneity and inconsistency were evaluated using the test with the I^2 parameter, the variance between Tau2 studies and the Cochrane Q test. The publication bias was also evaluated with the Egger method.

RESULTS. Ten clinical trials met the inclusion criteria with a total of 4249 patients (2122 in the PCT-guided therapy arm and 2127 in the control group). The control group of a clinical trial included an algorithm based on C-reactive protein. All the studies included patients with severe sepsis except one that was performed in patients with ventilation-associated pneumonia. The antimicrobial therapy guided with PCT was a protective factor of 28-day mortality (RR = 0.88, 95% CI 0.79-0.99, p = 0.040). Q test = 5.4; p = 0.788. There was no heterogeneity among studies (variance between studies Tau2 = 0, Q test = 5.4, p = 0.788). This strategy also decreased the duration of antimicrobial therapy (-1.97 days, IC95% -1.19, -2.76; p< 0.001) as well as the ICU length of stay (-1.2 days 95%CI -4.15, 1.74; p< 0.001).

CONCLUSION. Our meta-analysis produced evidence that, in critically ill adults with sepsis, a procalcitonin-guided strategy is associated with a significant reduction in mortality and also in the duration of antimicrobial therapy as well as in the length of ICU stay.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0256

INTRODUCTION. Sepsis and septic shock are life-threatening conditions that arise when the dysregulated host response to microbial infection injures their own organ system (1). It affects millions of people worldwide, and one of the leading causes of morbidity and mortality (2). The SCC guidelines recommend broad-spectrum antibiotic therapy to be initiated as soon as possible after recognition and within 1 hour of for both sepsis and septic shock (3).

OBJECTIVES. We investigated the effect of timing of antibiotic therapy on outcomes assessed by the changes in surrogate markers of organ failure including platelet, serum bilirubin, and serum creatinine, which are components of SOFA score.

METHODS. This was a single-center, retrospective observational study of patients with critically-ill septic patients who presented to the emergency department (ED). The study period was from August 2008 to September 2016. The primary outcome was 48 hours changes in platelet, serum bilirubin, and serum creatinine (δ platelet=platelet count at ED enrolled - platelet count after 48 hours, δ serum bilirubin=serum bilirubin at ED enrolled - serum bilirubin after 48 hours, δ serum creatinine=serum creatinine at ED enrolled - serum creatinine after 48 hours, respectively). A multivariable linear regression model was developed to assess variables related to outcomes (δ platelet, δ serum bilirubin, and δ serum creatinine).

RESULTS. We analyzed 1,784 patients who met the inclusion criteria. Of the eligible patients, the overall 28-day mortality was 14% (n =256/1784). In multivariable linear regression analysis, hourly delay of antibiotic therapy was significantly associated with an increase in the δ platelet (coefficient, 1636.468; standard error, 749.786; P=0.029), and decrease in the δ serum bilirubin (coefficient, -0.055;

standard error, 0.021; P=0.008). hourly delay of antibiotic therapy was not associated with δ creatinine (coefficient, -0.008; standard error, 0.010; P=0.437)

CONCLUSIONS. Hourly delay of antibiotic therapy was associated with decreased platelet count and increased serum bilirubin concentration in critically-ill septic patients during the first 48 hours after ED arrival.

Relationship between antibiotic desescalation and microbiological documentation. Influence on outcome of sepsis patients detected by a sepsis team in a teaching hospital

R. Zaragoza, V. Ramirez, S. Sancho, R. González, C. Ibañez, C. Martínez, C. López, J.J. Camarena
Hospital Universitario Dr. Peset, Valencia, Spain
Correspondence: R. Zaragoza
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0257

INTRODUCTION. Although threre is positive evidence for desescalation in ICU patiens, no enough data about this strategy in sepsis patients and its relationship with microbiological documentation (MD) has been provided.

OBJECTIVES. The aim of this study were to asses the principal factors associated to desescalation strategy (DS) in patients with severe sepsis and septic shock, to describe the relationship of DS and MD, to know their updated prognosis and specially to analyze the influence on global mortality of antibiotic desescalation of these septic patients.

METHODS. During a four years and a half period (October-2012-March 2017), 2405 severe sepsis and septic shock patients detected by a sepsis unit form ICU using an electronic automatic alert in a teaching hospital were prospectively evaluated. Clinical and microbiological variables were recorded. Any patient with a confirmed sepsis was potentially eligible through the whole hospital. DS was

defined as narrowing of the antimicrobial spectrum based on the susceptibility of the pathogen or based in clinical criteria of good evolution. Several multivariate analysis was performed to describe independently factors associated to global mortality in these patients using SPSS package (16.0).

RESULTS. Among 2405 electronic activations 667 of them corresponded to septic shock (27.7%). Only 27.1% of patients were admitted to ICU. Their mean APACHE II and SOFA score were 17.9±6.06 and 5.18±3.3 respectively. The most frequent sources of infections were the respiratory focus (39.5%), urinary (26.6%) and abdominal (18.5%). Global mortality was 20.7%. The majority of episodes were community adquired (56.4%). Associated bacteremia was present in 34.2% of episodes. MD was achieved in 52.6 %. DS was present in 29.1% of the episodes. Statistical significant factors associated to DS in univariate analysis (p< 0.05) were: MD (39,7% vs. 19%), ICU admission (40% vs. 23.7%), septic shock (34,4% vs. 26.8%), bacteremia (45.2% vs. 24.8%) and adequate empirical antibiotic treatment (31.4% vs. 15.1%). DS was associated to a lower global mortality (13% vs 28,4%; p= =0.0001) There were no differences in mortality rates among DS in patients with MD or not. (12.2% vs 14.4%) Multivariate analysis did not confirm DS (OR 1.7; CI95% 0.59-4.94) as a independently factor associated to global mortality.

CONCLUSIONS. DS was achieved in almost one of three patients with sepsis detected by a sepsis team in a teaching hospital. MD, ICU admission, bacteremia, adequate empirical antibiotic treatment and septic shock were associated to DS. DS with no MD was nor associated with higher mortality. DS had no any influence on global mortality.

Impact of appropriate empirical antibiotics on clinical outcome in *Klebsiella pneumoniae* bacteraemia in the intensive care unit

M.Y. Man, K.C. Li, H.P. Shum, W.W. Yan
Pamela Youde Nethersole Hospital, Department of Intensive Care, Hong Kong, Hong Kong, China
Correspondence: K.C. Li
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0258

INTRODUCTION. Klebsiella Pneumoniae (KP) is a common Gram-negative bacterium causing a myriad of infections such as pneumonia, liver abscess, urinary tract infection and other nosocomial infections. Treatment options have been reduced due to the emergence of multi-drug resistant strains worldwide. Inappropriate empirical antibiotics in septic shock are associated with poor outcome, yet the impact on confirmed bacteremia is not well studied.

OBJECTIVES. We aim to evaluate the impact of appropriate empirical antibiotics on clinical outcomes in KP bacteraemia in critical care setting.

METHODS. Adults admitted to intensive care unit of a regional hospital in Hong Kong with KP bacteraemia from January 2009 to June 2017 were retrospectively reviewed. Demographics, antibiotics, microbiology and outcomes were identified and analyzed. Cox regression analysis was performed to determine independent predictors for 90-day mortality and logistic regression analysis was used to identify independent predictors for patients to have received inappropriate empirical antibiotics.

RESULTS. During the study period, a total of 205 patients with KP bacteraemia were identified, in which 148 received appropriate empirical antibiotics (72.20%) while 57 did not (27.80%). Inappropriate or no empirical antibiotics was associated with significantly higher 90-day mortality (HR 3.001; 95% CI 1.856-4.854; p< 0.001). Other independent predictors include: patient with concomitant congestive heart failure (HR 2.281; 95% CI 1.141-4.561; p=0.02), medical patients (HR 1.944; 95% CI 1.132-3.340; p=0.016), higher total SOFA score (HR 1.169; 95% CI 1.101-1.242; p< 0.001). Patients with chronic kidney

disease or end stage renal failure (OR 4.802, 95% CI 1.563-14.759, p=0.006), infection caused by ESBL or carbapenam resistance strain (OR 4.339, 95% CI 1.667-11.259, p=0.003), patients who were mechanically ventilated (OR 4.066, 95% CI 1.831-9.030, p=0.001) were more likely to have received inappropriate empirical antibiotics.

CONCLUSIONS. Appropriate antibiotics improve mortality of patients with KP bacteraemia. Patients with pre-existing chronic kidney disease or end stage renal failure, infection by ESBL or carbepenam resistance strain and mechanically ventilated patients are more likely to have received inappropriate antimicrobials treatment.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0259

INTRODUCTION. Indiscriminate antibiotic use is a significant concern in critical care medicine and is known to be associated with increased drug-induced bacterial resistance among other adverse effects. Although evidence shows that early administration of antibiotics in patients with septic shock decreases in-hospital mortality[1], there is a lack of studies evaluating the role of early empirical antibiotics in patients with suspected nosocomial infection without sepsis.

OBJECTIVES. To compare early empiric antibiotic treatment with a conservative approach in critically ill surgical patients with suspected nosocomial infection without sepsis.

METHODS. A retrospective cohort of adult patients admitted to a Surgical ICU of a tertiary university hospital between 2012-2016. Early empiric antibiotic group was defined by immediate initiation of antibiotic therapy once infection was suspected, while in the conservative group, antibiotics were initiated only if a clear infectious focus, positive cultures, or sepsis/septic shock (Sepsis 3.0 definition) developed. The primary outcome was a composite of death, sepsis or septic shock in 14 days. A logistic regression model, including variables with p-value < 0.2 in the univariate regression and other clinical relevant variables, was used to estimate the association of risk factors and primary outcome.

RESULTS. From 2007 ICU admissions, 342 patients with suspected nosocomial infection without an obvious source or sepsis were included. Patients characteristics and outcomes are shown in table 1. Trauma represented 70% of the study population. There was no difference in age, SOFA at inclusion, SAPS 3, mechanical ventilation at inclusion, or in-hospital mortality between groups. Only 57% of patients in the conservative group had received antibiotics by day 14.

The multivariate analysis (table 2) showed that early antibiotic therapy, mechanical ventilation, and age were associated with the primary outcome. Vasopressors at inclusion, SAPS 3, SOFA, gender, SIRS, traumatic brain injury, and cause of ICU admission were not associated with the outcome.

DISCUSSION. Our results show that early empirical antimicrobial therapy does not decrease the incidence of sepsis, septic shock or death within 14 days. The concept of giving early empirical antibiotic treatment for critically ill patients with suspected infection is extrapolated from data of patients with sepsis or septic shock. However, our study shows that early empirical antibiotic treatment does not prevent sepsis in critically ill surgical patients with suspected nosocomial infection and might be harmful. A conservative approach can decrease antibiotic use by 43% and might be associated with better outcomes.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0260

Within the goals of the management of sepsis, it has been pointed out that the shorter time to antibiotic has a positive impact on survival, although the exact time of greatest impact has not been defined (1-3). In Mexico it is estimated that close to 50 to 60% of emergency admissions were related to sepsis, of which 10% were admitted with septic shock (4).

OBJECTIVES. To establish the risk of 30-day mortality associated with the time of administration of the first dose of antibiotic in patients with sepsis and septic shock in the Emergency Department.

METHOD. A multicentre, single-day study was conducted (September 13, 2017), where all patients diagnosed with sepsis or septic shock were included, according to the Sepsis-3 criteria (5), admitted to the Emergency Department during the 24 hours a day, they were recorded on a digital platform (www.sepsismexico.org) and followed up for 30 days. The data analysis was performed in SPSS v.21.

RESULTS. 68 hospitals participated, 307 patients were included (56% women), of which 287 received antibiotic during their stay in the Emergency Room, the common odds ratio was estimated by the Mantel-Haenzel method to compare by hour, among the first six hours of treatment, to obtain the risk of mortality, days of stay> 5 days and to develop shock during the following 30 days Risk of mortali... Risk of length ... Risk of develop...

DISCUSSION. We observed a tendency to increase mortality and the risk of progressing from sepsis to septic shock to longer time to antibiotic, however, it is not a significant result, this can be explained by other elements of the treatment such as quantity and type of intravenous solutions employees, accumulated fluid balance, time of hypotension before vasopressors, time to surgical resolution and others. We found a significant risk to increase the days of stay in relation to time to antibiotic.

Association of antibiotic pharmacodynamic indices with survival in human septic shock

G. Vázquez-Grande[1,2], K. Meghairbi[2,3], A. Kumar[1,2]
[1]University of Manitoba, Section of Critical Care, Winnipeg, Canada; [2]University of Manitoba, Medical Microbiology, Winnipeg, Canada; [3]Dr. Soliman Fakeeh Hospital, Jeddah, Saudi Arabia
Correspondence: G. Vázquez-Grande

INTRODUCTION. Septic shock and sepsis associated multiple organ failure are a major cause of morbidity and mortality in intensive care units (ICUs) globally. Despite major improvements in sepsis treatment, septic shock remains a major challenge to ICU clinicians, with a mortality of 30-50%. Source control and an early administration of appropriate antimicrobial therapy remain the most important and powerful clinical interventions for sepsis treatment.

Animal studies suggest that the key for improving septic shock outcomes relay on the appropriate delivery of existing antimicrobials. Thus, understanding the pharmacodynamic indices (PDI) may be the cornerstone to improve sepsis outcomes.

OBJECTIVE. To assess the association of β-lactam pharmacokinetic indices and outcome in human septic shock in a wide range of bacterial pathogens.

METHODS. Retrospective analysis of a septic shock cohort treated with a b-lactam as the only effective antimicrobial, from a local validated high-quality database.

We collected patient, pathogen and treatment characteristics. And calculated b-lactam pharmacodynamic indices (PDI) during the first 24 hours of treatment, including: time above MIC; time above four times the MIC; peak drug concentration over MIC; and area under the drug concentration curve divided by MIC (AUC/MIC).

We applied logistic regression to examine survival to hospital discharge as a function of b-lactam PDI. And performed a multivariate regression model adjusting for age, time to appropriate antibiotic and APACHE II score.

RESULTS. 342 patients with septic shock treated with b-lactam as only effective antibiotic. 59.6% were males, with an average age of 63.8(±15.6) years, and a mean APACHE II score of 26.97(±8.8) points. The median time to appropriate drug administration following documentation of hypotension was 3.67 (1.0-7.5 IQR) hours.

Logistic regression analysis demonstrated that, during the first 24 hours, time above MIC (OR 1.17, 95%CI 1.07-1.28 per 10% increment, p=.0005) and time above 4xMIC (OR 1.12, 95%CI 1.05-1.20, p=.0003) were both strongly associated with an improved survival in septic shock patients.

In a multivariate regression model (controlling for age, time to appropriate antibiotic and APACHE II score) the relationship between time above the MIC (OR 1.12, 95%CI 1.04-1.29, p=.006) and time above four times the MIC (OR 1.13, 95%CI 1.04-1.22, p=.002) and hospital survival remained significant.

CONCLUSIONS. Our study shows that for β-lactams time-related PDI are associated with improved survival in a broad range of human
septic shock; even after adjusting for time to appropriate antimicrobial therapy, age and severity of illness.

This suggests that there is potential value in using PDI to guide optimal dosing regimens of b-lactam therapy for the treatment of septic shock patients.

Table 1 (abstract 0261). Cohort characteristics (n=342 patients)

Parameters	Units	
Age	years (mean, SD)	63.9 (+/-15.6)
Sex	male (%)	202 (59.1%)
APACHE II	score (SD)	27.0 (+/-8.8)
IBW	Kg (median, IQR)	70.2 (53.5-73.3)
Serum creatinine at shock	µmol/L (median, IQR)	165 (113-273)
Serum creatinine at 24 hours post shock	µmol/L (median, IQR)	171(98-271)
Creatinine clearance estimated from serum creatinine closest to 24 hours post shock onset	µmol/L/min (median, IQR)	37.1 (23.3-63.1)
Time to appropriate antibiotic	hours (median, IQR)	3.67 (1-7.5)
Microbiologically inappropriate initial empiric therapy	n (%)	52 (15.2%)

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0262

INTRODUCTION. Sepsis is a life-threatening medical emergency which requires fast management to provide the best patient outcome.[1] Patients with an National Early Warning Score (NEWS) of 3 should be screened for sepsis, and if diagnosis is probable, the 'sepsis six' care bundle should be started.[2] The most important intervention to improve patient outcomes is administration of antibiotics within 1 hour.[1]

OBJECTIVES. This study aimed to assess whether patients in Morriston Hospital Emergency Department who are diagnosed with sepsis are receiving antibiotic therapy within 1 hour of diagnosis.

METHODS. The study was done in a single centre University Teaching Hospital which sees approximately 100,000 patients annually. Data was collected retrospectively between August 2017-November 2017. Information obtained using the sepsis screening tool filled in by ED staff, was inputted onto an excel spread sheet. The data collected included: age, sex, date of admission, admission time, NEWS, SIRS criteria, septic (Yes/No), severe sepsis identified time, presenting complaint, Sepsis 6 elements completed (yes/no), sepsis six completion time, sepsis six completed within 1 hour, sepsis six not completed, septic shock screening criteria, diagnosis, discharge outcome.

RESULTS. The antibiotic administration within 1 hour for all septic patients improved from 32% to 41% during the study period. Focussing specifically in patients with NEWS ≥ 6 the 1-hour antibiotic compliance rose from 42% in June 2017 to 47% in February 2018.

CONCLUSIONS. There was a steady improvement in antibiotic compliance for all septic patients and also for patients with a NEWS ≥ 6 during the study period. There is more room for improvement and further changes are being implemented to achieve this.

Adherence to antibiotic guidelines in patients admitted to ICU with severe sepsis and septic shock: does it affect clinical outcome?

O. Lindberg

Linköping University Hospital, Intensive Care, Linköping, Sweden

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0263

Background: Sepsis remains associated with high morbidity and mortality and is a common reason for requiring intensive care. Several landmark studies have demonstrated the benefit of prompt antibiotic usage and the Swedish Society of Infectious Disease Medicine has since 2008 provided national guidelines for the treatment of sepsis in Sweden. Compliance with the Swedish national guidelines is largely unknown and further it is unknown if compliance to guidelines improves patient outcome. The aim of this study is to assess the current compliance to Swedish guidelines and secondly to investigate whether compliance to guidelines improves outcome for patients admitted to a mixed intensive care unit for severe sepsis and septic shock.

METHODS. A retrospective, journal audit was conducted on all patients admitted to the general ICU at Linköping University hospital from the 1st of January 2011 to the 31st of December 2015 with ICD-10(SE) diagnosis codes 65: 1 (Severe Sepsis) and 57: 2 (Septic Shock) identified through the Swedish ICU Registry (SIR).

RESULTS. Full compliance to national antibiotic guidelines was observed in 35.3 % of patients, partial compliance in 45.7%, and no compliance in 18.9%. Partial compliance was significantly associated with a 2-fold increase in risk of 30-day mortality (OR 2.155 [CI 1,19-3,87], p=0.01). Furthermore no significant association was observed between time to appropriate antibiotics and patient outcome. No compliance to guidelines was surprisingly not associated with an increased risk compared to full compliance.

CONCLUSIONS. Only 35 % of the most critically ill patients receive antibiotics in line with Swedish national guidelines for severe sepsis and septic shock. Full compliance with guidelines was associated with decreased mortality. Efforts should be made to increase the awareness and compliance to the current guidelines.

Ceftazidime-avibactam to treat severe deep-seated infections due to KPcp in the critically ill

P. Mandelli, I. Cigada, A. Veronese, S. Silvia, F. Cantarero, C. Soru, A. Corona

University of Milano, Milano, Italy

Correspondence: A. Corona

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0264

INTRODUCTION. In the critially ill patients, carbapenemases producing (cp) *Klebsiella pneumoniae* (KP) infection rate ranges between 5-50% and is associated with a high mortality (19-51%). In our hospital ICU, KP strains are resistant to carbapenems in 45% of isolates.
OBJECTIVES. The use of ceftazidime-avibactam - a 3-generation cephalosporin plus a new inhibitor of class A (KPC), C (AmpC) and D (OXA48) ESBL, may resolve life-threatening conditions (1).
METHODS. Observational audit of 18 patients undergoing compassionate treatment with ceftazidime-avibactam after local Ethic Committee authorization.
RESULTS. From April 2017 to February 2018, 18 patients (pts) (13 M and 5 F), median age 59.5 (IQR = 42.5-70.5) were given ceftazidime/avibactam for major KP-cp (meropenem MIC > 16ng/ml) infections: 10 bacteramia (B) (3 abdominal sepsis, 2 mediastinitis, 2 CVC, 3 primary); 6 secondary peritonitis and 2 complicated UTI. 13/18 (72.2%) pts, developed a septic shock [median (IQR) SOFA score 10 (8-17)] and needed mechanical ventilation [median (IQR) 8 (4-17) days], norepinephrine infusion [median (IQR) 3 (2-5) days] and lactate values [median (IQR) 3.5 (2.4-7.3) mMol/l]; 5 patients underwent renal replacement therapy. The median treatment duration (IQR) was 14 (13-14) days. In 7/18 of cases, ceftazidime/avibactam was given in combination [fosfomycin + colistin (3 pts.), fosfomycin + aztreonam (2 pts.), fosfomycin + gentamicin (1 pt), colistin (1 pt)]. All the patients experienced a clinical response and improved by 72/96 hours from the ceftazidime/avibactam commencing. In 9/10 bacteraemic patients negativitation of blood culture occurred by 96 hours, as well as of the rectal swab in 6/18 patients. A (B) recurred twice in the same patients and two further treatments were necessarily given. 12/18 (66.7%) patients survived. Only 4 out of 6 deaths (2 patients died because of cerebrovascular accident) were directly or indirectly related to KP-cp severe infections, therefore we recorded a likely attributable death of 22.3%. The susceptibility test of strains showed sensitivity to ceftazidime/avibactam, whereas (i) 100% of resistance to carbapenems (meropenem/imipenem/ertapenem), quinolones and III/IV generation cephalosporin, tigecycline and piperacillin/tazobactam. 62.5% of strains were susceptible to fosfomycin and colistin and less than 50% to main aminoglicosides (amikacin and gentamicin).
CONCLUSIONS. The 18 strains of KP-cp were susceptible to ceftazidime-avibactam despite the high carbapenem-resistance recorded in our ICU, because od rare identification of KP-cp VIM / NDL +. Our data seems to confirm the efficacy and clinical utility of this antibiotic for the critically ill patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0265

INTRODUCTION. Timely effective antibiotic usage is crucial for survival of patients with septicemia. However, cultured-based microbiological diagnosis are time consuming, leading to poor clinical outcomes and rising antibiotic resistance.
OBJECTIVES. This study aimed to establish a rapid antibiotic susceptibility test (AST) protocol based on surface-enhanced Raman spectroscopy (SERS), which was a sensitive, specific and high-speed optical analytic technique.
METHODS. The samples from 32 patients with bacteremia of *S. aureus* and 43 of *E. coli* were aspirated from the positive-culture bottles. Sample pretreatment with cell lysing agent and repetitive wash procedure recovered the blood-culture isolates from complex blood-broth septic mixture. The SERS measurements of the samples with and without 2-hr antibiotic treatment were performed on SERS-active substrates made of Ag nanoparticle array. The Raman peaks at 730 and 724 cm^{-1}, signifying the metabolites released from *S. aureus* and *E. coli* respectively, were designated as their SERS biomarkers. Their signal ratios (r730 and r724) obtained from the antibiotic-treated sample and the untreated one were used to determine AST.
RESULTS. r730 of susceptible *S. aureus* decreased with the treated oxacillin concentration, while that of resistant *S. aureus* remained relatively invariant for all drug concentrations. Similar character was observed for *E. coli* treated with cefotaxime. The sensitivity and specificity of AST were 0.94 and 0.93 for *S. aureus* and 0.97 and 1.00 for *E. coli*. The antimicrobial activity of antibiotics was accurately indicated by SERS biomarkers.
CONCLUSIONS. A rapid AST protocol based on SERS was successfully demonstrated for positive blood culture of *S. aureus* and *E. coli*. This first proof-of-concept study lights the potential of a new high-speed microbiological analytic method assisting in fighting sepsis. The rapid and reliable AST results yielded by SERS would be of vital importance not only to guide the early antibiotic therapy but also reduce the emergence of antimicrobial-resistant strains.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0266

INTRODUCTION. Tie2 is a tyrosine kinase receptor expressed by endothelial cells (ECs) that maintains vascular barrier function. We recently reported that diverse critical illnesses acutely decrease Tie2 expression and that experimental Tie2 reduction suffices to recapitulate cardinal features of the septic vasculature.
OBJECTIVES. Here we investigated molecular mechanisms driving Tie2 suppression in settings of critical illness.
METHODS. Molecular biology assays (western blot, qPCR) + flow and transendothelial electrical resistance (TER) experiments in human umbilical vein endothelial cells (HUVECs); murine cecal ligation & puncture (CLP) and LPS administration. Kidney biopsies from deceased septic AKI patients (n=16) and controls (n=12) & serum from septic shock patients (n=57) and controls (n=22).

RESULTS. We observed rapid reduction of both Tie2 mRNA and protein in mice following CLP. In cultured ECs exposed to TNFa, suppression of Tie2 protein was more severe than Tie2 mRNA, suggesting distinct regulatory mechanisms. Evidence of protein-level regulation was found in TNFa-treated ECs, septic mice, and septic humans, all three of which displayed elevation of the soluble N-terminal fragment of Tie2. The matrix metalloprotease MMP14 was both necessary and sufficient for N-terminal Tie2 shedding. Since clinical settings of Tie2 suppression are often characterized by shock, we next investigated the effects of laminar flow on Tie2 expression. Compared to absence of flow, laminar flow induced both Tie2 mRNA and the expression of GATA3. Conversely, septic lungs exhibited reduced GATA3, and knockdown of GATA3 in flow-exposed ECs reduced Tie2 mRNA. Post-mortem tissue from septic patients showed a trend toward reduced GATA3 expression that was associated with Tie2 mRNA levels.

CONCLUSIONS. Tie2 suppression is a pivotal event in sepsis that may be regulated both by MMP14-driven Tie2 protein cleavage and GATA3-driven flow regulation of Tie2 transcript.

Right dose, right now. developing autokinetics for personalised, real time, big data driven, antibiotic dosing

L.F. Roggeveen[1], T. Guo[1], B. van Dijk[1], R. Driessen[1], P. Thoral[1], L. Fleuren[1], A.R.J. Girbes[1], P.H.J. van der Voort[2], R. Bosman[2], P.W.G. Elbers[1]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0267

INTRODUCTION. Antibiotic dosing in critically ill patients is difficult because of altered pharmacokinetics[1]. Most intensive care units rely on standard dosing. Pharmacokinetic targets are only reached in about half of cases[2]. Several dosing tools exist for guiding antibiotic dosing. However, these require laborious manual data entry and pharmacometric knowledge and support and may be impractical, error prone and time consuming. Thus, truly personalized antibiotic dosing is currently lacking. We set out to change this by integrating large amounts of data from electronic patient records (EPRs) with complex pharmacometric models at the bedside for instantaneous advice.

OBJECTIVES. To develop real time antibiotic dosing software that interacts with common EPRs and can be implemented for personalised antibiotic dosing in critically ill patients in septic shock.

METHODS. We created AutoKinetics, a clinical decision support system for real time antibiotic dosing advice. We integrated AutoKinetics with two EPRs. We use a SQL database for backend support. We created a Windows- and Web-based front-end application.

In a separate study, we identified or developed models for 5 commonly used antibiotics, namely meropenem, ciprofloxacin, ceftriaxone, cefotaxime and vancomycin. Model performance was validated on retrospectively and prospectively collected data and were calibrated on prospectively collected plasma levels. Selected models were incorporated into AutoKinetics.

RESULTS. We successfully developed AutoKinetics. The software calculates predicted serum concentrations on a minute to minute basis. Upon request, it provides the treating physician and other healthcare professionals with personalized graphical advice on optimal antibiotic loading and maintenance dose at any given moment. AutoKinetics can handle numerous pharmacokinetic model structures and therefore potentially all antibiotics. While not required to function, AutoKinetics does provide automatic personalized Bayesian maximum a posteriori correction if plasma level are available.

CONCLUSION. We developed a clinical decision support system for real time personalised antibiotic dosing in the critically ill. We hypothesize that our solution may contribute to improved antibiotic dosing in the critically ill. Therefore, we recently started a multi-centre randomised control trial to validate this concept in 420 patients with severe sepsis and septic shock. EudraCT-number: 2017-002478-37.

OBJECTIVES. To know if standard dosing of meropenem (MER) and piperacillin / tazobactam (PTZ) administered to critically ill patients including subjects on continuous renal replacement techniques (TCRR) achieve optimal levels to treat severe infections caused by Gram-negative bacilli including "difficult-to treat" pathogens.

METHODS. Prospective study including patients with septic shock under treatment with standard doses of MER (1g / 8h in extended infusion) and PTZ (4gr / 6h in extended infusion). Levels were monitored before the administration of the antibiotic (T0) and in 50% of the administration interval (T50), in equilibrium state (after the fourth dose) by liquid chromatography coupled to an ultraviolet detector. The creatinine clearance (CrCl) was determined in three-hour urine. Patients with a creatinine clearance $\geq$ 130 ml /min were considered patients with hyperfiltration. CRRT was started for oliguric renal failure. Optimal concentrations of the drug are considered if 100% of the time exceeds four times the minimum inhibitory concentration (MIC). The target is set at T0> 8 mg /L for MER and T0> 64 mg /dL for PTZ. Normally distributed continuous variables were expressed as means with standard deviations and compared with Student´s test for independent samples and compared with Mann-Whitney U test for non-normally distributed continuous variables.

RESULTS. In 26 patients treated with MER (11 on CRRT), there were no statistically significant differences in the T0 and T50 values between patients with or without CRRT (20.6 ± 4.5 mg / dL in patients with TCRR vs 17.2 ± 2.4 mg / dL in patients without CRRT for determination values at T0, with p = 0.52; 32.6 ± 4.3 mg / dL in patients with CRRT vs 38.2 ± 6.4 mg / dL in patients without CRRT for values in T50, p = 0.47). Among patients without CRRT (15/26), only one presented hyperfiltration and id not reach T0> 8mg / dL (7.54 mg / L).In 16 patients treated with PTZ, there were statistically significant differences in T0 values between patients who received standard doses (4 g / 6 h) and patients with non-standard doses (4 g / 8 h): 120.1 ± 33.6 mg/L in patients with standard doses vs 28 ± 11.4 mg/L in patients with non-standard doses for determination values at T0, with p=0,025. Otherwise, there were no statistically significant differences in T50 values between the groups: 161.2 ± 29.1 in patients with standard dose vs 102.6 ± 22.1 in patients with non-standard dose for determination values at T50, with p=0,13. Among patients with PTZ 3 were on TCRR (1 with standard dosing), only the patient on TCRR with standard regimen of antibiotic reached MIC>64 mg/L.

CONCLUSIONS. Given the variability of the concentrations and the different pharmacodynamic objectives that can be marked, it is recommended to measure the levels of MER and PTZ in critically ill patients with serious infections.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0269

INTRODUCTION. β-lactam antibiotics effectiveness is time-dependent and requires that their plasmatic concentration is constantly over the Minimal Inhibiting Concentration (MIC) of the targeted bacterial strain. Doses recommended by the pharmaceutical companies are based on data derived from patients with non-severe diseases and may not be appropriate for ICU patients with sepsis, due to variable alteration of clearance or distribution volume.
OBJECTIVES. To assess the prevalence of insufficient plasma concentrations of β-lactam antibiotics in ICU septic patients.
METHODS. A retrospective analysis of therapeutic drug monitoring using liquid chromatography-mass spectrometry (LC-MS/MS) was performed between December 2016 and November 2017 for 6 molecules. Dosing and frequency of beta-lactams and their adjustment to renal function were based on the recommendations of the French Vidal database of pharmaceutical drugs. We selected those assessments performed between 4 and 8 hours after IV administration for amoxicillin (AMX); 3 and 6 hours for cloxacillin (CLO), 6 and 12 hours for piperacillin (PIP), 6 and 12 hours for meropenem (MEM), 8 and 12 hours for cefepime (FEP), and 12 and 24 hours for ceftriaxone (CRO). EUCAST inferior breakpoint was used for each molecule to approach usual MICs.
RESULTS. 178 samples were assessed, of which 125 were residual concentrations (AMX = 24, CLO = 7, PIP = 61, MEM = 14, FEP = 6, CRO = 13) in 78 patients. Age = 61 ± 14, SAPS 2 = 50 ± 19, weight = 75 ± 22 kg, body mass index = 28 ± 6 kg/m^2, shock = 56 %, renal replacement therapy = 17%, LOS in ICU = 15.2 ± 12.8 d, mortality = 25 %. 30/125 plasma concentrations (24%) were below four-time the EUCAST inferior breakpoint: AMX = 4 (17 %), CLO = 1 (14 %), PIP = 15 (24.6%), MEM 8 (57.1%), FEP = 1 (16.7%), and CRO = 1 (7.7%). Except for MEM and CRO, plasma concentrations were poorly correlated with the time from infusion to sample. Patients with insufficient concentrations were younger (52 ± 15 versus 64 ± 13, p 0.006) and had longer ICU stays (23 ± 19 versus 12 ± 9 d, p = 0.02), while they had similar sex ratio, SAPS 2 score, weight, BMI, shock, RRT use, and mortality.
CONCLUSIONS. In our ICU population, dosing and frequency of β-lactam antibiotics based on the recommendations of the French Vidal database of pharmaceutical drugs led to low β-lactam exposure in 24 % of cases, particularly for antibiotics with short half-lives and in younger patients. Insufficient concentrations were associated with longer LOS in the ICU.

INTRODUCTION. Procalcitonin (PCT) has been studied as sepsis marker in different clinical scenarios and its values are higher in gram-negative infections compared to gram-positive ones. PCT raise is more evident in bacterial then in invasive fungal infections. PCT values were higher in surgical than in medical patients, and in abdominal and urinary infections than others.
OBJECTIVES. The aim of our study was to identify the most important clinical determinant that influences PCT values in a population of medico-sukrgical ICU patients.
METHODS. Retrospective analisi of a prospective 4 year-data collection. 927 consecutive patients were analyzed and we collected clinical parameters, laboratory, microbiological and radiographic exams, antibiotics and vasopressors administration, C-Reactive Protein (CRP) and PCT values, in order to recognize etiology and site of infections. We daily classified the clinical states of patients into six diagnostic classes and the intensive care admission as medical or surgical. An optimal scaling analysis was performed in order to assess the most important clinical determinant of PCT.
RESULTS. PCT values were lower in fungal sepsis than in gram-negative and gram-positive ones (p< 0.05). We analyzed peak values of PCT during septic events: gram-negative sepsis have higher mean peak value than gram-positive and fungal ones (p< 0.05). PCT values of abdominal (3.84 ng/ml - IC95% 3.35-4.36) and urinary tract (6.63 ng/ml - IC95% 4.71-11.52) septic events were higher than in soft tissues (4,03 ng/ml - IC95% 3.42-4.81), lung (2.31 ng/ml - IC95% 2.09-2.68), and BSI (1.78 ng/ml - IC95%1.22 -2.35) ones (p< 0.05). PCT mean peak value was higher in abdominal than in lung sepsis (p< 0.05). There was no statistical significance for the other sites of infection in PCT peak means values.We found higher PCT values in surgical patients than in medical ones, anyway there's a difference due to the site of infection: actually there is prevalence of abdominal infection in surgical patients (61.6%), and prevalence of lung infection (73.2%) in medical patients. At optimal scaling analysis we found that septic events were the strongest determinant of PCT values (partial correlation=0.432 and importance=0.702), site of infection presents a high importance (=0.22), while type of patient (medical/surgical) (=0.08) and etiology (=0.02) importance were similar. Analyzing PCT peak values we found that the septic event was the most important clinical factor of the septic events PCT peak value (partial correlation=0.28, importance=0.8) than other ones.
CONCLUSIONS. Our study identified that PCT moves in different ways according to etiology, site of infection and type of patient admission (medical/surgical), anyway the most important clinical determinant factor of PCT peak value during a septic event is etiology.

INTRODUCTION. Excessive duration of antibiotic therapy in critically ill patients can result in antibiotic overuse,increasing the risk of emergence and spread of multi drug resistant microorganisms in hospitals.In the last years,the utility of serial measurement of procalcitonin (PCT) for reduction the duration of antibiotic treatment has been reported.
OBJECTIVES. The objective of the study was to evaluate the usefulness of PCT in reducing the duration of antibiotic treatment compared with the standard treatment in patients admitted in ICU.
METHODS. A descriptive and prospective study was carried out in our 30-bed polyvalent ICU.Inclusion criteria:patients aged ≥ 18 years admitted to the ICU for a proven infection,and who received their first dose of antibiotics no longer than 24h before inclusion in the study.The patients included in the study received a minimum of five days of antibiotic treatment,and after the treatment was stopped if clinical signs of infection improved and the PCT values was either < 0.5 ng/L or decreased by 80% or more of its peak value.Patients with infections,which require prolonged antibiotic therapy, viral or parasitic infections and those immunocompromised or pregnant were excluded.For this study,data were collected for the period 1 June to 31 December 2017 and compared with the same period of the previous year,in which duration of antibiotic treatment was according to standard care.

RESULTS. A total of 43 intensive care patients receiving antibiotic therapy after confirmed infections were enrolled in this study,mostly due to community-acquired infections.Pneumonia was the most frequent.In the PCT-guided period the duration of antibiotic therapy was shorter (5.8 +/-0.9 days in community-acquired infections and 7.6 +/- 3.2 days in nosocomial infections)than compared to standard-of-care period in which the duration of treatment was according to local antibiotic protocols. Median consumption of antibiotics was reduced by 6.5 % according to daily defined doses(DDD)and 5.45% according to days of therapy(DOT)in the PCT-guided period compared to the standard-of-care period,with a reduction of antibiotic treatment costs of 8.9%.The number of patient-stays and the incidence of community-acquired infections and nosocomial infections reported during both periods was not different.

CONCLUSIONS. Our results suggest that a protocol based on serial PCT measurements may contribute to reduce antibiotic treatment duration and contribute to an antibiotic stewardship program in our intensive care unit.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0272

INTRODUCTION. Lung transplant (LT) is the therapy of choice for a number of end-stage lung diseases. Although post-transplantation survival has steadily improved, long-term survival is still low with a median survival of 5.8 years [1]. As the number of LT and survival has been increasing, it is expected that ICU readmissions (ICUr) will continue going up [2]. Factors influencing the UCIr of this unique subgroup of immunocompromised patients after the post-operative period have been described for few studies, mainly retrospective. In the general population, there are clinical variables and scoring systems that can predict the outcome of patients that are admitted to the ICU. It is of paramount importance to study causes of admission, outcomes and potential predictors of ICU mortality in lung transplant patients. Better knowledge of these factors could be useful to patients, their families and their physicians.

OBJECTIVES. To identify causes of ICUr in LT patients, report outcome at ICU discharge, to determine the independent risk factors associated with ICU mortality and suggest interventions that may modify outcome. We hypothesised that pneumonia influences UCI mortality, over the need of invasive mechanical ventilation (IMV) or vasoppressors.

METHODS. Multicentre prospective study of all lung transplant patients readmitted to ICU after perioperative ICU discharge between 2012 and 2016 in five tertiary hospitals. Patients were followed until hospital discharge or death. Logistic regression analysis was performed to determine which factors were independently associated with ICU mortality.

RESULTS. There were 174 ICUr after a median of 7 month of LT. The main diagnosis at ICUr was pneumonia 67/174(38.5%). ICU mortality was 41.8%, with multi-organ failure (48.4%) and hypoxemia (45.4%) as the most common causes of death. On multivariate analysis the independent predictors of death were invasive mechanical ventilation

>72h (OR =4.7, 95% CI, 2.1-10.4), SOFA score >6 (OR =2.9, 95% CI, 2.1-9.9), time after LT at ICUr >1 month (OR =3.4, 95% CI, 1.2-10.9), history of acute rejection (OR =2.8, 95% CI, 1.2-7.1), vasopressors (OR =2.3 95% CI, 1.1-6.5) and pneumonia (OR =2, 95% CI, 1.1-7.1). P < 0.05.

CONCLUSIONS. It is critical to recognize pneumonia in LT patients undergoing ICUr, because besides being the main etiology of ARF, sepsis and septic shock, it portends lower ICU-survival (independently of ARF, shock or associated organ dysfunction during ICUr or previous conditions prior to ICUr as CLAD or FEV1). In view of this, prompt pneumonia recognition and pathogen detection for targeted therapy, implies the need for development of rapid diagnostic tests at the patient`s bedside for both microbiology identification and resistance detection.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0273

INTRODUCTION. Acute respiratory failure (ARF) is a common event in patients with primary malignant brain tumors (PMBT) [1]. Even if many factors (corticosteroid therapy, swallowing disorders) suggest a specific etiologic spectrum, few data are available regarding its precipitating factors.

OBJECTIVES. Our first aim was to compare the causes of ARF between patients with PMBT and those with other type solid tumors. Our second aim was to identify, among PMBT, the factors influencing survival in ICU.

METHODS. Bicentric case-control study from March 1996 to May 2014. Patients with PMBT (cases, primary central nervous system lymphoma included) admitted for ARF were compared to patients with other kind of solid tumors (controls). The causes of ARF were determined by three experienced respiratory physicians and were required for inclusion: a respiratory rate > 20 cycles/min and a $PaO_2/FiO_2 < 300$ for patients in spontaneous breathing and only a $PaO_2/FiO_2 < 300$ for patients under mechanical ventilation. In both groups were excluded patients with metastatic solid tumors, benign tumors or tumors with more than 5 years of complete remission, recent post-operative patients, and patients with other immunodeficiency.

RESULTS. A total of 84 cases and 133 controls were included. Acute infectious pneumonia was the leading cause of ARF in both groups but was more frequent among cases (77 vs. 36%, p< 0.001). Cardiogenic pulmonary edema and exacerbation of chronic respiratory diseases were more frequents in controls (10 vs. 37%, p< 0.001). Pulmonary embolism was similar between the two groups (10 vs. 4%, p = 0.143). Among acute infectious pneumonia, pneumocystis pneumonia (PCP) and aspiration pneumonia were more frequent in cases (19 vs. 2%, p < 0.001 and 19 vs. 8%, p< 0.001 respectively). The date of admission did not influence the incidence of PCP (p=0.950). ICU (24% vs. 24%, p=0.966) and hospital (46% for cases vs. 49%, p=0.687) mortality were similar in both groups. In multivariate analysis cancer progression (OR 7.25 95%CI [1.13-46.45], p=0.034), need for intubation (OR 7.01 95%CI

[1.29-38.54], p=0.022) and respiratory rate (OR 1.17 95%CI [1.05-1.30], p= 0.003) independently predicted ICU mortality of PMBT patients.
CONCLUSIONS. In PMBT patients, the causes of ARF differ significantly from other cancer patients. Up to 30% of the admissions was related to preventable causes (pulmonary embolism, PCP) and a curable cause was identified in the majority of cases. Our results suggest that PMBT alone is not a relevant criterion for ICU recusal.

INTRODUCTION. Spontaneous breathing efforts in acute respiratory distress syndrome patients on mechanical ventilation, has been associated with strong diaphragmatic activity and the generation of excessive strain and high regional pleural pressures in the dependent lung regions [1]. However, these mechanisms may will be present before intubation [2]. We hypothesize that the dependent lung regions are subjected to high levels of strain and subsequent inflammation in patients with acute hypoxemic respiratory failure breathing spontaneously, before intubation.
OBJECTIVES. To determine the effects of spontaneous breathing, during the early stage of acute hypoxemic respiratory failure, on strain and inflammation in lung dependent regions.
METHODS. Prospective observational clinical and physiological study. Patients with acute hypoxemic respiratory failure were included before intubation. An electrical impedance tomography belt was placed and physiological data recorded at baseline and then hourly after intubation for the first 4 hours of mechanical ventilation. A bronchoalveolar lavage was performed immediately after intubation both in dependent and nondependent lung regions.
RESULTS. Five patients were included (age 73 ± 9.9 y.o). After connection to mechanical ventilation, respiratory rate and minute ventilation decreased (36.8 ± 15.1 to 24.4 ±1.51 bpm, p< 0.05; and 21.9 ± 5.2 to 8.7 ± 1.1 L/min, p< 0.05, respectively) and PaO_2/FiO_2 ratio increased from 110.4 ± 44.9 to 252.2 ± 106.8 (p = 0.01). Also, after connecting to mechanical ventilation, ventral to dorsal impedance ratio increased from 0.75 ± 0.25 to 1.27 ± 0.53, p= 0.03 (Fig. 1 and 2). No differences were observed for the other electrical impedance tomography indices (tidal variation of impedance, end-expiratory lung volume and global inhomogeneity index). Regional cytokine quantification showed a tendency to greater inflammation in the dependent lung regions (3850 ± 2802 vs 643 ± 907.9 ng/ml, p= 0.06), before connection to mechanical ventilation, but without statistical significance (Fig. 3).
CONCLUSIONS. Connection to mechanical ventilation changes the distribution of ventilation from dorsal to ventral regions. In the pattern of pre-intubation ventilation, a tendency to greater inflammation can be observed in the dorsal regions of the lung.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0275

INTRODUCTION. The 6-minute walk test (6MWT) is an established surrogate outcome measure in COPD due to its correlation with baseline functional dyspnea for what Modified Medical Research Council (mMRC) scale is commonly used to determine both the stage of the disease and the appropriate medical treatment.

OBJECTIVES. To explore the discriminative properties of the 6MWT in the prediction of changes in mMRC dyspnea grade and the delay to the return to baseline level of dyspnea for COPD survivors after ICU stay

METHODS. A prospective observational cohort study was performed in a Tunisian ICU between February 2017 and January 2018, including all consecutive survivors of AE/COPD. The 6MWT is performed the day of ICU discharge according to the international guidelines. The walked and predicted distances were calculated. Patients' severity of dyspnea is rated on mMRC scale ranging from 0 to 4 recorded at admission and at 3 months of ICU discharge via phone calls. Receiver operating characteristic (ROC) curves and the area under the curve (AUC) with 95% confidence intervals (CI), sensitivity, specificity, predictive values (PV) and likelihood ratios (LR) were used to assess test performance to predict return to baseline level of dyspnea at 3 months after ICU discharge.

RESULTS. Among 90 patients admitted for AECOPD during the study period, 62(69%) were included. General characteristics were: age, 66.4 ±9.5 years; sex ratio, 4,5/1; Charlson index, 3.9±1.8; COPD GOLD D, 55(88%); 34(55%) patients in classes III and IV of mMRC scale. SAPSII score, 29.8±9.9; initial invasive mechanical ventilation, 17 (27.4%); mean length of stay, 13.6±10.1days.

Mean 6-min walked distance, 223±96m; mean walked/predicted (W/P) distance ratio, 0.41±0.17. Three months after discharge, 58(93%) patients could be interviewed via phone, among them 44(77%) patients were in classes III and IV of mMRC scale. Median[IQR] delta mMRC (at 3months-at admission) was 0[0,1].

There was a significant difference in distance walked between those with mMRC class 0, I and II, compared with those classified as III or IV (257m vs 201m; p=0.03).

Return to baseline level of dyspnea prior to ICU stay was shown in 28(48.2%) patients and the mean delay to return was 65±29.2days. 6MWD was significantly correlated with return to level of dyspnea prior to ICU admission (p=0.012). ROC curve of W/P distance ratio and the return to basic functional dyspnea identified interesting AUC (AUC=0.7, 95%CI, [0.56-0.83], p=0.009); the optimal cut-point for the W/P distance ratio was 0.41 with sensitivity 69%[49-84], specificity 72.4%[52.5-86.6]. Positive and negative PV were respectively 71.4%[51.1-86] and 70%[50.4-84.6], positive and negative LR were respectively 2.46 and 0.43.

CONCLUSIONS. In this cohort, walked/predicted Six-Minute Walk Test distance in AE/COPD at ICU discharge seems to demonstrate interesting discriminative properties to predict the return to baseline level of dyspnea for COPD survivors.

CHU Habib Bourguiba Sfax, Intensive Care Unit, Sfax, Tunisia
Correspondence: O. Turki
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0276

INTRODUCTION. Pulmonary embolism (PE) is a well-established complication of ICU stay. Although well documented in the general population, there is little written about PE peculiarities in ICU, where it is more difficult to diagnose and to treat.

THE AIM OF THIS STUDY was to analyze the prevalence, delay of onset, diagnostic features and prognosis of PE among ICU population.

METHODS. This was a prospective cohort including all patients admitted to our ICU between the 01/06/2015 and the 30/06/2016. Patients with positive of PE at any point during ICU stay were included.Patients were classified according to their outcome. Factors associated with poor prognosis were identified using both univariate and multivariate analysis.

RESULTS. During the study period's, 75 patients (10.1 %) with positive diagnosis of PE, were included, among which 40 (53.3%) cases were admitted for post traumatic injuries.The average age was 53 ± 18,1 years and mean SAPS III was 43,4 ± 12,43.All patients had DVT prophylaxis with a mean delay of 24hours after admission.

PE diagnosis was revealed by hypoxemia in 73(97.3%) patients and fever in 31(41.3%).Twenty-two (29.3%) presented with circulatory failure and thirty-four (45.3%) were found to haveechographic signs of right ventricular (RV) dysfunction. Clinical assessment showed that 55 patients (73.3%) had sinus tachycardia and 38 had an increased shock index. Diagnosis was confirmed using CT-scan in 98.7% of the cases. PE was associated to a deep venous thrombosis in 8(23%) cases. Moreover, in this study, PE occurred within the first week in 60% of patients and within 5 days in 46.6% of them.

Although 92% of patients had anticoagulant therapy, there were 4 cases of recurrent PE. Among patients sustaining a PE, overall mortality was 38.6%.

Comparing to the survivors, non-survivors had older age, higher SAPSIII score, lower Glasgow-coma-scale and a higher Shock-index. Howevercirculatory failure and RV dysfunction were found to be the only predictive factors of mortality on multivariate analysis.

CONCLUSIONS. PE is a life-threatening complication of deep venous thrombosis.Based on this single-center data set, it appears to be associated witha high mortality rate among ICU patients. Consequently, prevention is highly warranted. Additionally, further study and understanding of thromboembolism in ICU patients is needed to improve our evaluation, prophylaxis, and treatment of this complication.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0277

INTRODUCTION. Intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS) could be associated to severe AE/COPD. But little is known about its etiopathogenetic mechanisms.

OBJECTIVES. To identify risk factors of IAH in severe AE/COPD in a Tunisian medical ICU.

METHODS. Retrospective observational study conducted in a 9bed Tunisian medical ICU during 3 years from January 2015 to December 2017. Were included all consecutive patients admitted for AE/COPD who were mechanically ventilated (MV). Were compared, underlying conditions, circumstances, onset and natural history of IAH, the presence of deep and sustained episode of hypoxemia, clinical

characteristics at ICU admission, management and outcomes. Univariate and multivariate analyses were performed to identify factors independently associated to IAH. AUC/ROC curves were used to check for the discriminative properties of the significant factors.

As reported by the World Society of the Abdominal Compartment Syndrome (WSACS)(1), IAH was defined by a sustained or repeated pathologic elevation of IAP ≥ 12mmHg.

RESULTS. Among the total of 717 admissions within the 3 years study period, 195(27%) patients presented with AE/COPD, 103(52.8%) patients were mechanically ventilated. 27(26.2%) presented an associated IAH at ICU admission. They were 68[61-77] years aged, 89(86,4%) male. 47(45,6%) had mMRC≥3. Median SAPSI, 32[26-42]. 63(61,2%), severe hypercapnic encephalopthy. Mean pH and PaCO2 were respectively 7,28[7.22-7.34] ; 62[48-82]mmHg. Median length of stay and mortality were respectively 14[6-25]days and 52,4%.

Univariate analysis identified the following to be associated with IAH, BMI≥30, 9(33.3%) vs 6(7.9%), p=0.001 ; diabetes mellitus, 10(37%) vs 7(9.2%), p=0.001 ; episode of deep and prolonged hypoxemia 21(77.8%) vs 19(25%), p=0.000 ; consultation delay, 17(63%) vs 31(40.8%), p=0.045 ; inadequate ventilation 16(59.3%) vs 25(32.9%), p=0.016 ; and severe obstructive ventilator disorder, 20(74.1%) vs 31(40.8%), p=0.003.

Multivariate analysis identified the male sex (OR=51.7, 95%CI, [3.89-688], p=0.003), severe obstructive ventilator disorder (OR=16.2, 95%CI, [2.57-101], p=0.003), severe hypercapnic encephalopathy at the admission (OR=0.12, 95%CI, [0.02-0.69], p=0.018) and an episode of deep prolonged hypoxemia (OR=42.1, 95%CI, [6.68-265], p=0.000) as independent risk factors of IAH in COPD patients.

CONCLUSIONS. The present study identified an at-risk-profile of severe AE/COPD patients presenting with IAH. They are male, presenting with severe hypercapnic encephalopathy associated with the highest resistive mechanics and experienced an episode of prolonged and deep hypoxemia.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0278

INTRODUCTION. Nowadays, only few validated markers are available to evaluate exacerbation of chronic obstructive pulmonary disease (COPD) and to assess the efficacy of treatment. New markers are required to better characterize the entire clinical spectrum of the disease and to guide the development and evaluation of new more effective treatments

OBJECTIVES. 1° / To know the clinical characteristics of COPD patients admitted to ICU and their prognosis. 2° / To evaluate inflammatory markers and determine the optimal cut-off point associated with COPD exacerbation

METHODS. Patients with diagnosis of exacerbated COPD upon admission to Intensive Care Unit (ICU) were included, and different inflammatory markers were analyzed to determine their association with COPD exacerbation. Patients with COPD in stable phase, were obtained from the follow-up one year after discharge.

The differences between stable and exacerbated groups were analyzed using the chi squared test for categorical variables and the Student t test for quantitative variables. Sensitivity, specificity and ROC

curves were calculated, using the diagnosis of exacerbated COPD performed by the intensive care physician upon admission to ICU, as a standard reference.

The optimal cut-off point was the value that minimizes the sum of false positives, maximizes sensitivity, specificity and AUC ROC. Statistical analysis with STATA software 13.0

RESULTS. 55 patients (p) were analyzed, with a mean age of 68.5 years, mean severity APACHE of 26 and mean stay in ICU of 6 days. 48 p (87.5%) required non-invasive mechanical ventilation and 16 p (29.1%) required orotracheal intubation during their admission. The overall mortality was 17.7% and 29% had annual readmission to hospital.

In the comparative study of serum inflammatory markers in acute and stable phase, significant differences were obtained in fibrinogen (510.8 vs 314.5: p < 0.001), C-reactive protein (CRP) (7.8 vs 0.9, p: 0.004), Leukocytes (13.4 vs 9.2, p: 0.012), neutrophils (11.26 vs 6.5, p: 0.007) and lactic (17.5; vs 10.2; p: 0.005). There were no significant differences in eosinophils, platelets and hematocrit.

The comparison of predictability made by analysis with ROC curves of CRP, fibrinogen, leukocyte and lactic variables shows that CRP presents the best prediction of COPD exacerbation (ROC area: 0.85 CI 95%: 0.74-0.95). The moderate elevation of CRP (1 to 10mg / dl) obtained a Sensitivity: 32- 68% and Specificity: 85-100%

CONCLUSIONS. Although the diagnosis of COPD exacerbation is clinical, the CRP value is the inflammatory marker that can help us the most when diagnosing COPD exacerbation. According to published data, being CRP a marker of inflammation in the respiratory tract, these patients should be treated with anti-inflammatory drugs

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0279

INTRODUCTION. Prone positioning is a recommended intervention for refractory hypoxemia in patients with ARDS. Diffuse atelectasis commonly occurs in the lung dependent regions in ventilated patients.

OBJECTIVES. To demonstrate the potential benefit of prone positioning in severe non-ARDS acute respiratory failure.

METHODS. A retrospective case series study of all consecutive patients within a period of 2 years (2016-2017). Were included patients who developed within their ICU stay a severe hypoxemic acute respiratory failure related to diffuse atelectasis without pulmonary edema or inflammation context and received at least one session of prone positioning.

RESULTS. 12 patients were collected within the study period among a total of 486 ICU admissions. Nine patients presented with AE/COPD. Median Charlson index, 5[3-7]; Median SAPSII, 35[31-40]; median P/F ratio, 87[71-97]mmHg ; median Plateau pressure, 23[19-27]cmH2O; median PEEP, 9[5.25-11.5]cmH2O. Median duration of prone positioning, 12.5[8-16]H ; median number of prone positioning sessions 1[1-2]. Post - prone positioning P/F ratio, 312[248-374]mmHg. Favorable ICU outcome was only achieved in 5(42%) patients.

CONCLUSIONS. In this case series of severe hypoxemic acute respiratory failure patients related to dependent lung regions atelectasis, prone positioning may improve oxygenation.

Is the routine use of antipseudomonal antibiotics as empiric treatment of AECOPD in ICU indicated? A retrospective study

F. Marcy, T. Schroeder, C. Storm, J.M. Kruse
Charité - Universitätsmedizin Berlin, Medical Department, Division of Nephrology and Internal Intensive Care Medicine, Berlin, Germany
Correspondence: F. Marcy
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0280

NTRODUCTION. Chronic Obstructive Pulmonary Disease (COPD) is one the most frequent causes of death worldwide.[1] Patients benefit from an empiric antibiotic treatment when admitted to intensive care units (ICU) for acute exacerbations (AECOPD).[2] There is not sufficient evidence justifying the regular empiric treatment with antibiotics against *Pseudomonas aeruginosa*. However, their use seems to have increased over the last decade.[3]

OBJECTIVES. As antibiotic resistance remains a major challenge to modern medicine, proper antibiotic choice is crucial. This is especially important in pathogens with pronounced resistance mechanisms like *P. aeruginosa*. The aim of this study was to question a beneficial outcome in the routine use of antipseudomonal antibiotics in the empiric treatment of AECOPD in ICU.

METHODS. From January 2009 to June 2017, all patients with AECOPD admitted to two medical ICUs of Charité - Universitätsmedizin Berlin from outpatient care were retrospectively analyzed. The antibiotic treatment given within 72 hours of admission was documented considering its activity against *P. aeruginosa*. Samples taken from sputum, bronchoalveolar lavage and blood cultures were analyzed. The influence of SOFA score at admission and time of mechanical ventilation upon survival was investigated by a multivariate analysis.

RESULTS. A total of 437 patients were included in the study. Mean age was 68 years, 46,5% were female. 271 patients (62%) were initially treated with antipseudomonal antibiotics (PAA), 166 (38%) were given antibiotics inactive against *P. aeruginosa* (PIA). Age, sex, comorbidities and median length of stay in ICU did not differ significantly between the groups. The initial median SOFA score was 3 in the PIA group and 5 in the PAA group (p=0,002). Median time of mechanical ventilation was 66 hours in patients with PAA vs. 22 hours in PIA (p=0,003). Positive samples were found in 107 patients (24,5%). *P. aeruginosa* was positive in one patient with PIA (0,6%) vs. 15 patients in the PAA group (5,5%) (p=0,008). There was no significant difference in 30-day ICU mortality (20,4% ± 11,6 in patients with PIA vs. 29,3% ± 10,8 in patients with PAA, p=0,113).

CONCLUSIONS. In this study, antibiotics active against *P. aeruginosa* showed no benefit in the empiric treatment of AECOPD in ICU regarding ICU mortality. However, antibiotic choice should still be guided by an individual risk stratification.

INTRODUCTION. Intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS) in critically ill patients are frequent and are reported to be associated with poor outcomes. Little is known about the association between AE/COPD and IAH.

OBJECTIVES. To compare the prognosis of AE/COPD patients with and without IAH in a Tunisian medical ICU.

METHODS. A retrospective observational study conducted in a 9bed Tunisian medical ICU during 3 years from January 2015 to December 2017. Were included all consecutive patients admitted for AE/COPD who were MV. Were assessed, underlying condition, clinical characteristics and outcomes. Were compared the length of stay (LOS), mechanical ventilation duration, ventilator free days and a composite outcome (LOS>14days and/or death).

As reported by the World Society of the Abdominal Compartment Syndrome (WSACS)(1), IAH was defined by a sustained or repeated pathologic elevation of IAP $\geq$ 12 mmHg.

RESULTS. Among the total of 717 admissions within the 3 years study period, 195(27%) patients presented with AE/COPD, 103(52.8%) patients were mechanically ventilated. 27(26.2%) presented an associated IAH at ICU admission. They were 68[61-77] years aged ; COPD GOLD D, 97(94.2%) ; mMRC dyspnea scale$\geq$3, 47(45.6%) ; long term oxygen therapy, 22(21.4%) and home NIV use, 13(12.6). Median SAP-SII was 32[26-42]. 63(61.2%) presented with a severe hypercapnic encephalopathy. Mean pH and PaCO2 were respectively 7,28[7.22-7.34] and 62[48-82]mmHg. 17(62.9%) patients presented with severe obstructive ventilatory disorder with high airway pressures (mean peak pressure, autoPEEP respectively 36.5[30-42.75] and 7[4-10]cmH2O).

Univariate analysis identified the following respectively for IAH+ and IHA : LOS, 20.78±17.03 days vs 16.93±13.94 days, p=0.198 ; MV duration, 18.63±16.92 vs 14.34±13.95 days, p=0.198 ; ventilator free days, 6(22.2%) vs 25(32.9%), p=0.299 ; composite outcome, 23(85.2%) vs 61(80.3%), p=0.571 and mortality, 14(51.9%) vs 40(52.6%), p=0.944.

CONCLUSIONS. In the present study with a small sample and highly selected severe AE/COPD patients, the association with IAH did not alter any of these studied outcomes.

INTRODUCTION. Intra-abdominal hypertension (IAH) is frequent in critically ill-patient. It is classified into primary (related to intra-abdominal disease or injury) and secondary IAH. Therefore, it is important to understand different therapeutics and their efficiencies.

OBJECTIVES. To describe our experience in the management of AE/COPD patients who presented with a secondary IAH.

METHODS. A retrospective observational study conducted in a 9bed Tunisian medical ICU during 3 years from January 2015 to December 2017. Were included all consecutive patients admitted for AE/COPD associated with IAH. Were assessed, frequency of IAH, patient´s characteristics, underlying condition, circumstances, natural history, clinical characteristics at ICU admission, management and outcomes. As reported by the World Society of the Abdominal Compartment Syndrome (WSACS), IAH was defined by a sustained or repeated

pathologic elevation of IAP ≥ 12 mmHg. The abdominal compartment syndrome (ACS) was defined as a sustained IAP≥20 mmHg (with or without an abdominal perfusion pressure < 60 mmHg) that is associated with new organ dysfunction/failure.

RESULTS. Among the 717 patients admitted within the 3 years study period, 195(27%) presented with AE/COPD. Thirty-Two patients (16.4%) were diagnosed with IAH. They were 68.5[58.5-75.75]years aged ; COPD GOLD D, 30(93.8%). SPASII, 33[28-43.5]. 14(43.8%), severe hypercapnic encephalopathy. Median pH and PaCO2 were respectively 7.32[7.22-7.35] and 56[42-79]mmHg. 17(62.9%) presented with severe obstructive ventilatory disorder with high airway pressures (median peak pressure, autoPEEP and plateau respectively 40[35.5-47], 9.5[7-10.75] and 22[20-26]cmH2O).

First line noninvasive ventilation (NIV) was used in 19(59.4%) with NIV failure in 14(73.7%) within a median delay of 24[5.5-48] hours. Overall mechanical ventilation use was 27(84.3%) with VFD in 6 (22.2%). Median length of stay was 11.5[5-28.5] days. Overall mortality rate was 43.8%. In all patients IAH was present at admission. Median intra-abdominal pressure was 23.5[20.5-28.7]. 19(59.4%) patients had evolved to ACS.

Management in all patients with IAH was when appropriate: sedation cessation, mobilization, weaning of vasopressors, hydration with avoiding excessive fluid resuscitation, feeding, reduction of patient ventilator asynchrony and electrolyte disorders correction mainly hypokalemia and hypomagnesemia (n=5). All these interventions were systematic. When insufficient, other procedures were performed : nasogastric and rectal decompression (n=27), purgative drugs (n=5), lactulose (n=22), prostigmin (n=5), erythromycin as prokinetic, evacuation enema (n=16) and coloexsufflation (n=2). No surgical procedure was performed.

CONCLUSIONS. In the present study, the management of IAH in severe AE/COPD patients was stuttering. Yet, it went along with latest recommendations of WSACS.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0283

OBJECTIVES. The aim of this study is to investigate the factors affecting cost in patients with severe community-acquired pneumonia (CAP) who admitted to the intensive care unit.

METHODS. This retrospective cohort study was conducted at Süreyyapaşa Göğüs Hastalıkları Eğitim Araştırma Hospital, Dokuz Eylül University Hospital, Ankara University Hospital, Akdeniz University Hospital intensive care unit between January 2013 - December 2016. A total of 291 patients with severe CAP were included in the study. Demographic and clinical data were obtained from medical records of all cases.

RESULTS. Of 291 patients, mean age was 68.4 ± 16.8yrs, 61% were female. Median length of intensive care unit stay was 7 days (1st - 3rd percentiles: 4-11 days). Forty-six percent of patient had chronic obstructive pulmonary disease (COPD). Hypertension is the second comorbidity of the patients (42%). Mean cost was found as 2722 $ (5578 TL). The highest cost was found in the group of patients aged 50-59, lowest cost was found in the < 50 aged patients. Statistically significant relationship was found between PSI, APACHE II, CURB-65 scores and health cost (p=0.001, p=0.001, p=0.009 respectively). The cost of patients in PSI class V, APACHE II (>20 points) and CURB-65 score ≥3 points were higher. The presence of concomitant COPD (p=0.009), atrial fibrillation (p=0.046), congestive heart failure (p< 0.042), hypoalbuminemia (p=0.001), mental status disorder (p=0.013), in-hospital mortality (p=0.014), severe sepsis (p< 0.001),

septic shock (p< 0.001), mechanical ventilation requirement (p< 0.001), use of haloperidol (p< 0.001) and vasopressor (p< 0.001) were associated with higher cost; while use of florokinolon (p=0.033) was associated with lower cost.

CONCLUSIONS. IMV and NIMV requirement, presence of sepsis, atrial fibrillation, COPD, congestive heart failure were associated with increased cost in patients with severe CAP. Hypoalbuminemia and impaired mental status were also associated with higher cost. Patients with high mortality rates were are also associated with higher cost.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0284

INTRODUCTION. Intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS) are increasingly recognized in the critically-ill and may seriously impede the respiratory mechanics. Various clinical conditions are associated with this syndrome and include mainly surgical ones. We were recently challenged by a growing frequency of IAH in the setting of severe AE/COPD patients.

OBJECTIVES. To determine the frequency of IAH in AE/COPD patients during ICU stay and to establish a clinical and prognostic profile.

METHODS. Retrospective observational study conducted in a 9bed Tunisian medical ICU during 3 years from January 2015 to December 2017. Were included all consecutive patients admitted for AE/COPD. Were assessed, frequency of IAH, patient´s characteristics, underlying condition, circumstances, natural history, clinical characteristics at ICU admission, management and outcomes.

As reported by the World Society of the Abdominal Compartment Syndrome (WSACS)(1), IAH was defined by a sustained or repeated pathologic elevation of IAP ≥ 12 mmHg. ACS was defined as a

sustained IAP≥20 mmHg (with or without an abdominal perfusion pressure < 60 mmHg) that is associated with new organ dysfunction/failure.

RESULTS. Among the 717 patients admitted within the 3 years study period, 195(27%) presented with AE/COPD. 32 (16.4%) patients were diagnosed with IAH. They were 68.5[58.5-75.75] years aged ; COPD GOLD D, 30(93.8%) ; mMRC dyspnea scale≥3, 12(37.5%) ; long term oxygen therapy, 7(21.9%) ; home NIV use, 4(12.5%) and median SPA-SII, 33[28-43.5]. Tracheobronchitis, 17(53.1%) ; left heart failure 6(18.8%) and pneumonia 14(12.5%) were among the most common triggering factors. 14(43.8%) presented with a severe hypercapnic encephalopathy. Median pH and PaCO2 were respectively 7.32[7.22-7.35] and 56[42-79] mmHg. 17(62.9%) presented with severe obstructive ventilator disorder with high airway pressures (median peak pressure and autoPEEP respectively 40[35.5-47] and 9.5[7-10.75] cmH2O). Firstline noninvasive ventilation (NIV) was used in 19(59.4%) patients with NIV failure in 14(73.7%) within a median delay of 24[5.5-48] hours. Overall mechanical ventilation use was 27(84.3%). Median length of stay was 11.5[5-28.5] days. In all patients, IAH was present on admission. Median intra-abdominal pressure was 23.5[20.5-28.7]. Median abdominal distension duration was 12.2 ±9.8days. 15(62.5%) patients had difficulty of weaning requiring tracheostomy in 28.1%. 19(59.4%) patients evolved to ACS. Only purgative drugs were used and no surgery was performed. Overall mortality rate was 43.8%.

CONCLUSIONS. IAH and ACS seem to be common in this selected setting of severe AE/COPD. It is associated to therapeutic challenges and poor outcomes.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0285

INTRODUCTION. Severe Acute respiratory infections occurring seasonally are a major health problem. Surveillance protocols aim to detect pandemics and any new viruses' species responsible for SARI cases. Intensive care unit of Farhat Hached university hospital is one of six Tunisian centres involved in national and international SARI surveillance program.

AIM. To assess frequency and microbiology, severity and outcome in patients admitted for SARI in Farhat Hached ICU.

METHODS. This is a retrospective study, including all patients admitted in ICU for SARI, over two seasons, going from September 2016 to May 2017 and from September 2017 to March 2018. SARI was defined according to the World Health Organisation (WHO) Global Epidemiological Surveillance Standards for Influenza 2014 [1], where patient report a fever or an objective measurement of temperature ≥ 38℃, associated to a cough, appearing ten days prior to consultation and requiring hospitalization.

RESULTS. Among 344 admissions, 77(22.4%) patients met SARI definition and were included in the study. They were 56±19 years old mean aged, 40(59%) AECOPD. Symptoms' onset was at a median delay of 4[1-7] days prior to consultation. ICU hospitalization occurred at a median of 4[1-5] days from first

medical contact. On admission, SAPS II, 30±12; Acute Respiratory Distress Syndrome, 21(27,3%); invasive mechanical ventilation, 36(46.8%); vasopressors, 21(27.3%). Nasal swabs for viral polymerase chain reaction (PCR) were performed for 25(32,5%), 6(24%) were positive, AH1N1 (n=5), and Coronavirus OC43 (n=1). A bacterial pathogen was isolated in 3 patients *(Pseudomonas aeruginosa, Acinetobacter baumannii and staphylococcus aureus)* among 27(35,1%) sampled patients. 36(46,8%) patients did not have PCR or any other microbiology sampling. Mortality was estimated at 45,5%.

CONCLUSION. SARI patients were relatively frequent. PCR sampling for viral identification was performed in only one-third of cases. It can be considered insufficient in terms of surveillance system performance to identify viral species involved in SARI.

The effect of the ventilator care bundle on ventilator acquired pneumonia, length of stay and mortality rate: a systematic review and meta-analysis

L. Dolman
Imperial College Healthcare Trust, London, United Kingdom
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0286

BACKGROUND. Ventilator associated pneumonia (VAP), has the highest incidence rate of all healthcare-associated infections within critical care (Vincent et al 2006). VAP can increase mortality rate by 30% (Kollef et al 2006). The ventilator care bundle aims to reduce a patient's risk of these by grouping five elements of best practice: elevation of head of the bed, daily sedation interruption and daily assessment for readiness to extubate, peptic ulcer, deep vein thrombosis and gastrointestinal bleed prophylaxis. Previous reviews have been performed in this area looking at the effect of the ventilator care bundle on VAP rates, however these were unable to conclude a causal relationship due to the poor methodological quality of previous research and high risk of bias. New evidence has since to come to light that have hitherto not been systematically reviewed.

AIM. To investigate the effect of the ventilator care bundle on VAP rate, mortality rate and length of ICU stay, through a systematic review and meta-analysis.

METHODS. Following the Cochrane Handbook for systematic reviews, a comprehensive search of CINAHL, EMBASE and Medline was performed from 2004 - January 2017. The review included all study designs comparing the ventilator care bundle to a control group (no ventilator care bundle) in mechanically ventilated patients. Data was extracted and risk of bias evaluated independently by a single reviewer. The meta-analysis was performed using Review Manager (RevMan 5.3) following a random-effects model.

RESULTS. A total of fourteen studies were included within this review. The analysis showed that the ventilator care bundle decreases the risk of VAP by 55% (RR=0.45, 95% CI=0.33-0.61, p < 0.00001). The ventilator care bundle showed to decrease mortality rate (RR 0.80, 95% CI=081-0.9, p= 0.007) and also a decrease on length of stay (MD=-2.67 days, 95% CI = -5.88-0.55, p = < 0.00001).

CONCLUSIONS. Based on a very low quality body of evidence, this study revealed statistically and clinically significant reductions in VAP rate, mortality and length of stay resulting from the adoption of the ventilator care bundle. The low quality nature of the evidence do not allow for causal conclusions to be confidently drawn. Further methodologically robust research needs to be conducted. In the meantime, and in the absence of any adverse effects, the ventilator care bundle should continue to be supported in practice.

Influence of hypophosphatemia at ICU admission on the duration of mechanical ventilation in sepsis

J. Shima, S. Katayama, K. Koyama, K. Tonai, Y. Goto, T. Koinuma, S. Nunomiya Jichi Medical University School of Medicine, Division of Intensive Care, Department of Anesthesiology and Intensive Care Medicine, Shimotsuke, Japan
Correspondence: J. Shima
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0287

INTRODUCTION. Hypophosphatemia occurs in 30% of intensive care unit (ICU) patients and up to 70% in septic patients. Hypophosphatemia induces muscle weakness, arrhythmia, decreased myocardial contractility, acute respiratory failure, impairment of diaphragmatic contractility and death at worst. It is also reported that hypophosphatemia prolonged liberation from mechanical ventilation (MV) in ICU patients, but its influence in septic patients is not clear.

OBJECTIVES. The objective of this study was to evaluate the association between hypophosphatemia and duration of MV in patients with sepsis.

METHODS. A single-center, retrospective observational study was performed. Consecutive septic patients, diagnosed with Sepsis-3 criteria under MV admitted to a general ICU from June 2011 to December 2017, were included. Exclusion criteria were patients who received hemodialysis, with deep neck infection and who died within twenty-four hours from ICU admission. Included patients were allocated to two groups: hypophosphatemia group who had hypophosphatemia at ICU admission, defined as serum phosphorus concentrations < 2.0mg/dL, and non-hypophosphatemia group. Demographic data, infection sites, comorbidities, use of steroids, APACHE II score and SOFA score, hospital mortality, lengths of ICU stay and duration of MV were collected and analyzed from patients' records. The primary outcome was duration of MV (defined as the number of days from ICU admission to liberation from MV or discharge from ICU, whichever came first) and analyzed using the t-test. Time to liberation from MV was compared using log-rank tests and presented as Kaplan-Meier curves. To evaluate the relationship between duration of MV and hypophosphatemia, a multivariable logistic regression model was performed.

RESULTS. Five-hundred and sixty-six patients were included and 40 patients (7.5%) had hypophosphatemia at ICU admission. Hypophosphatemia group had longer duration of MV (median [IQR], 10 [7-17] vs. 7 [5-11] days; *P*=0.003). Lengths of ICU stay was also longer in the hypophosphatemia group. The severity of illness was not statistically different between two groups. Time to liberation from MV was compared and shown by Kaplan-Meier curves (Figure). Hypophosphatemia was one of the independent factors of prolonged duration of MV in the multivariable logistic regression model (Table).

CONCLUSIONS. This study revealed that hypophosphatemia at ICU admission in septic patients was one of the independent risk factors of prolonged duration of MV.

INTRODUCTION. To study the delay between hospital and ICU admission and the initiation of invasive ventilatory support and its association with patients outcomes.

OBJECTIVES. We performed a retrospective analysis of a prospective database of those patients admitted to our polivalent ICU in last 7 years and that required mechanical ventilation during their stay. We excluded patients admitted due to planned surgery. For statistical analysis we used Chi-square, T-Sudent or Fisher tests as appropriate.

METHODS. We performed a retrospective analysis of a prospective database of those patients admitted to our polivalent ICU in last 7 years and that required mechanical ventilation during their stay. We excluded patients admitted due to planned surgery. For statistical analysis we used Chi-square, T-Sudent or Fisher tests as appropriate.

RESULTS. During the study period, 1312 patients received invasive mechanical ventilation due to unplanned reason. Mean age was 61.9 (CI 95% 61-62.8), APACHE II 22.5 (22.1-22.9), SAPS II 51.6 (50-52.9), Glasgow at admission 10.8 (10.5-11.1). 54.3 % of patients were admitted from community and 75.3 % were medical. 43.1 % had some kind of comorbidity (20.9% diabetes, 9.5% inmunodepression, 9% malignancy, 7.9% COPD, 7.5% chronic kidney disease, 3% hepatopathy)

Mean duration of mechanical ventilation was 8.2 days (7.4-8.9) 8.4 % of patients had been under non-invasive ventilation (NIV) before intubation. In 14.9 % of patients, tracheostomy was performed and 8.3 % required subsequent intubation.

Mean length of ICU stay was 11.9 days (11-12.7) and hospital 22.3 days (20.9-23.6) 385 patients (29.3 %) died in ICU and 481 (36.7%) in hospital.

ICU non-survivors were significantrly older, had higher severity scores and had higher incidence of inmunodeppression, kidney disease and hepatopathy. Medical condition (31.6 vs 22.5 %, p 0.003) and admission from hospital (32.1 vs 27.1 %, p 0.048)showed higher mortality (31.6 vs 22.5 %, p 0.003)

No association was observed between duration of mechanical ventilation, subsequent intubation or tracheostomy and mortality. Non-survivors showed longer time from ICU admission to intubation (0.8

vs 0.45 days, p 0.003, and use of NIV before intubation was associated to higher mortality (41.2 vs 26 %, p < 0.001) Reintubation, tracheostomy, prior NIV and any kind of delay to intubation resulted in significant longer ICU and hospital stay.

CONCLUSIONS. In a general ICU population of mechanically ventilated patients, delay to intubation and prior use of NIV involved worse outcomes. The unselected nature of the sample may limit our conclusions.

CRRT & RRT for AKI

Acute kidney injury and renal replacement therapy in patients on ECMO: a single center experience

R. Avila, N. Carrizo, A. Fernandez, M.M. Filippi, C. Zuchela, H. Alassia, R. Schmuck, M. Peralta, H. Molina, M. Irazusta
Hospital Cullen, Santa Fe, Argentina
Correspondence: R. Avila

INTRODUCTION. Extracorporeal life support (ECMO) has proven to be effective in pulmonary and cardiovascular failure when standard therapies have failed. The incidence of AKI in this population is very high and the initiation of renal replacement therapy (RRT) is a critical situation. According to the literature, these patients have a high mortality rate despite the extracorporeal support offered.

OBJECTIVES. To evaluate the incidence and outcomes of ECMO patients who developed AKI and required RRT in our center.

METHODS. Our internal database was tapped into looking for patients who underwent ECMO at Jose Maria Cullen Hospital, a tertiary-level referral public health center, from June 2015 to March 2018. Statistical analysis was performed with STATA 14.

RESULTS. Over a 2-year period, 20 ECMO therapies were performed (18 ECMO V-V and 2 ECMO V-A), mean age was 23 years, and most patients were males (80%). The survival rate was 45% (50% ECMO V-A y 44% ECMO V-V). Of the 20 patients analyzed, 10 (50%) developed some AKI stage; one presented renal failure and the need for RRT 48 hours before the start of ECMO, while the remaining 9 developed AKI on 5-day average of ECMO run. (3 AKI patients in stage 1 and 6 AKI patients in stage 3). Seven patients required RRT (4 independent vascular access and 3 connected to the ECMO circuit). The most frequent indication was oligo-anuria (100%), followed by fluid overload (57%), metabolic acidosis (28%) and rhabdomyolysis (14%). The most frequent RRT modality was CVVH (5 patients 71%), followed by SLED 3 patients (42%) and SCUF 1 patient (14%). The average negative daily balance was: CVVH 660 ml/day, SLEED: 653 ml/day, and SCUF: 3200 ml/day. Survival of patients in ECMO who did not develop AKI was 50%, but for those who presented some degree of AKI 30% and much lower (15%) in those who needed RRT.

CONCLUSIONS. In our study, the incidence of AKI was high (50%) with a significant reduction in survival rate compared to those patients who did not develop AKI (30% vs. 50%). The implementation of some RRT did not improve the results of those with more severe renal failure. CVVH was the most frequent modality of RRT.

Urinary liver-type fatty acid-binding protein point-of-care kit for the prediction of renal replacement therapy requirement in critically ill patients with acute circulatory failure

K. Ishimura, A. Tsuruoka, R. Hiroshi
Osaka City General Hospital, Emergency and Critical Care Medical Center, Osaka, Japan
Correspondence: K. Ishimura

INTRODUCTION. Acute kidney injury (AKI) requiring renal replacement therapy (RRT) is common in critically ill patients with acute circulatory failure. RRT requirement is difficult to predict. Some AKI biomarkers can predict RRT requirement. However, they are associated with problems with respect to convenience and quickness of use. Recently, the liver-type fatty acid-binding protein point-of-care kit (L-FABP POC Kit, CMIC Holdings Co., Ltd., Tokyo, Japan), which can rapidly measure urinary L-FABP, was developed.

OBJECTIVE. The purpose of this study was to evaluate the usefulness of the L-FABP POC kit.

METHODS. This was an observational retrospective study that included patients admitted in our intensive care unit who required any vasoactive agents between December 2017 and February 2018. Urinary L-FABP level was measured using the L-FABP POC kit adopting the immunochromatography technique. Urine was added to the kit, and the L-FABP concentration in the urine sample was visually measured in 15 minutes. The results were classified as negative (< 12.5 ng/ml), 1+ (≥12.5 and < 100 ng/ml), or 2+ (≥100 ng/ml).

RESULTS. Thirty-five patients were included in our study (males: 66%; median age: 71 years). The median sequential organ failure assessment and acute physiology and chronic health evaluation II scores were 8 and 22, respectively. All intensive care unit admissions were emergencies. The main reasons of admission were sepsis in 19 patients (54%), acute respiratory failure in 7 patients (20%), and other in 9 patients (26%). The median lactate level was 1.9 mmol/l. Noradrenaline or dopamine, adrenaline, and vasopressin were used in 31 (89%), 5 (14%), 5 (14%), and 4 (11%) patients, respectively. Dobutamine and milrinone were used in 10 (29%)and 2 (6%) patients, respectively. Fourteen patients required RRT (40%), and the 28-day mortality was 26% (9 patients). In this study, the patients were divided into two groups according to the results of the L-FABP POC kit measurements. In the L-FABP POC-positive (1+ or 2+) group, renal replacement therapy was more frequently required than in the L-FABP POC-negative group (54.5% vs 15.4%, p = 0.034). The RRT duration was 3 days in the L-FABP POC-positive group and 5 days in the L-FABP POC-negative group (p = 0.19). The sensitivity and specificity of the L-FABP POC kit to predict RRT requirement were 85% and 52%, respectively.

CONCLUSIONS. This retrospective study shows that positive results from the L-FABP POC kit are associated with RRT requirement. The L-FABP POC kit may serve as a novel tool to predict RRT requirement.

Urinary L-FABP level predicts initiation of renal replacement therapy and prognosis in patients with septic shock

A. Tsuruoka[1,2], Y. Inoue[1], A. Kawamoto[1], H. Rinka[2]
[1]Kyoto Min-iren Chuo Hospital, Kidney and Cardiovascular Center, Kyoto, Japan; [2]Osaka City General Hospital, Emergency and Critical Care Medical Center, Osaka, Japan
Correspondence: A. Tsuruoka

INTRODUCTION. Acute kidney injury (AKI) in sepsis patients is associated with high morbidity and mortality. Despite improvements in intensive care medicine and renal replacement therapy (RRT), patients with AKI have much higher morbidity and mortality rates than patients without AKI. In recent years, novel AKI biomarkers, such as NGAL, KIM-1, IL-18, L-FABP, IGFBP7, TIMP2 have been discovered and validated to improve early detection for progressive renal failure, need for RRT, or death.

OBJECTIVES. This study was to evaluate whether urinary L-FABP at intensive care unit admission can predict initiation of RRT and mortality in septic shock patients.

METHODS. This was a single-center retrospective observational study of patients with septic shock admitted in our intensive care unit from December 2015 to December 2016. A total of 26 patients with septic shock were screened and 21 patients were included, 5 patients with maintenance dialysis and anuria were excluded. We examined the relation of urinary L-FABP level at ICU admission and initiation of RRT, 28-day mortality and 90-day mortality.

RESULTS. A total of 21 patients were included. Median age was 82 years (IQR 70-84) and 8 (38%) were male. 6 patients (28.6%) had chronic kidney disease and 15 patients (71.4%) acquired AKI based on KDIGO criteria. Median urinary L-FABP(ng/ml) level was 31.51⬚ (IQR 13.9-125.8). SOFA score and APACHE2 score were 9 and 21(median), respectively. 18 patients (85.7%) had received mechanical ventilation and 6 patients (28.6%) had received RRT. 28-day and 90-day mortality was 28.6% and 38.1%, respectively. The sensitivity and specificity of urinary L-FABP level for predicting initiation of RRT were 73.3 and 66.7% (area under the ROC curve 0.711, 95% CI: 0.447-0.975) at 54.0 ng/ml. The patients were divided into 2 groups according to the urinary L-FABP(ng/ml) quartiles (Q1, Q2, and Q3 = low group [L] vs. Q4 = high group [H]).Kaplan-Meier curves showed 28-day and 90-day mortality were significantly higher in the H group than in the L group (p = 0.014 and 0.000675, respectively).

CONCLUSIONS. Urinary L-FABP level is an effective biomarker for predicting initiation of RRT and mortality in septic shock patients.

Predictors of 90 day survival in CRRT patients
J.Y. Koh[1], H.K. Chua[1], C.H. Loh[2]
[1]Singhealth, Internal Medicine, Singapore, Singapore; [2]Changi General Hospital, Respiratory and Critical Care Medicine, Singapore, Singapore
Correspondence: C.H. Loh
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0292

INTRODUCTION. Survival rates for patients requiring CRRT are generally around 40-50%. The ATN study demonstrated 60 day all-cause mortality around 50%, while 90 day mortality in the RENAL study was 44%.

OBJECTIVES. To study the outcomes of our cohort of patients in our institution requiring CRRT and determine factors contributing to 90 day mortality in our MICU.

METHODS. We performed a retrospective chart review of patients requiring CRRT in our institution over 3 months between 1 April 2017 to 30 Jun 2017. This observational retrospective audit was part of the multicentre study by SICM-NICER and is approved by the NHG DSRB Ethics Review Board. Variables such as age, gender, comorbidities, ICU diagnosis, inotrope score, APACHE II score, fluid balance 24 hours prior to CRRT and D1-5 of ICU admission, modality of CRRT, dialysis dose were recorded. Univariate analyses and binary logistic regression with these variables were performed to determine factors contributing to 90 day survival.

RESULTS. 71 patients were included in this study. The mean age was 70.6 +/- 11.8. 63.4% of patients had preexisting CKD, of whom 60% had CKD stage 3-4. Mean inotrope score 2.5 and APACHE score was

27.2. Mean ICU days 3.8 +/- 4.1. Majority of patients were admitted to ICU for sepsis (44%), 16% for cardiovascular events, 13% for fluid overload.

CVVHDF was prescribed 96.4% of the time. Mean prescribed dose was 30.4 +/- 3.0 ml/kg/h. Citrate anticoagulation was used in 86.8%, followed by nil (9%) and heparin (3.8%). 70.6% patients survived upon ICU discharge while 90 day survival was 60%. 38% of survivors continued to require RRT on discharge. Among the survivors who did not have preexisting CKD, 50% who required RRT in ICU developed CKD at 90 days.

CRRT was stopped due to resolution of AKI (30.8%), death (27.7%), but renal replacement continued in 27% due to ESRF.

Cardiogenic shock was associated with lowest survival at 90 days at 30%, compared to 60.6% for sepsis. In a univariate analysis, survivors had significantly lower APACHE II scores (mean 23.9 +/- 6.8) compared to non survivors (33.4 +/- 10.1, p=0.009). They were also younger (68.4 +/- 12.3 compared to 73.0 +/- 11.5 in non survivors), had more negative fluid balance (-275ml versus 1424ml in non survivors), higher prescribed dose (31.1 +/- 3.2 compared to 30.0 +/- 2.6), but these were not clinically significant (p>0.05).

90 day survival was not significantly associated with age, APACHE or inotrope score, ICU fluid balance, prescribed dialysis dose in our regression model.

CONCLUSIONS. 90 day mortality for patients requiring CRRT was high at 40% and comparable to prior studies. APACHE II score was significantly associated with 90 day survival in a univariate analysis, but no significant factors were associated with 90 day survival in our regression model.

Comparison of hemodynamic parameters among continuous, intermittent and hybrid renal replacement therapy in acute kidney injury: a systematic review of randomized clinical trials
D. Russo[1], S. Vieira Rios[2], R. Rosa Goulart[3], A. Stein[3], I. George Balestrin[3], D. Barbosa da Silva[3]

Correspondence: D. Russo
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0293

PURPOSE. The use of renal replacement therapy (RRT) in acute kidney injury (AKI) patients in the intensive care unit (ICU) is associated with high hemodynamic instability leading to an in hospital mortality of about 50%. The aim of this study was to compare hemodynamic parameters among continuous, intermittent and hybrid renal replacement therapy in acute kidney injury.

METHODS. Systematic review conducted in accordance with the PRISMA and registered at the PROSPERO Database. Randomized clinical trials involving patients with AKI in the ICU submitted to continuous, intermittent or hybrid RRT will be included. We will investigate the electronic databases: PubMed, Embase and Cochrane. Two reviewers will independently carry out study selection, evaluation of methodological quality and data extraction.

RESULTS. Most of the studies did not find differences in hemodynamic parameters across different RTT modalities, except a CVVH group heart rate decrease after 1 and 4 hours in comparison with IHD group, an increase in systolic blood pressure after 0.5 and 2h of CVVH in contrast with IHD, and doses significant higher of Dobutamine in patients from the CVVHDF group, when compared to IHD. Lower baseline MAP, greater MAP variation on dialysis, higher number of pressors at baseline, and increase in pressor dose during dialysis were associated with shorter survival time; and greater MAP variation on dialysis negatively was correlated to renal recovery.

CONCLUSIONS. We believe that this study can provide important insights for further clinical trials designed specifically to evaluate hemodynamic parameters across different types of RRT.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0294

INTRODUCTION. A reduction of antibiotic dosage is recommended in patients with acute kidney injury (AKI) who are undergoing continuous renal replacement therapy (CRRT). However, CRRT may impact on the antimicrobials pharmacokinetic/pharmacodynamic (PK/PD) causing both the antibiotic underdosing and the consequent likely therapeutic failure and microorganism resistance (1).
OBJECTIVES. Prospective observational study to verify CRRT removal of more frequently used antimicrobial agents and their PK/PD parameter changes in the critically ill patients experiencing AKI.
METHODS. Since January 2017, we recruited all the patients admitted to our ICU experiencing anuric AKI and the consequent needing of CRRT. On all patients demographics, clinical data and ICU parameters were collected. Rifle and AKIN criteria were used to define renal failure levels. Samples of each patient's blood and ultrafiltrate were taken (trough and peak levels) at 48 hrs. from the CRRT commencing to investigate PK/PD of mainly used antibiotics [vancomycin, linezolid, piperacillin/tazobactam, ciprofloxacin, levofloxacin and meropenem; (no cephalosporin TDM is determined in our hospital)]. Posology of the single antibiotic was standard as suggested by Sanford Antimicrobial Guide for patients with severe AKI. CRRT was based on only convective (standard effluent total dose of 25 ml/kg and M150 haemofilter) technique, using Prismaflex® SW 5.XX system set with anticoagulant citrate protocol.
RESULTS. Over the study period a total of 21 patients (M:F=3:1) has been recruited. We recorded respectively a median (IQR):

(i)   age 64 yrs. (54-68);
(ii) 1st 24 hrs. SAPS II: 49 (38-52) and SOFA at the admission: 10 (7-11); Rifle: 3 (2.5-3) and AKIN: 2.8 (2.25-3), indicating severe AKI; length of CRRT: 5 (4-7), ICU-los 14 (10-18) and hospital-los 30 (22-34); albumin plasmatic levels: 22.5 (21.5-25.5).

The percentage of patient in septic shock was about 65% and the recorded hospital mortality was 33.3%. The ultrafiltrate/plasma concentration mean (SD) ratios were respectively: ciprofloxacin: 0.89 (0.11); vancomycin: 1.1 (0.33); meropenem: 0.89 (0.02); piperacillin/tazobactam: 0.79 (0.05); linezolid: 0.75 (0.1). The mean (SD) antibiotic clearances of CRRT (ml/min) were respectively: ciprofloxacin: 25.5 (6.4); vancomycin: 33.5 (13.1); meropenem: 20.1 (3.1) ; piperacillin/tazobactam: 22.3 (4.9); linezolid: 20,4 (0.39). Drugs were significantly cleared during CVVHF, with a sieving coefficient >0,8 for every antibiotics.
CONCLUSIONS. The high-flux membranes used in CRRT seems to make no filtration barrier to all studied antibiotics. Further progression of the study is warranted.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0295

INTRODUCTION. Acute Kidney Injury (AKI) affects up to 60% of patients admitted to the intensive care unit (ICU), with continuous renal replacement therapy (CRRT) as one of the most common modalities. In the last decade regional anticoagulation with citrate (RAC) has gained its space as an anticoagulant for the extracorporeal circuit.
OBJECTIVES. The main aim of this study was to evaluate different levels of citrate concentration on a nurse driven protocol. Although PrismaFlex has an institutional protocol that advises a 3.0 mmol/L concentration of citrate, the authors design a prospective multicenter observational study in which lower concentrations of citrate were administered, not only reducing the odds of citrate accumulation but also allowing to understand what was the lowest level that could be achieved, without increasing the circuit coagulation.
METHODS. Citrate concentration was reduced, every 6-8 months, in 0.2 mmol/L. Several data were collected in order to evaluate the impact of different citrate doses in filter patency, citrate accumulation, duration of dialysis, outcomes and technical complications, for which patients were divided in citrate classes and compared either by the ANOVA One-way or by Kruskall-Wallis test. The study was approved by hospital's ethical committee.
RESULTS. Between 1 April 2016 and 31 December 2017, 58 patients required CRRT with citrate (325 days total) with 93 periods of continuous dialysis. The 2.6 mmol/L citrate group had a lower number of randomized patients (17 patients) compared with the 2.8 mmol/L and the 3.0 mmol/L group (respectively 39 and 41 patients). There was a predominance of men (70.7 vs 29.3%), mean APACHE of 27,2 ±7,8, with a mortality of 55.2%. Mean duration of filter circuit lifespans was 3±2,0 days, mean duration of CRRT of 5,8 days and mean length of stay in the ICU of 14±21,1 days.
There was a statistical significant association between the prescribed and the administered citrate concentration (p< 0,001).
There were no differences between the 3 groups concerning percentage of coagulated filters and filter lifespan, although there was a trend to higher total-to-ionized calcium in the 3.0 mmol/L group. Mean postfilter calcium (0,42±0,05), calcium compensation (95,9±17,1%) and ionized calcium (1,15±0,6) was similar in all groups. The depuration was also similar in all groups, as well as the electrolytes and acid-base balance. There were no significant differences concerning length of stay in ICU, renal replacement therapy time or mortality.
CONCLUSIONS. Our study showed that a citrate-RRT nurse driven protocol is safe with low levels of complications, extends circuit lifespans and limits the development of citrate accumulation.
The authors showed that a lower citrate concentration has a trend to lower citrate acumulation, without any significant impact on filter lifespan or coagulation.

Renal replacement therapy under extracorporeal membrane oxygenation

N. Tsekouras, J.B. Bouchet, J. Morel
CHU Saint Etienne, Saint Etienne, France
Correspondence: N. Tsekouras
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0296

Different methods are described to perform renal replacement therapy(RRT) on patients under ECMO with even the possibility of connecting directly the RRT machine on the ECMO system.
The aim of this study is to present our experience using this type of connection.
This study was performed retrospectively in the Intensive Care Unit of the University Hospital in Saint Etienne from February 2014 until August 2016. All adult patients under ECMO venoarterial (VA) and venovenous (VV) who had at least one session of RRT were included. The connection between the RRT machine and the ECMO circuit was elaborated as follows: the dialysis inflow was connected on the oxygenator (purge line) and the outflow directly onto the arterial

cannula on a Luer port downstream of the oxygenator. We performed an analysis per patient and per dialysis sessions.

16 ECMO VA and 9 ECMO VV were evaluated, thus 69 filters (34 ECMO VA and 35 ECMO VV). The median lifespan of a filter was 39 IQR [15-65] hours. 74% of all filters were ceased prematurely (< 72hours), mainly due to excessive pressure (24%) among which transmembrane pressure (3%), filter pressure (20%), outlet pressure (1%). The median rate the RRT's blood flow and of dialysis dose for all ECMO's combined was respectively: 150[140-181]ml/min, 34[23-39]ml/kg/h. Patients presented mostly hemorrhagic complications (n=10). No case of air embolism was noticed

The combination of RRT and ECMO as described in our study may be efficient. Further comparative studies seem necessary in order to recommend such practice.

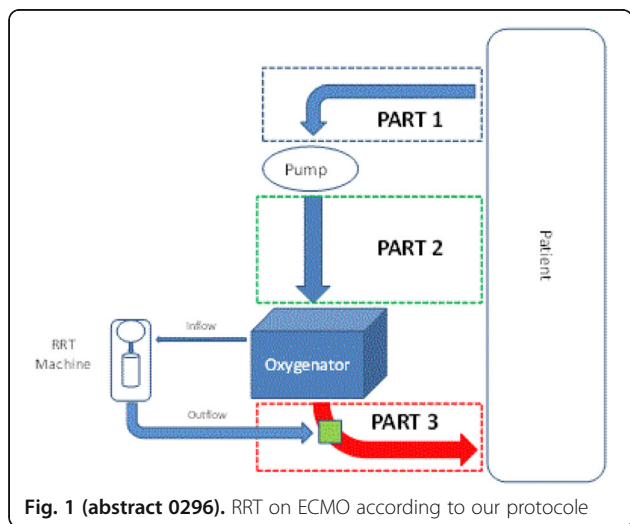

Fig. 1 (abstract 0296). RRT on ECMO according to our protocole

Table 1 (abstract 0296). Population of the study

Patients	Total n=25	ECMO VA n=16	ECMO VV n=9
Age (years)	64[54-71]	67[62-72]	54[49-56]

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0297

INTRODUCTION. Acidemia is a frequent disorder in critically ill patients. Blood chloride removal may increase blood pH. Extracorporeal chloride removal may be achieved through: 1. Electrodialysis (ED), a technique that selectively move anions from one solution to another through ion-exchange membranes using electricity (1); 2. ultrafiltration (UF) and postdilution with hypochlorous reinfusate; 3. UF through anion Exchange Resin (*a-ER*) which replaces chloride with bicarbonate ions.

OBJECTIVES. To evaluate, in-vitro, the chloride removal efficacy of these three different strategies.

METHODS. A standard reinfusate solution (CB 32, Novaselect) (technique 1) and a bicarbonate-based solution (Multibic®) (technique 2 and 3) were pumped through an hemodiafilter at 150 mL/min. The following strategies have been studied:

1. "ED group": the UF entered an ED chamber where chloride ions were replaced by hydroxide ions (OH-). Subsequently OH- ions were combined with CO_2 to form bicarbonate within a membrane lung and the solution was reinfused in the main stream;
2. "Hypochlorous group": the UF was discarded and the same volume was reinfused in postdilution as sodium bicarbonate 140 mEq/L;
3. "a-ER group": the UF was pumped through an a-ER and then reinfused in postdilution.

In Hypochlorous and aER groups, UF flows of 11.4, 22.7 and 34.1 mL/min were tested. In the ED group, 3 different UF flows 15, 30 and 45 mL/min were tested, with a fixed amperage (4 Amp) and recirculating flow was set to equalize the UF tested, to achieve a theoretical removal of 1.25, 2.5, 3.75 mEq/min of chloride, respectively. Before the hemodiafilter and downstream after reinfusion the solution was sampled for UF gas analysis and then wasted. The change in chloride among the two sampling sites was calculated to quantify chloride removal. The experiment was repeated three times. Data are reported as mean±SD.

RESULTS.

1. In the "ED group", chloride removal was 0.47±0.06, 0.96±0.11 and 1.22±0.17 mEq/min at 15, 30 and 45 mL/min of UF flow, respectively.
2. In the "Hypochlorous group", chloride removal was 1.45±0.09, 2.65±0.09 and 4.50±0.15 mEq/min at 11.4, 22.7 and 34.1 mL/min of UF flow, respectively.
3. In the "a-ER group", chloride removal was 1.20±0.15, 2.05±0.09 and 3.35±0.09 at 11.4, 22.7 and 34.1 mL/min of UF flow, respectively (see Figure).

CONCLUSIONS. The three different extracorporeal techniques effectively removed chloride. Chloride removal proportionally increased with the rise of the UF flow. Further investigations will be required to confirm these findings and to prove safety and feasibility studies in-vivo.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0298

INTRODUCTION. Acute kidney injury (AKI) is common in patients treated with veno-venous extracorporeal membrane oxygenation (vv-ECMO) and continuous renal replacement therapy (CRRT) is required in up to 50% of cases(1). Systemic heparinization is considered the standard anticoagulation technique(2), as it is suitable both for CRRT and ECMO circuit. However, in the last few years, we opted for regional citrate as additional anticoagulation for CRRT during ECMO(3), as systemic heparinization often fails to avoid CRRT circuit clotting. The CRRT system (Fresenius multiFiltrate®) was directly connected to the ECMO circuit, a solution chosen by only a minority of the ECMO centers(1).

OBJECTIVES. To assess efficacy, safety and advantages of regional citrate anticoagulation compared to systemic heparin anticoagulation in patients undergoing RRT during ECMO.

METHODS. We performed a retrospective chart review (2009-2018) on patients treated with renal support therapy during ECMO. We evaluated filter lifespan, rate of CRRT circuit clotting, platelet consumption and the safety profile of citrate anticoagulation.

RESULTS. Among 110 adult vv-ECMO patients, 49 were treated with RRT between 2009 and 2018. A total of 259 RRT circuits were used, 171 anticoagulated with regional citrate (RCA group) and 88 with systemic heparin only (UFH group). Median circuit duration was 53 ± 23h for RCA circuits and 51±27h for UFH circuits. Filter clotting was the main cause to circuit change in the UFH group (50% vs 10% in the RCA group, p< 0,01). Most of the CRRT circuits in the RCA group were changed after 48-72h even in the absence of signs of clotting, following the manufacturer recommendation. A significant reduction of the platelet count was observed in the UFH group (104 ± 72 vs 122 ± 76 in the RCA group). No complication ascribable to citrate anticoagulation was recorded, total to ionized calcium ratio was less than 2.5 in all patient samples and no severe electrolyte imbalance occurred.

CONCLUSIONS. Regional citrate seems a feasible, safe and effective technique to anticoagulate CRRT circuits connected to ECMO. Compared to systemic heparinization alone, this technique may provide some advantages in terms of reduction of circuit clotting and platelet consumption.

The relationship between base excess unmeasured anions and mortality in patients with acute kidney injury receiving continuous renal replacement therapy

B. Gucyetmez
Acibadem Mehmet Ali Aydınlar University School of Medicine, Department of Anesthesiology and Reanimation, Istanbul, Turkey
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0299

INTRODUCTION. It is known that acute kidney injury (AKI) is a reason for increased unmeasured anion (UA) and it can be corrected with continuous renal replacement therapy (CRRT) (1). Furthermore, it is demonstrated that increased UA is associated with higher mortality in critical ill patients (2). Base excess unmeasured anion (BEua), which leads to effect of UA on standard base excess (SBE), is a component of SBE and it can be calculated by using partitioned BE approach (3).

OBJECTIVES. The aim of this study is to investigate the association between increased negative BEua value and mortality in patients with AKI receiving CRRT.

METHODS. This study was designed as prospective obsevesional in 2017. Sixty three patients with AKI who were diagnosed in accordance with KDIGO Guideline required CRRT were included. ABL-800 blood gase analyser was used to measure arterial blood gas samples. BEua was calculated in accordance with partitioned BE approach (3). Demographic data and blood gas parameters, serum albumin, creatinine, blood urea nitrogen (BUN) and thrombocyte count (T_C) in the pre and 24th hour of CRRT and outcomes were recorded. Mann-Whitney U and Pearson correlation tests were used for statistical analysis. For likelihood of mortality, sofa score, systolic ejection fraction (SEF), 24th hour $PaCO_2$, HCO_3, lactate, SBE, BEua levels and T_C were added to the logistic regression model.

RESULTS. In this study, mortality rate was 36.5%. In non-survivors, BEua levels in pre and 24th hour of CRRT were significantly lower than survivors. There was a positive correlation between the timing of initiation of CRRT after detecting negative BEua value and lenght of ICU stay (r^2=0.28 p< 0.001). In logistic regression analysis, likelihood of mortality was increased 3.8-fold (1.1-6.9) and 4.7-fold (1.4-8.1) by 24th hour lactate level>2.3mmol/L and 24th hour BEua≤-8.5mmol/L respectively (p=0.016 and p=0.005 respectively).

CONCLUSIONS. Increased negative BEua value is associated with higher mortality in patients with AKI receiving CRRT. Moreover, in patients with AKI, it should be discussed whether it may be an indicator together with known traditional indications for CRRT.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0300

INTRODUCTION. Impaired liver function was initially a contraindication to the use of citrate in continuous renal replacement therapy (CRRT). However, increasingly, new articles defend the use and safety of this regional anticoagulation in critical patients with liver failure.

OBJECTIVES. To analyze the safety of a regional citrate anticoagulation protocol (RCA) for CRRT in critical patients with acute liver failure and decompensated cirrhosis.

METHODS. Prospective observational study from January to December 2017 in a intensive care unit (ICU). Patients with acute liver failure and any degree of decompensated liver cirrhosis were included during their admission in ICU. In all of them CRRT was indicated. Standard RCA protocol was applied in all patients. RCA protocol provides for a periodic analytical control to determine possible metabolic complications, among which toxicity stands out for the accumulation of citrate. Accumulation of citrate was detected indirectly by total serum calcium/ionised serum calcium (tCa/iCa) ratio. Statistical data are expressed through the median (minimum-maximum).

RESULTS. 8 patients (5 men and 3 women) with an age of 62 (41-70) years and APACHE II 26.5 (21-41) points were included. The sample consisted of 2 patients with acute liver failure in the context of a multi-organ dysfunction for septic shock and 6 chronic patients with decompensated liver cirrhosis during admission to ICU: 4 septic, 1 cardiac arrest and 1 postoperative cardiac surgery. Of these 6 chronic patients, they were able to stratify 2 in each stage of the Child-Pugh Classification and presented a CLIF-C ACLF Score 12.5 (8-14) points, corresponding to a grade 3 (1-3) of severity in the decompensation of liver disease. At the beginning of CRRT, MELD Score was 29.5 (19-33) points, Protrombin Time 53.5 (29-88) %, INR 1.64 (1.09-2.97), Platelets 55.5 x 10^9/L (19-118 x10^9/L), Fibrinogen 364 (84-555) mg/dL, Serum lactate 3,05 (1.3-11.5) mmol/L and Bilirubin 3.18 (1.6-11.6) mg/dL. No patient obtained a tCa/iCa > 2.5 that, due to toxicity, would have forced to suspend the RCA. Only 2 patients presented tCa/iCa > 2.2 that could be corrected by modifying the flow of therapy. Nor were other complications with clinical relevance in the acid-base balance motivated to stop RCA. The duration of the filters was 2.4 (1-5) days. The stay at the ICU was 14.5 (4-21) days with a mortality of 62.5%.

CONCLUSIONS. The use of citrate for CRRT in critical patients with acute liver failure or decompensated cirrhosis appears to be safe, regardless of the degree of liver disease. However, it's mandatory to practice strict metabolic controls in order to detect, control and correct a possible toxicity by accumulation of citrate.

Hemodinamic monitoring during continuous renal replacement therapy (CRRT) with oXiris filter in septic shock patients
M. Tengattini, F. Prato, U. Colageo, C. Pissaia
ASL BI - Ospedale Degli Infermi, Ponderano, Italy
Correspondence: M. Tengattini
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0301

INTRODUCTION. The immune dysfunction that characterizes sepsis is complex, affecting multiples pathways and it is still not well known.
The association of CRRT treatment with the oXiris filter, designed to adsorb endotoxin, remove cytokines and manage fluids, may positively affect the inflammatory cascade and it is safely used in clinical practice.
Optimizing hemodynamic status plays a key role in the treatment of sepsis-induced cardiovascular disturbances[1].
The combination of oXiris Continuous veno-venous haemodiafiltration (CVVHDF) with functional hemodynamic monitoring maintain an adequate tissue perfusion by regulating the immunomodulation process to overcome the consequences of multiorgan failure.
OBJECTIVES. The aim of this study is to retrospectively evaluate the patients' hemodynamic response during CRRT with oXiris membrane and its impact on tissue perfusion.
METHODS. A total of 10 septic shock patients (6 women, 4 men), with mean age 70,9 yr. (range 63-75), were treated and monitored during 2017.
Average baseline SOFA was 12,4.
oXiris was used as adjunctive therapy in combination with Standard of Care according to 2016 Surviving Sepsis Campaign guidelines in order to modulate immune patient response and improve hemodynamics.
CVVHDF was performed within the first 24 hours from ICU admission, using Prismaflex together with citrate anticoagulation.
Dosages of vasopressors, evaluation of hemodynamic status (tab.1) and blood lactates was monitored at T0 (admission in ICU) and subsequently every 12 hours until 192 hours.
Haemodynamic variables was obtained intermittently using transpulmonary thermodilution with fully calibrated pulse contour Picco technique (PulsioFlex, Maquet, Germany).
RESULTS. 6 treated patients survived and were discharged from ICU.

Neither CRRT nor citrate-related adverse events were observed.
During the treatment a rapid and progressive reduction in vasopressor demand was registered in all patients: norepinephrine mean dose significantly decreased from 0,84 to 0,13 mcg/kg/min (p< 0,05) (fig. 1).
Trends of haemodynamics (median values) values are reported in fig. 2; CI started from 2,72 and raised up to 3,54 l/min/m².
A sustained reduction in lactate blood levels (from 5,6 to 1,4 mg/dl - mean values) and in CRP (from 30,7 to 15 mg/dl - mean values) was observed. (fig. 3).
**CONCLUSIONS.** The timely application of oXiris-CVVHDF was accompanied by the reduction of vasoactive drugs and the improvement of tissue perfusion, as shown by the decline in lactate levels. A rapid stabilization of hemodynamics parameters, consistent with the reduction of vasoactive drugs need, was shown by the sequential evaluation of haemodynamic status.

Citrate anticoagulant does not influence CO2 extraction during CRRT

J. Jonckheer[1], H. Spapen[1], J. Demol[2], M. Diltoer[1], O. Costa[3], K. Lanckmans[3], T. Oshima[4], M. Malbrain[1], E. De Waele[1]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0302

BACKGROUND. Citrate is the preferred anticoagulation as it is associated with less complication during CRRT in a critical care setting. Citrate circulates through the body bound to calcium and in this state it is a weak acid. The resulting pH change will influence the balance between CO2 and bicarbonate. The use of CRRT is associated with CO2 extraction and thus citrate might alter their removal by CRRT. We studied the difference in CO2 removal between a citrate and a non-citrate setting of CRRT.

MATERIALS AND METHODS. In a prospective clinical trial in 8 patients receiving standard CVVH under citrate anticoagulation, total CO2 (tCO2) was measured by blood gas analysis before and after the filter. Citrate was then replaced by NaCl 0.9% and sampling was repeated. CO2 flow at the sample points was calculated by multiplying measured tCO2 with blood flow. CO2 extraction was calculated by subtracting CO2 flow after the filter from CO2 before the filter. Transmembrane tCO2 was calculated by subtracting tCO2 after the filter from the tCO2 before the filter. Values during citrate predilution were compared with values with NaCl predilution.

RESULTS. There is no statistical difference (p= 0,20) between mean CO2 extraction with citrate (26,3 +− 6,6 ml/min) versus NaCl predilution (25,9 +− 5,9 ml/min) during CRRT. tCO2 before and after the filter remained constant whether citrate or NaCl predilution was used (p=0,56 and p=0,63). Transmembrane tCO2 with citrate predilution (0,5 +− 1,4 mmol/l) did not differ significantly from NaCl predilution (0,4 +− 1,3)mmol/l (p=0,21)

CONCLUSION. Citrate has no impact on CO2 removal by CRRT.

Retrospective analysis of different CVVH-substitution fluids and their effects on the acid-base-metabolism

D. Schwärzler, S.J. Klein, M. Joannidis

Medical University Innsbruck, Division of Intensive Care and Emergency Medicine, Department of Internal Medicine, Innsbruck, Austria

Correspondence: S.J. Klein

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0303

INTRODUCTION. CVVH is one of the major modalities of continuous renal replacement therapy (CRRT). During CVVH, it is recommended to apply anticoagulation [1], either through systemic anticoagulation (heparin) or through regional citrate anticoagulation (RCA). Most CVVH substitution solutions were developed for use with heparin anticoagulation

with relatively high bicarbonate (HCO_3^-) levels. When applying RCA, HCO_3^- is additionally originating from citrate metabolism, often leading to metabolic alkalosis.

OBJECTIVES. Recently, a substitute solution with lower HCO_3^- levels (22 mmol/l; Biphozyl, Gambro) has become available. The goal of this study was to compare this solution to one with higher HCO_3^- levels (30 mmol/l; Phoxilium, Gambro) with regard to their effects on the acid-base-metabolism in patients with metabolic alkalosis.

METHODS. Retrospective cohort analysis including all patients between 09/2016 and 05/2017 who have been treated with CVVH using RCA and switched from Phoxilium to Biphozyl because of persistent metabolic alkalosis. Patients were deemed eligible for inclusion, if they had at least 12 hours CVVH treatment time with Phoxilium as substitution fluid, a blood HCO_3^- concentration $\geq$ 26 mmol/l and if a change of solutions was performed.

RESULTS. 26 patients and a total of 28 CVVH-cycles were analyzed. During the 48 hours prior to the change of solutions, HCO_3^-, base excess (BE) and pCO_2 levels increased. Those levels decreased significantly (p value for all < 0.05) after changing from Phoxilium to Biphozyl. No significant changes were observed for pH levels (p=0.827). Data is presented in Figure 1 and 2.

CONCLUSIONS. In this retrospective analysis of patients receiving two types of CVVH substitution fluids, we found an association between the fluid's HCO_3^- concentration and blood levels of HCO_3^- and BE, indicating, that in alkalotic patients, substitution fluids with lower HCO_3^- concentrations may be beneficial. Interestingly, also the pCO_2 appears to be directly affected by the HCO_3^- concentration of the substitution fluids. Although we cannot exclude other influences on these levels, due to the nature of this study. A prospective evaluation of different substitution fluids with standardized settings for CVVH and respiratory measures seams warranted.

Quality improvement project on efficacy of haemo-filters in intensive care care (ITU) by analysing various factors influencing the prescription in patients requiring RRT (renal replacement therapy) at Northampton General Hospital, ITU

A. Parthasarathy, P. David
Northampton General Hospital, ITU, Northampton, United Kingdom
Correspondence: A. Parthasarathy
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0304

INTRODUCTION. RRT is widely used for Acute Kidney Injury (AKI) in the intensive care units (ICU). Having multiple individual approaches between CRRT prescribers leads to wide variability and increases the possibility for errors in medication dosing, machine set-up, and nursing operations. This was overcome by an existing protocol within our ITU designed by a multidisciplinary team.Our project was to monitor the quality of CRRT by analyzing key components such as the modality, vascular access, anticoagulation and dose of effluent prescribed.
OBJECTIVES. By August 2018 to reduce the downtime of our filter in ITU by maintaining necessary Filtration fraction.
METHODS. A Prospective study was done to analyse the factors involved in prescription CRRT using a preformed template. Our study included 10 patients with 30 episodes. Each time the filter was started it was considered as single episodes. We analysed the various factors that could affect the prescription and this led to education being delivered to the nurses and caretakers involved with CRRT. We are currently trying to improvise the existing prescription for effective survival of our filters.
RESULTS. 8 patients required CVVH Central veno venous hemofiltration and 2 of them required CVVHDF Central veno venous hemodialfiltarion. (RFV) right femoral vein access was used in 6 patients, 2 of them required (LFV) left femoral vein and 2 required (RIJ) Right internal jugular vein as access. Among the 30 episodes, the most frequent dose of effluent prescribed was 35ml/kg/hr., which constituted around 17 episodes, and 13 of them were prescribed 25ml/kg/hr. The replacement fluid prescription for majority of the study was 30:70 in 24 episodes, 2 of them had ratio adjusted according FF and 4 of them had 50.50 ratios in view of access pressures. On analysing the filtration fraction only 10 of them were found to have < 20, 14 episodes had FF>30, 6 of them had FF 21-29.The filter failed 12 times overall, among which 4 times it failed twice in a day, Access pressure being the most common cause of failure constituting to 6 out of 8 times the filter failed.
CONCLUSIONS. 20 out of 30 episodes the filtration fraction was above 20. Higher fractions are associated with increased circuit clotting [3]. Filter life of CRRT is influenced by volume of blood processed. Maximum volume of blood is achieved by high blood flow rate, which can increase pressure alarms leading clotting. In our study it was found to be the most common cause for filter failure. Blood flows are consistently higher with RIJ catheters compared with left-sided catheters [1], due to additional resistance to flow from the two necessary bends and longer length of the catheter for left-sided access. In our study the most common access was RFV, followed by LFV and RJV. After analysing the above we decided to add in few more details to the existing renal prescription and is currently in progress.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0305

INTRODUCTION. Septic shock is one of the leading causes of mortality in the ICU. It has been proved that nucleoproteins, resulting from neutrophil production of extracellular DNA and protein traps, and from cell lysis, are increased in septic patients, contributing to create the endothelial injury underlying hyperinflammatory processes (1-2).

OBJECTIVES. To analyze the influence of continuous renal replacement therapy (CRRT) within the first 24 hours, in serum and effluent levels of nucleoproteins, procalcitonine (PCT), C reactive protein (CRP), and interleucine 6 (IL6).
METHODS. Prospective observational study. Patients with diagnostic of septic shock according to Sepsis-3 criteria who underwent CRRT were included. We excluded inmunodeficient, polytraumatized and patients with neoplasms. For CRRT we used : biocompatible semipermeable polysulfone filters 1.8 m2 and anticoagulation with tri-sodium citrate. Initiation of CRRT was based according to unit protocol. Nucleoprotein levels were analyzed using a home made ELISA in plasma and effluent samples at different times:

– T0: 1 hour before starting CRRT
– T1: after 1 hour of CRRT, both prefilter (T1 pre) and postfilter (T1 post) fractions, as well as effluent ones;
– T2: 24 hours after starting CRRT, prefilter.

We also analyzed biomarkers PCT CRP and IL6 at T0 and at T2 . Results are expressed in median and interquartile range, analysis were made using non-parametric tests; statistical significance of p-value 0.05.
RESULTS. 11 patients were enrolled during 1year. Patients baseline characteristics: APACHE II of 29 (19-37),SOFA at admission 10(7-15), age 66 years (50-78).
No nucleoproteins were detected in effluent samples.
CONCLUSIONS. There were no statistical differences between nucleoproteins, nor biomarkers, at different times in the small cohort of patients assayed. These preliminary data suggest that nucleoproteins are not removed by CRRT, but we identify a trend to reduction in plasmatic concentration after 24h.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0306

BACKGROUND. Targeted temperature management (TTM) currently represents the most efficacious treatment to improve neurological recovery in comatose patients after out-of-hospital cardiac arrest (OHCA). The effects of TTM with hypertension have not been reported. This study aims to investigate whether the effect of TTM on neurological recovery after OHCA differed between patients with or without hypertension.

METHODS. This study was conducted with the use of the national cardiac arrest registry of OHCA patients with presumed cardiac etiology who survived to hospital admission between 2009 and 2016. The primary exposure was TTM. The endpoint was cerebral performance category (CPC) 1 and 2 at discharge and survival to discharge. We compared outcomes between the TTM and non-TTM groups using multivariable logistic regression with an interaction term between TTM and hypertension for calculating adjusted odd ratios (AORs) and 95% confidence intervals (CIs) after adjusting for confounding factors.

RESULTS. Among 25,985 patients following OHCA that survived till hospital admission with presumed cardiac etiology, TTM was performed on 12.2%. The TTM group showed better outcomes than the non-TTM group: 28.1% vs. 15.5% for good neurologic recovery (P< 0.01). The AOR (95% CI) of TTM for good neurological recovery for all study groups was 1.65 (1.47-1.85). In interaction model, the AOR (95% CI) of TTM for good neurological recovery was 1.87 (1.26-2.76) in patients without hypertension vs. 0.87 (0.75-1.02) in patients with hypertension.

CONCLUSIONS. Hypertension modified the effect of TTM on neurological outcomes for OHCA patients. TTM is associated with good neurological recovery in the non-hypertension group, but is not a significant effect in the hypertension group.

Prediction of neurologic outcome after return of spontaneous circulation in out-of-hospital cardiac arrest: retrospective analysis using fast and frugal tree

S.M. Shin, G.J. Suh, Y.S. Jung, T. Kim, K.S. Kim
Seoul National University Hospital, Emergency Medicine, Seoul, Korea, Republic of
Correspondence: S.M. Shin

INTRODUCTION. Prediction of neurological prognosis in out-of-hospital cardiac arrest (OHCA) patients remains difficult. We wanted to develop a simple decision rule to predict the neurologic outcome after the return of spontaneous circulation (ROSC) in OHCA patients using Fast and Frugal Tree (FFT) analysis.

OBJECTIVES. Prediction of neurological prognosis in out-of-hospital cardiac arrest (OHCA) patients remains difficult. We wanted to develop a simple decision rule to predict the neurologic outcome after the return of spontaneous circulation (ROSC) in OHCA patients using Fast and Frugal Tree (FFT) analysis.

METHODS. Prospective post-cardiac arrest registry including 3 hospitals were retrospectively analyzed. Among 1609 patients in registry, 456 patients were enrolled after excluding 132 patients transferred from other hospitals, 133 patients with baseline cerebral performance category (CPC) 3 or 4, and 721 patients without sustained return of spontaneous circulation. A good neurologic outcome was defined as having CPC 1 or 2 at hospital discharge. Variables used for FFT analysis included age, gender, witnessed cardiac arrest, bystander CPR, initial shockable rhythm, prehospital defibrillation, prehospital ROSC, no flow time, low flow time, prompt light reflex and GCS after ROSC. Enrolled patients were randomly split into a training set and a test set (228 patients in each set).

RESULTS. Among 456 patients enrolled, 83 (18.2%) patients had a good neurologic outcome. Prehospital ROSC (True = good), prompt light reflex after ROSC (False = bad) and Cardiac cause (True = good, False = bad) were selected for the nodes constructing decision tree. Sensitivity, specificity, and accuracy of the decision tree to predict a good neurologic outcome were 96% (44/46), 89.6% (163/182), and 90.8% (207/228) in a training set and 94.6% (35/37), 80.6% (154/191), and 82.9% (189/228) in a test set.

CONCLUSIONS. A simple decision rule developed by FFT analysis can predict the neurologic outcome after ROSC in OHCA patients.

Optimum chest compression point for cardiopulmonary resuscitation in children revisited using a three-dimensional coordinate system imposed on computed tomography: a retrospective, cross-sectional study

S.-B. Chon[1], M. Park[1], W.S. Oh[2], S. Cho[1]
[1]CHA Bundang Medical Center, CHA University, Emergency Department, Seongnam, Korea, Republic of, [2]Kangwon National University School of Medicine, Department of Internal Medicine, Chuncheon, Korea, Republic of

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0308

INTRODUCTION. The optimum chest compression site (P_optimum) in children aged 1 y to puberty is debated: the European Resuscitation Council (ERC) recommends one finger breadth above the xiphisternal joint, while the American Heart Association (AHA) proposes a wider range, the lower sternal half.

OBJECTIVES. Using a 3-dimensional coordinate system imposed on computed tomography (CT), we aimed to discover the pediatric P_optimum to maximize stroke volume (SV) while minimizing hepatic injury.

METHODS. A retrospective, cross-sectional study was performed in children aged 1-15 y who underwent chest CT. We defined zero point (0, 0, 0) as the center of the xiphisternal joint and designated leftward, upward, and into-the-thorax directions as positive on each axis. The ultimate target, P_optimum (x_max. left ventricle (LV), y_max.LV, z_max.LV) was defined as the center of the maximum diameter of the LV, compression of which was assumed to produce maximum SV, the key point for successful CPR. We defined P_aorta (x_aorta, y_aorta, z_aorta), the reference structure separating the LV from the aorta, as the center of the aortic annulus. To compress the LV (vs. aorta) and not to compress the liver, we confined the compression range above the y coordinate of highest hepatic dome (y_liver_dome) and below y_aorta. Within this range, y_max.LV was located. To apply to pediatric CPR regardless of age, y coordinates were converted into relative ones with unit of sternal top (UST): 1 UST was the height from (0, 0, 0) to the sternal top. Data were presented as median (interquartile range) and compared among 3 age groups using Kruskal-Wallis test: 1.0-5.0, 5.1-10.0, and 10.1-15.0 y. As x_max.LV differed according to age, we investigated whether it could be expressed in terms of height by performing a linear regression analysis.

RESULTS. A total of 163 patients were enrolled, aged 8.8 (4.2-14.3) y; 49 (30.1%) were female. No significant difference was observed in the y_max.LV, relative y_max.LV, y_aorta, and y_liver_dome among age groups: 1.0 (0.1-1.9) cm, 0.10 (0.01-0.18), 0.39 (0.30-0.47), and −0.14

(−0.25-−0.03) UST, respectively (all P>0.05). The probability that neither the aorta nor the liver was compressed was ≥96% when placing hand at 0.05-0.20 UST, which embedded the y_max.LV centrally. X_max.LV (mm) was estimated as '0.173×(height, cm)+13' (n=106, P< 0.001, R2=0.278).

CONCLUSIONS. The study demonstrates that the optimum chest compression point is located 1 cm (or 0.1 UST) above the xiphisternal joint in children aged 1 y to puberty, supporting ERC and refuting AHA guidelines.

Impact of ischemic etiology-based difference on extracorporeal cardiopulmonary resuscitation in patients with refractory out-of-hospital cardiac arrest underlying cardiac diagnosis

K. Takeshige, Y. Kashima, H. Imamura
Shinshu University, Department of Emergency and Critical Care Medicine, Matsumoto, Japan

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0309

INTRODUCTION. Several studies have examined the impact of underlying causes of cardiac arrest on extracorporeal cardiopulmonary resuscitation (ECPR) survival. The ELSO registry demonstrated superior survival among pediatric patients with underlying cardiac pathology vs. non-cardiac reason for cardiac arrest.[1] However, it remains unclear whether the effectiveness of ECPR for refractory out-of-hospital cardiac arrest (OHCA) differ in patients with cardiac etiologies, such as acute coronary syndrome (ACS) vs. non-ACS.

OBJECTIVES. We investigated the prognostic effect of ECPR on refractory OHCA due to cardiac origin in patients with ACS or non-ACS.

METHODS. A consecutive patients with refractory OHCA due to cardiac cause who underwent ECPR at 7 tertiary centers were enrolled in this study. The exclusion criteria were as follows: aged < 20 years; non-cardiac cause, including pulmonary embolism, aortic dissection, trauma; successful return of spontaneous circulation before ECPR implantation; hypothermia (< 32°C); and not performed coronary angiography. A refractory cardiac arrest was defined as an absence of return to spontaneous circulation after continuous CPR for at least 30 min. ACS was diagnosed according to previous symptoms of cardiac arrest, laboratory data, 12-lead ECG, and coronary angiography. Patients with ACS were defined as the ACS patients, while the remaining patients formed the non-ACS patients. We assessed survival and neurological outcomes at 30 days after cardiac arrest. Neurological outcomes were assessed using the Cerebral Performance Category scale (CPC) and CPC1 and CPC2 were classified as a favorable neurological outcome.

RESULTS. We enrolled a total of 110 patients, including 71 ACS patients and 39 non-ACS patients. No significant intergroup differences were observed for age, sex, time from collapsed to ER arrival, the percentages of patients with shockable rhythm on arrival, witnessed, received countershocks during transportation, or administered CPR by a bystander. 30-day survival rate was significantly higher in the ACS patients than in the non-ACS patients (19.7%, n = 14 vs. 5.1%, n = 2, P < 0.05). The multivariate analysis showed that ACS was found to be an independent predictor of 30-day survival after cardiac arrest (odds ratio=7.15; 95% confidence intervals 1.04-48.94; P < 0.05). Kaplan-Meier analysis showed that patients with ACS had a significantly lower 30-day mortality rate compared to those with non-ACS patients (P < 0.05). However, no difference was noted in the neurological intact survival rate between the 2 groups (12.7%, n = 9 vs. 5.1%, n = 2, P = 0.24).

CONCLUSIONS. ECPR might be more effective for improving a survival outcome, but not a neurological outcome, in refractory OHCA patients due to cardiac origin with ACS than in those with non-ACS.

INTRODUCTION. Cerebral edema in cranial computed tomography, after the return of spontaneous circulation (ROSC), can be a marker of hypoxic brain injury for poor neurological outcome prediction; this appears as a loss of differentiation between the gray matter (GM) and the white matter (WM) on the cranial CT scans. Several studies demonstrated that low GM/WM ratio (GWR) values could predict poor neurological outcomes in cardiac arrest survivors. Nevertheless, the prognostic accuracy of the GWR varied by the location of the measurement on the cranial CT scans, among studies.

OBJECTIVES. This study aimed to evaluate the prognostic accuracy of the gray matter to the white matter ratio (GWR) in predicting the neurological outcomes in post-cardiac arrest patients treated with target temperature management.

METHODS. We systematically searched MEDLINE and EMBASE (Search date: 13 Sep 2017). Included studies were those evaluating neurological outcomes using the cerebral performance categories scale. We performed a subgroup analysis based on the location of the measurement. The Quality Assessment of Diagnostic Accuracy Studies-2 tool was used to assess the risk of bias of the included studies.

RESULTS. A total of 1150 patients from 10 observational studies were included in the meta-analysis. In evaluating the prognostic accuracy using area under the curve, the GWR of basal ganglia average showed the highest value (area under the curve 0.96, SE 0.02, Q 0.90) compared with the putamen/ posterior limb of internal capsule (area under the curve 0.93, SE 0.05, Q 0.87), overall average (area under the curve 0.91, SE 0.02, Q 0.85), and the cerebrum (area under the curve 0.89, SE 0.05, Q 0.82). Furthermore, the pooled diagnostic odd ratio values of GWR for predicting poor neurological outcomes also showed the highest value in the basal ganglia average (21.00, 95% confidence interval 6.85 - 64.40) followed by the overall average (20.71, 95% confidence interval 9.53 - 44.98), putamen / posterior limb of internal capsule (16.08, 95% confidence interval 4.36 - 59.23), and the cerebrum (13.96, 95% confidence interval 4.26 - 45.76).

CONCLUSIONS. The GWR in cranial computed tomography has a high prognostic value in predicting poor outcomes in post-cardiac arrest patients. In particular, it was easier to measure the GWR of basal ganglia average, which showed a higher prognostic accuracy, than the other cerebral locations.

Survival following witnessed out-of-hospital cardiac arrests during nights and weekends

H. Ryu[1], H. Kim[2]
[1]Chonnam National University Hospital, Gwangju, Korea, Republic of; [2]Chosun University Hospital, Gwangju, Korea, Republic of
Correspondence: H. Ryu
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0311

BACKGROUND. The relationship between neurological outcomes following out-of-hospital cardiac arrests (OHCAs) and time of day or day of week is unknown.

METHODS. A nationwide, prospective, population-based observational studies of witnessed adult OHCAs (>18 years) with resuscitation attempts was conducted from January 2009 to December 2016. Days were defined as 9:00 am to 5:59 pm, nights as 6:00 pm to 8:59 am, weekdays as Mondays to Fridays, and weekends as Saturdays, Sundays, and national holidays. Primary outcome was survival to discharge and secondary outcome was survival with favorable neurologic outcome, defined as cerebral performance category 1 or 2.

RESULTS. A total of 11,748 bystander-witnessed adult OHCAs were included. Survival to discharge was significantly lower during nights than days (11.4% [95% CI: 9.4%-13.4%] vs. 22.8% [95% CI: 20.3%-25.3%]; P< 0.0001 and during weekends/holidays (15.7% [95% CI: 13.6%-18.0%] than weekdays (20.4$ [95% CI: 18.7%-22.2%]; P=0.0001. Survival rate with favorable neurologic outcome was substantially lower during night 7.5% [95% CI:6.3%-8.8%] than days (12.2% [95% CI: 10.6%-14.1%]; P< 0.0001), and during weekends/holidays (7.7% [95% CI: 6.2%-9.5%] than weekdays (10.4% [95% CI: 9.2%-11.8%]; P=0.012). After adjusting for potential confounding factors, survival to discharge remained significantly lower during nights compared to days (0dds ratio 0.79; 95% CI, 0.65-0.97).

CONCLUSIONS. Survival to discharge rate following bystander-witnessed adult OHCAs was lower during nights and weekends/holidays than days and weekdays, even when adjusted for potentially confounding factors.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0312

INTRODUCTION. Cardiopulmonary resuscitation (CPR) by laypersons plays a key role in improving outcomes from out-of-hospital cardiac arrest (OHCA). Chest compression-only CPR has the potential physiological advantage of fewer compression interruptions as compared with conventional CPR, although at a possible cost to oxygen. In observational studies of bystander-initiated CPR for witnessed OHCA, two CPR approaches led to similar outcomes. However, it remains

uncertain whether chest compression-only CPR should be applied for unwitnessed OHCA.

OBJECTIVES. To investigate whether chest compression-only CPR is non-inferior to conventional CPR in patients with unwitnessed OHCA. **METHODS.** We performed retrospective analysis using data from Japan's nationwide OHCA registry from January 2005 through December 2012, in which patients had unwitnessed OHCA and chest compression-only or conventional CPR by laypersons, were transported to the hospital by EMS personnel. The primary endpoint was neurologically intact 30-day survival. We created well-balanced two groups (compression-only CPR group and conventional CPR group) using propensity score-matching. Non-inferiority of the proportion of patients with good functional status was analysed by Farrington and Manning test (significance level 5%, non-inferiority margin 0.35%).

RESULTS. Among the 210752 patients, compression-only CPR was performed in 154352 patients and conventional CPR was in 56400 patients. The propensity-score matching process selected 53863 patients each from both groups. Compared with conventional CPR group, compression-only CPR group incurred a lower rate of return of spontaneous circulation before hospital arrival (3.8% vs. 4.5%) and a lower survival rate (2.4% vs. 2.9%), and a similar rate of good functional status (1.1% vs. 1.2%). The non-inferiority of compression-only CPR was verified (percentage difference, -0.15%; 95%CI, -0.28% to -0.02%, p=0.0014 for non-inferiority). In multivariable logistic regression analysis, no association was observed between compression-only CPR and functional status (adjusted odds ratio, 0.96; 95%CI, 0.84 to 1.09).

CONCLUSIONS. Among patients with unwitnessd OHCA, chest compression-only CPR compared with conventional CPR did not result in an inferior rate of good functional status. Chest compression-only CPR may be a reasonable alternative to routine CPR approach for unwitnessed OHCA.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0313

INTRODUCTION. Prognosis of patients after cardiac arrest (CA) is still unsaatisfactory despite better care (5-20% survival to discharge).The anoxic phase of injury is followed by the reperfucion phase leading to postcardiac arrest syndrom.The oxidative stress is one of the main causes of postcardiac arrest syndrome.There is a data showing that increasing of the antioxidative protection by the supplementation of selenium in patients in septic shock or severe sepsis may have some impact on prognosis. But there is scarce data on the effect of this approach in patients after CA.

OBJECTIVES. Due to similarity between circulation impairment in sepsis and postcardiac arrest syndrome and because the most vulnerable system is the brain that consists of great amount of lipids easilly targeted by oxidative stress,we anticipated that we could decrease the damage by selenium substitution in the similar way as in septic shock

METHODS. We randomized 35 patients in 2 groups.The first group was treated by standart therapy.The second group received selenium intravenously (sodium selenite) in addition to the standart therapy.

3mg of selenium was administered as initial bolus (the first day) in 30 minutes infusion followed by continuous infusion of 2mg of selenium per day for the next 5 days.We measured the products of reactive oxygen species reactions (ROM test and 8-hydroxy-guanosin as marker of the damage of RNA),serum antioxidative capacity (BAP test),markers of inflammation and tissue injury and parameters of clinical outcome .

RESULTS. Patients treated by selenium had less pronounced oxidative stress.The results of ROM test showed significantly lower oxidative stress in the selenium group in the 2nd (p=0,005), 3rd (p=0,001), 4th (p=0,004) and 5th day (p=0,02). The results of BAP test implied significantly higher serum antioxidative capacity in the selenium treated group in the 2nd (p=0,04),3rd (p=0,008) and 4th day (p=0,01). There was significantly lower concentration of 8-hydroxy-guanosin in selenium treated group in the 3rd day (1,1 vs. 2,3 ng/ml, p=0,03).There was no difference in the levels of the markers of renal, hepatal or cerebral (neuron specific enolase) injury and no difference in inflamation markers (leukocytes,CRP,procalcitonin,incidence of infection). There was insignificantly better neurological outcome in the selenium treated group in 30day follow up (average CPC 2.1 vs. 3.1, p=0,06) and significantly more ventilator free days in 30day follow up in the selenium treated group (p=0,03).

CONCLUSIONS. Our data imply that intravenously administered selenium in patients after CA is safe and may decrease the oxidative stress and increase the antioxidative capacity. Although numerical trend to better neurological outcome and more ventilator free days do not mean necessarily positive effect on prognosis it shows that it might be the adjunctive way to influence prognosis of patients after CA.

Outcomes of in-Hospital cardiac arrest in a British District General Hospital

E. Landymore, J. McLoughlin, P. Morgan
Surrey and Sussex Healthcare NHS Trust, Anaesthetics / Intensive Care, Redhill, United Kingdom
Correspondence: E. Landymore
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0314

INTRODUCTION. Return of spontaneous circulation following cardiac arrest in the adult population is a common reason for admission into intensive care. It is known that there is a substantial mortality rate following admission even if the patient survived the initial arrest.

OBJECTIVES. To compare the outcome of adult in-hospital cardiac arrests at East Surrey Hospital to a national Cardiac Arrest Audit database and to also assess outcome by age.

METHODS. A retrospective search of a critical care data base of 3576 patients from 03/10/2010 until 02/11/2017 revealed 151 in-hospital adult cardiac arrests that were subsequently admitted to intensive care.

RESULTS. The overall unadjusted discharge rate from the intensive care unit (ICU) to the wards was 42.4%. This does not reflect the number that were discharged home or later died on the wards. This rate falls within the rates of survival to discharge from hospital of 10.5% to 49.0% as per a 2014 UK National Cardiac Arrest Audit database [1]. Table 1 shows the discharges to back to the ward following ICU admission categorized by age.

CONCLUSION. These results show that the greatest number of ICU admissions post in hospital cardiac arrests peaks in the 8th decade of life. The proportion of patients who survive following in-hospital cardiac arrest decreases with each subsequent decade. This retrospective analysis allows us to better prognosticate and to be able to provide more accurate information to relatives of these patients.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0315

INTRODUCTION. Rapid response teams (RRT) assess patients at early stage of clinical deterioration, preventing serious adverse events in hospitalized patients[1]. Previous studies showed a reduction in cardiac arrest after the implementation of RTT[1]. However, there is no data to assess if the profile of in-hospital cardiac arrest changes after implementation of RRT.
OBJECTIVES. To evaluate changes in the characteristics of in-hospital cardiac arrest after the implementation of RRT.
METHODS. Prospective observational study that included patients that presented a cardiac arrest from January 2013 to December 2017. Exclusion criteria was cardiac arrest in intensive care unit, emergence department and operating room. Rapid response team started in July 2014. Patients were classified in two groups pre-RRT (cardiac arrest before RRT implementation) and post-RRT (cardiac arrest after RRT implementation). Patients were followed until hospital discharge or death.
RESULTS. We had total of 308 cardiac arrest (64.6 ± 15.2 years, 60.3% were men, 13.9% had a shockable initial rhythm, 61% were post-RRT). Cardiac arrest reduced from 4.2/1000 to 2.5/1000 admissions after implementation of RRT and we have approximately 124 calls/1000 admission. Pre-RRT patients had more hypoxia (29.4% vs 14.3; p=0.006) and tachypnea (14.7% vs 4.2%; p=0.004) before cardiac arrest compared to post-RRT. There was no difference between groups regarding initial rhythm, return of spontaneous circulation (ROSC), and mortality between groups (Table 1). However, the main reason for cardiac arrest was different between pre-RRT and post-RRT groups (Table 2). In multivariate logistic regression [OR, 95% CI], ROSC was positively associated with shockable rhythm [0.36 (0.16-0.78)], but not with age [1.01 (0.99 -1.02)] and post-RRT [0.74(0.46-1.21)]. In multivariate logistic regression [OR, 95% CI], in-hospital survival was associated with age [1.03 (1.01-1.05)] shockable rhythm [0.187 (0.080 -0.439)] but not post-RRT [0.893(0.395-2.02)].
CONCLUSION. Even though implementation of RRT is associated with reduction of in hospital cardiac arrest, it does not change the mortality of in-hospital cardiac arrest victims. There was a significant reduction in cardiac arrest due to respiratory causes after RTT implementation.

INTRODUCTION. The potential benefit of extracorporeal cardiopulmonary resuscitation (ECPR) for patients with refractory cardiac arrest (CA) remains unsettled.
OBJECTIVES. To compare the survival and neurologic outcome following ECPR or conventional cardiopulmonary resuscitation (CCPR) in CA victims.
METHODS. Retrospective analysis of database from our prospective observational cohort of CA patients. All consecutive adult patients referred to the Department of Intensive Care with CA between January 2012 and December 2017. The decision to initiate ECPR was dependent on the attending physician and initiated by the ECPR team, which is composed of ICU physicians. A propensity score was derived using a logistic regression model, including characteristics that varied between groups with a p < 0.10 and others that potentially related to outcome. The primary outcomes were survival to ICU discharge and 3-month favorable neurologic outcome, assessed by the Cerebral Performance Categories (CPC) of 1-2.
RESULTS. On a total of 635 CA patients admitted over the study period (ECPR, n =120), 80 patients with ECPR were matched to 80 patients who underwent CCPR (median age: 57 years - out-of-hospital CA, 62%). Time from arrest to termination of CPR (i.e. return of spontaneous circulation - ROSC, ECMO initiation or death) was 54±22 and 54±19 min in the ECPR and CCPR groups, respectively. ROSC rates

were 77/80 (96%) and 30 (38%) in the two groups (p< 0.001). Survival at ICU discharge was 18/80 (23%) vs. 14/80 (18%; p=0.55), respectively. Also, 3-month favorable outcome was higher, although not statistically significant, in ECPR (15/80, 19%) than CCPR (9/80, 11%; p=0.26)

CONCLUSIONS. ECPR after cardiac arrest may be associated with improved outcomes.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0317

BACKGROUND. The mortality rate of cardiogenic shock (CS) following acute myocardial infarction (AMI) is still high nowadays. Patients with cardiac arrest post AMI turning into CS has never been studied specifically. The aim of this study was to compare the mortality rate, with or without extra corporeal life support (ECLS), of CS post cardiac arrest following an AMI. Secondary objectives were factors associated with mortality.

METHODS. In this retrospective study conducted in Grenoble's universitary hospital, we compared patients with CS post cardiac arrest, due to AMI, implanted or not with ECLS. Demographical, clinical and biological datas were recorded. Univariate and multivariate statistical analyses have been performed looking for mortality risk factors at one month.

RESULTS. From January 2008 to December 2015, 85 patients have been included: 42 in the ECLS group versus 43 in the group without ECLS. Survival rate was 45%. There was no statistical difference of mortality rate between ECLS group (n=24, 57%) and non-ECLS group (n=23, 53%) (p=0.74). This lack of difference was confirmed on multivariate analysis (OR=1.43 IC $_{95\%}$ [0.44-4.69]). Other risk factors associated with mortality were age, lactates on arrival and no-flow duration. Intra-aortic balloon pump was a protective factor.

DISCUSSION-CONCLUSION. Only patients with refractory CC were implanted by ECLS. They were in a worse condition without an increase of mortality rate. In conclusion, ECLS was an efficient assistance in the CS post cardiac arrest due to AMI.

INTRODUCTION. Experimental studies suggest that continuous insufflation of oxygen (CIO) could improve cardio-pulmonary resuscitation (CPR). Since 2017, our fire department uses a specific device for CIO without tracheal intubation for prehospital CPR.

OBJECTIVES. To evaluate if CIO improves the quality of CPR

METHODS. All CPR performed by the firemen are monitored prospectively since 2011. Rate, duration and depth of the chest compressions (CC) are extracted from the automated external defibrillator. For each CPR, rates of CC with depth and rhythm respecting the guidelines and CPR fraction (ratio of the duration of CC on the duration of CPR) were measured. Results before and after implantation of CIO were compared.

RESULTS. CPR was performed by the firemen in 1270 patients (mean age 66.6 years) before and in 296 (mean age 67.3 years) after spreading of CIO. The proportion of CC with depth respecting the guidelines was similar (35.9% before, 38.9% after (p 0.07)). The proportion of CC with rate respecting the guidelines increased from 57.2% to 76.6% (p < 0.001) with CIO and the CPR fraction increased from 75.2% to 81.6% (p < 0.001).

CONCLUSIONS. Routine use of CIO without tracheal intubation by firemen was associated with an improvement of CPR quality.

INTRODUCTION. Cerebral tissue O_2 saturation measured by near infra-red spectroscopy (NIRS) is a novel method for monitoring the response to cardiopulmonary resuscitation (CPR). There is evidence that higher cerebral tissue O_2 saturation during CPR after cardiac arrest (CA) is associated with return of spontaneous circulation (ROSC). The NIRO Pulse mode in the NIRO-200NX system (Hamamatsu Photonics, Japan) can measure the tissue oxygenation index (TOI) and O_2 saturation of the pulse wave (SnO_2). TOI reflects hemoglobin oxygenation in the arteries, capillaries, and veins. SnO_2 reflects hemoglobin oxygenation in the pulse wave flowing into the brain. SnO_2 is an important feature of the NIRO Pulse mode and may be a useful monitor during CPR. However, there are few studies on the association of ROSC with SnO_2.

OBJECTIVES. This was a single-center pilot study that investigated the ability of SnO_2 during CPR to predict ROSC in patients with CA.

METHODS. This study was conducted from October 2017 to March 2018. We included subjects who arrived in CA at the emergency department of Yamagata University Hospital and had a probe placed on their forehead for NIRS. Patients were treated according to the Japan Resuscitation Council Resuscitation Guidelines 2015. We calculated the average SnO_2 and TOI over 1 minute after the start of NIRS monitoring (Initial SnO_2, Initial TOI), the average TOI from the start of NIRS monitoring to the end of resuscitation (Mean TOI), and the maximum SnO_2 and TOI during the period of resuscitation (Highest SnO_2, Highest TOI).

RESULTS. The study included 24 cases with a median age of 83.5 years. CA was witnessed in 41.7%, bystander CPR was started before the arrival of emergency medical services (EMS) in 83.3%, and ROCS cases were 25%. An automatic external defibrillator was used in 2 cases (8%), and the initial ECG waveform when EMS arrived was pulseless electrical activity (25%) or asystole (67%). The causes of CA were acute coronary syndrome (21%), other cardiac etiology (17%),

or foreign body airway obstruction (17%). The median Initial SnO_2 was significantly higher in the ROSC group (41.2, IQR 33.7-69.7) than the Non-ROSC group (31.0, IQR 15.2-38.7, p=0.005). The median Highest SnO_2 was significantly greater in the ROSC group (78.9, IQR, 70.3-100.3) than the Non-ROSC group (59.0, IQR 50.7-71.5, p=0.006). The median Mean TOI and Highest TOI were significantly larger in the ROSC group, but the Initial TOI was not significantly different between the groups.

DISCUSSION. In this study, the Initial SnO_2 was significantly higher in CA patients with than without ROSC. Cerebral tissue oxygenation and cerebral blood flow pulse wave oxygenation were improved when ROSC was achieved. These results suggest that the Initial SnO_2 can predict ROSC in CA patients; however, more CA cases are needed since this was a pilot study.

CONCLUSIONS. The Initial SnO_2 was significantly higher in CA cases with than without ROSC.

INTRODUCTION. Survival to hospital discharge after in-hospital cardiac arrest (IHCA) is poor. There are some reports about target temperature management (TTM) improve survival in patients with out-of-hospital cardiac arrest (OHCA). However the association of body temperature and survival rate of IHCA is uncertain.

OBJECTIVES. We aimed to analyze the relationship between body temperature and survival discharge of IHCA.

METHODS. This retrospective observational study of IHCA was performed during 2010 to 2015 at a tertiary care hospital in South Korea. We included patients who admitted to an ICU after IHCA at the general ward. We reviewed the medical records of 270 adult patients who survived for longer than 72h after IHCA. The patients were divided into four groups by the highest (T_{max}) and lowest body temperature (T_{min}) of 72 hours after return of spontaneous circulation (ROSC): normothermia (BT=36.0-37.9℃), hypothermia (T_{min} < 36.0℃ and T_{max} = 36.0-37.9℃), hyperthermia (T_{min}= 36.0-37.9℃ and T_{max} ≥ 38.0℃), and hypo-hyperthermia (T_{min} < 36.0℃ and T_{max} ≥ 38.0℃). The primary outcome was survival to discharge. Multivariate logistic regression models were used to examine differences in survival to discharge.

RESULTS. A total of 270 patients were enrolled, the survival rate at hospital discharge was 61.5% (166 cases). Normothermia had a significantly better survival rate than the other groups (74.4%, p=0.006). In hypothermic group, no induced hypothermia had a better survival rate than induced hypothermia (57.6% vs 26.1%, p=0.009). In the multivariate analysis, survival at hospital discharge was associated with defibrillation (OR 2.72, 95% CI 1.22-6.06, p=0.015), duration of CPR (min) (OR 0.96, 95% CI 0.93-0.99, p=0.037), and severity of disease(SOFA1)(OR 0.80, 95% CI 0.73-0.87, P< 0.001). Induced hypothermia was not associated with survival to discharge (OR 0.45, 95% CI 0.19-1.10, p=0.079).

CONCLUSIONS. Normothermia is associated with improved survival to discharge in IHCA. Survival to discharge in IHCA was associated to defibrillation, shorter time of CPR, and lesser severity of disease (SOFA1).

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0321

INTRODUCTION. Cerebral performance category (CPC) scores (1) have been widely used to determine outcomes post cardiac arrest. However, there is less research into CPC scores on long term follow up.

OBJECTIVES. This study investigated the change in CPC scores on long term follow up in a cohort of patients admitted to the general intensive care unit after suffering out of hospital cardiac arrest (OOHCA). We also investigated the effect on mortality of Targeted Temperature Management (TTM) which was adopted in our unit towards the end of 2014, prior to which Therapeutic Hypothermia (TM) was used.

METHODS. Patients who had OOHCA and were admitted to the general intensive care unit between 25 July 2010 and 28 July 2017 were included. CPC on primary hospital discharge was determined by case note review; CPC of 1-2 was classed as a favourable outcome and 3-4 was classed as unfavourable. Follow up CPC was determined by telephone consultation in Mar 2018 using a questionnaire. Kaplan-Meier analysis was used to demonstrate survival over time. The data was then split into two cohorts; data up to and including 2014 vs data from 2015 to 2017, to investigate the effects of TTM adoption.

RESULTS.
· A total of 370 patients were included. The majority of the patients were male (80%) and mean age was 62.4 (SD 14.9). Average length of hospital stay was 22.7 days (SD 47.3, range 0 to 649). 177 were discharged alive from hospital giving overall mortality of 52.1%. 8 patients were excluded. 169 notes were reviewed retrospectively. Of these, 139 (82%) patients were CPC 1-2 and 30 (18%) were CPC 3-4.
· Follow up CPC status was available for 132 patients. Of these there were 19 deaths (14%), 99 (75%) were CPC 1-2 and 14 (11%) were CPC 3-4.
· 6 patients improved from CPC 3-4 on discharge to 1-2 on follow up whereas 3 patients changed from favourable (CPC 1-2) to unfavourable (CPC 3-4).
· There was no statistically significant difference in mortality before and after TTM adoption (mortality 2010-2014 vs Mortality 2015-17, p = 0.50). A somewhat higher proportion of patients were discharged with CPC 1-2 after 2014 (44%) as compared to the period up to and including 2014 (32.4%) although this did not reach statistical significance (p=0.45).

CONCLUSIONS. Our results suggest the majority of patients had a favourable outcome on discharge which was maintained on follow up, once they survived the initial insult and hospital admission. A small proportion of patients switched CPC classes. A switch to TTM did not have a significant effect on mortality but seems to have increased favourable outcomes on discharge. More research is needed to investigate the link between TTM and long term neurological outcomes in patients who survive out of hospital cardiac arrest.

Cardiac hyaluronan may be associated with the persistence of atrial fibrillation

Y. Kashima, K. Takeshige, H. Imamura
Shinshu University, Department of Emergency and Critical Care Medicine, Matsumoto, Japan
Correspondence: Y. Kashima

INTRODUCTION. Hyaluronan (HA), a primary component of the extracellular matrix (ECM), is associated with several cardiovascular diseases. HA is a key ECM regulator of inflammation, cell migration and proliferation, and fibroblast activity during normal response to injury and inflammatory diseases.[1] Recent studies have shown that atrial fibrosis and diffuse left ventricular fibrosis are associated with atrial fibrillation (AF) and that fibrosis represents an excessive deposition of ECM components, that play a critical role in the pathogenesis of AF by interrupting cardiomyocyte-bundle continuity.[2,3] AF is the most common arrhythmia encountered clinically and the presence of AF has a negative impact on the mortality in critically ill patients. However, irrespectively of whether HA is associated with AF, the precise cardiac source of HA, and its role in AF patients remain unclear.

OBJECTIVES. We investigated chamber-specific HA levels and its relationship with oxidative stress, brain natriuretic peptide (BNP) levels in patients with paroxysmal AF (PAF) and persistent AF (PSAF) to further elucidate the pathophysiology of AF.

METHODS. We investigated chamber-specific HA levels in patients with PAF (n = 50) or PSAF (n = 35). Peripheral blood was drawn from the left cubital vein via a 20-gauge peripheral venous catheter before radiofrequency catheter ablation. Before ablation, a luminal coronary sinus (CS) catheter was used for plasma sampling from (1) the CS and advance transseptal guiding sheaths, (2) the right ventricle and atrium before transseptal puncture, and (3) the left atrium immediately after transseptal puncture. The levels of HA and a diacron-reactive oxygen metabolite (dROM) as a marker for oxidative stress at different cardiac sites, and peripheral brain natriuretic peptide (BNP) levels were measured.

RESULTS. HA levels in the CS (CS-HA) were significantly higher than those at other sites, in both PAF and PSAF patients, and CS-HA levels were significantly higher in PSAF patients than in PAF patients (37.1 [interquartile range, 31.2-48.3] vs. 30.6 [23.7-40.2] pg/mL, $P < 0.01$). CS-HA levels correlated with CS-dROM levels and peripheral BNP levels in PSAF patients ($r = 0.417$, $P = 0.03$ and $r = 0.579$, $P < 0.001$, respectively), but not in PAF patients ($r = -0.115$, $P = 0.421$ and $r = 0.048$, $P = 0.740$, respectively).

CONCLUSIONS. Our data suggests that cardiac HA could either be a cause or consequence of AF. Cardiac HA levels positively correlate with cardiac oxidative stress and peripheral BNP levels in PSAF patients, although this was not the case in PAF patients. These results indicate that cardiac HA may be associated with the persistence of AF.

A reduction in skin perfusion can reliably predict tissue hypoperfusion during ultrafiltration

W. Mongkolpun, J.-L. Vincent, J. Creteur
Erasme Hospital, Intensive Care Department, Brussels, Belgium
Correspondence: W. Mongkolpun

INTRODUCTION. After hemodynamic stabilization, a number of critically ill patients need continuous veno-venous hemofiltration (CVVH) with ultrafiltration (UF) to reduce fluid overload and tissue edema. Excessive fluid removal may impair tissue perfusion so that careful monitoring is necessary to guide the UF.

OBJECTIVES. To determine whether change in skin blood flow (ΔSBF) is related to tissue hypoperfusion and could be used to guide UF during CVVH.

METHODS. We included 30 patients who required UF with CVVH. All were hemodynamically stable after resuscitation from circulatory shock (septic (24), cardiogenic (6)). Sequential organ failure assessment (SOFA) and APACHE II scores were calculated at baseline. UF parameters were set by the attending physician and unchanged during the study.

SBF was measured (Periflux 5000, Perimed; Perfusion unit: PU) on the same finger for 3 minutes at the start of the study (H0), and 1 (H1) and 6 (H6) hours after start of UF.

Hemodynamic parameters and blood lactate levels were obtained at each time point.

ΔSBF was defined as the relative (%) change in SBF during the first hour of UF.

Tissue hypoperfusion was defined as an increase in blood lactate concentration (ΔL) of at least 10% at H6.
Receiver operating characteristic (ROC) curves were constructed and were reported as areas under the curve (AUC) with 95% confidence intervals. Data are reported as medians with 25th and 75th percentiles.

RESULTS. Median APACHE II and SOFA scores were 24 (17-26) and 11 (8-13), respectively. Mean arterial pressure (MAP) and cardiac index (CI) were 94 (92-112) mmHg and 3.0 (2.8-4.0) L/min/m², respectively, and the median norepinephrine (NE) dose was 0.2 (0.1-0.5) mcg/kg/min. UF rate was 100 (100-200) ml/hour. At baseline, there were no significant differences in hemodynamic variables, NE dose, or lactate concentrations in patients with and without ΔL ≥10% (Table 1). UF rate was similar in patients with and without ΔL ≥10% (150 (100-200) vs 100 (100-200) ml/hour, p=0.3). CI and MAP remained similar in patients with and without ΔL% ≥10% throughout the study, but NE dose was higher in patients with ΔL% ≥10 at H6 (p=0.03) (Table 1). Patients with ΔL% ≥10 had lower SBF at all time points and a higher ΔSBF at H1 than the other patients (Table 1). ΔSBF and baseline SBF predicted a ΔL ≥10% at H6 with AUCs of 0.96 and 0.83, respectively, and cut-off points of ΔSBF ≥ -46% (sensitivity 90%, specificity 99%) and SBF ≤ 57 PU (sensitivity 78%, specificity 87%) (Figure 1).

CONCLUSION. Baseline SBF and change in SBF at 1 hour represent early indicators of tissue hypoperfusion during UF.

Table 1 (abstract 0323). Hemodynamic and skin blood flow variables during the study period

	Baseline			H 1			H 6		
	ΔL<10% (N=11)	ΔL%≥10 (N=19)	p	ΔL<10% (N=11)	ΔL%≥10 (N=19)	p	ΔL<10% (N=11)	ΔL%≥10 (N=19)	p

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0324

INTRODUCTION. The brain-heart interaction has been previously described. Cardiac dysfunction is a well-documented phenomenon that can occur during significant brain injury -such as subarachnoid hemorrhage and stroke- and is associated with increased morbidity and mortality. Currently, scant evidence exists about heart function during traumatic brain injury (TBI) and its impact in outcomes.
OBJECTIVES. We sought to describe the cardiac function in critically ill patients who sustained a moderate or severe TBI.
METHODS. We prospectively collected data on patients admitted to our Intensive Care Unit (ICU) with a diagnosis of moderate or severe TBI. An echocardiogram was obtained within 24 hours of admission and repeated at 72 hours. Parasternal and apical views were used to obtained the following measures: left ventricular (LV) diameters and volumes, left atrium (LA) volume, right ventricular (RV) diameter and area, mitral and tricuspid transvalvular Doppler velocities and mitral and tricuspid valve annulus tissue Doppler velocities. Routine laboratory blood studies, including troponin T and pro NT-BNP, were obtained with each echocardiogram. Epidemiologic and clinical data were obtained from our ICU database. Patients were treated according to their underlying medical condition.
RESULTS. We collected data from 21 patients with moderate or severe TBI. They were mostly young adults with a mean age 26.4 ± 9.6 years old, predominantly males (76.2%) and were severely ill with a mean APACHE II score 15.9 and ISS score > 18. At admission, the incidence of LV systolic dysfunction was 14.3% and RV systolic dysfunction 14.3%. During follow up, the incidence of LV systolic dysfunction was 9.5% and there was no evidence of RV systolic dysfunction. Of note, a hyperdynamic LV function (EF > 75%) was noted in 19% of the patients at admission and in 42.9% during follow up. We did not find any patients with echocardiographic signs of elevated LV filling pressures (mean e' septal 0.12 ± 0.03 m/seg, mean e' lateral 0.17 ± 0.05 m/seg, mean E/e' 4 ± 0.92 with no patients with E/e' > 14) or elevated RV filling pressures (mean e' 0.15 ± 0.03 m/seg, mean E/e' 4 with no patients with E/e' > 6).
CONCLUSIONS. In critically ill patients with moderate or severe TBI, the LV systolic function is predominantly normal, followed by a hyperdynamic pattern and less frequently LV systolic dysfunction. We did not find any evidence of LV diastolic dysfunction in this population.

INTRODUCTION. The importance of right ventricular (RV) failure in critically ill patients is increasingly recognized as its occurrence is associated with significant mortality and morbidity[1-3].
OBJECTIVES. We aimed to assess the hemodynamic effects of non-invasively administering inhaled nitric oxide (iNO) in critically ill patients with acute RV failure, as well as demonstrate the feasibility and explore the safety profile of this approach.
METHODS. This is a retrospective cohort study in which we evaluated the clinical course of all patients in whom iNO was initiated without invasive mechanical ventilation in the intensive care unit (ICU) of two tertiary care centers. Primary outcome was acute variation in RV function parameters after starting iNO.
RESULTS. Eighteen patients were included in the analysis. Median (IQR) iNO concentration was 20 (20; 20) ppm and therapy duration was 24 (12; 46) hours. Most patients received iNO through nasal prongs (66.7%) or high flow nasal cannula (27.8%). Comparing the hemodynamic parameters just before the initiation of therapy and one hour after, iNO reduced pulmonary vascular resistance (PVR) from 219.1 to 165.4 dyn·s/cm^5 ($P< 0.001$), mean pulmonary artery pressure (PAP) from 28.4 to 25.3 mmHg ($P=0.01$) and central venous pressure (CVP) from 17.5 to 13.1 mmHg ($P=0.001$). Indexed cardiac output increased from 2.0 to 2.6 l/min/m^2 ($P=0.004$). ICU mortality was 27.78% and median ICU length of stay was 7 (5; 9) days. Two significant bleeding episodes and one acute kidney injury occurred during iNO therapy. No headache was reported.
CONCLUSIONS. Non-invasively administered iNO was associated with favorable hemodynamic effects in ICU patients with acute RV failure. Our results suggest the safety and feasibility of this therapy for which further prospective study is warranted.

INTRODUCTION. Pulmonary thromboembolism (PE) is a cardiovascular disease with a high incidence in Europe. In a number of cases, it is not diagnosed leading to a high mortality or disability in chronic phases.
OBJECTIVES.

- To describe the patients suffering from PE in our ICU.
- To assess the associated risk factors, the mortality and their prognosis in a medium term.

METHODS. Retrospective analysis of patients admitted in our Unit after being diagnosed with PE, as well as those who developed it during the admission, between 2010 and 2014.
We analysed different variables like risk factors, symptoms, diagnosis methods and long term prognosis. The connection between mortality, risk scores and treatment modality was evaluated by Pearson's Chi-square test and Fisher's exact test.
RESULTS. From 2010 to 2014, 55 patients were diagnosed with PE, 13 of them were diagnosed while admitted to the ICU.
We observed that 100% of patients treated with fibrinolysis had higher PESI score (p< 0,02); the mortality was also higher in this group (not statistically significant).
We have not found statistically significant correlation between mortality and poor prognosis in the available data, nor have discovered important morbidity in survivors.
CONCLUSIONS.

- The rates of mortality were similar to other series (29,1%), 12,7% of deaths were due to obstructive shock.
- In our study, we did not find data to predict prognosis properly.
- According to recommendations of the current guidelines, in our serie fibrinolysis was used in patients with higher severity rates: 100% patients whose PESI score is ≥ III (p < 0,02).

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0327

INTRODUCTION. Fluid responsiveness is defined by a relative increase in cardiac output after fluid administration. The relation with microvascular perfusion has not been adequately studied.
OBJECTIVES. To assess the microvascular response to a fluid challenge (FC) in critically ill patients.
METHODS. We prospectively collected data in patients and requiring a FC between February and June 2016, whilst cardiac index (CI) was monitored. The sublingual microcirculation was assessed using the incident dark field (IDF) CytoCam device (Braedius Medical, Huizen, The Netherlands). The proportion of small perfused vessels (PSPV) was calculated using the De Backer score, according to standard formulas. Fluid responders were defined by at least 10% increase in CI during FC. Responders according to changes in microcirculation were defined by at least 10% increase in PSPV at the end of FC. Cohen´s kappa coefficient was measured to assess agreement to categorize patients as "responders" to FC according to CI and PSPV.
RESULTS. A total of 41 FC were performed in 38 patients, after a median time of 1 [0-1] days after ICU admission. Most of the fluid challenges (39/41, 95%) were performed using crystalloids and the median total amount of fluid was 500 [500-500] mL. The main raisons for fluid challenge were oliguria (n=22) and hypotension (n=10). After FC, CI significantly increased in 24 (58%) cases; a total of 19 (46%) FCs resulted in an increase in PSPV. Both CI and PPV increased in 13 responders and neither in 11; the coefficient of agreement was only 0.19. We found no correlation between absolute changes in CI and PPV after fluid challenge.
CONCLUSIONS. Microvascular response to FC cannot be predicted by changes in cardiac output.

INTRODUCTION. Cardiorenal syndrome Type 2 (CRS) is defined by the occurrence of chronic progressive renal disease (CKD) in patients with chronic congestive heart failure (CHF) [1]. Given the increasing incidence of CHF [2], the resulting increase in SCR type 2 is of concern.

OBJECTIVES. To define the different predictive factors leading to the occurrence of CKD disease in patients with chronic abnormalities in cardiac function and its prognosis.

METHODS. Our work was a retrospective study of 70 patients with CHF included in the cardiology department of the Marsa FSI Hospital. It compared between two groups: G1 group control: patients with renal clearance> 60 ml / min (N=30) and G2 group CRS: patients with renal clearance $\leq$ 60ml / min (N=40). For all the patients we recorded epidemiological, clinical, biological, echocardiographic and therapeutic data as well as major events during the follow-up. The search for predictive factors was done by calculating the odds ratio.

RESULTS. The mean age of our patients was 58 and it appears as a predictive factor of the occurrence of SCR type 2 given that it was lower in group control (p=0,001), as well as arterial hypertension (p=0,001). Our results were consistent with the data found in several studies [3].

We concluded that the presence of CRS type 2 worsens the clinical features of CHF. In fact, dyspnea NYHA VI was more severe (68% versus 38%, p = 0.03) and blood pressure was higher for systolic (141 versus 122, p = 0.002) and diastolic (86% versus 75%, p = 0.01) in the CRS group type 2. Biologically, Hb was significantly lower in group 2 (p=0, 01).

As for the evolution of our patients, the occurrence of relapses of CHF as well as the mortality were significantly higher in the group SCR type 2 (OR were respectively 1, 33 and 1, 19), a result confirmed by the study of Campbell at al[4]. However, both groups were similar for duration of follow-up, number and duration of hospitalization, as well as for the occurrence of cardiovascular and thromboembolic complications.

CONCLUSIONS. Renal damage in the course of CHF worsens the prognosis and is associated with the most pejorative results. Thus, the prevention of cardiovascular risk factors remains the most effective way to limit the incidence of CHF and consequently the SCR.

INTRODUCTION. MINOCA (Myocardial Infarction with NonObstructive Coronary Aterosclerosis) is a well-known pathology in Cardiac Care Units. Its knowledge is important to decide how to treat these patients.

MATERIAL AND METHODS. Observational, retrospective and multicentre study of all MINOCA patients in the Andalusian hospitals taking part in the ARIAM Project. The ARIAM Cardiac Infarction Register is a multicentre database including the 11 public and private hospitals in Andalusia taking part in the ARIAM Project since its creation in 1998.

RESULTS. A total number of 1021 MINOCA patients from 34 Andalusian hospitals since 1998 were analyzed. Average age was 54 years (15-95 years), 64% being males. 63% of these patients showed no respiratory cardiac-related problem upon admission (Killip I), and 2% were admitted in ICU in Killip IV situation. MINOCA hospitalization death rate was 2.3% (no = 24 cases), ICU death rate was 1.5% (no = 15 patients), and the most frequently death cause was cardiogenic shock.

Table 1 shows average age, gender and death rate (both for ICU and hospital) for each subtype of diagnosis in the MINOCA patients analyzed.

CONCLUSIONS. Myopericardial affectation was the most prevalent cause among MINOCA patients. Etiologic causes remain unproved in a high percentage of these patients, who also show higher hospitalization death rates, probably because no suitable etiologic treatment was applied.

Table 1 (abstract 0329). MINOCA

DIAGNOSIS	n	%	Average age	% male	% ICU death	% Hospitalization death

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0330

INTRODUCTION. Neuromuscular electrical stimulation(NMES) is a technique that the beneficial effects were shown on acquired muscular weakness by creating passive muscular contractions in ICU patients, as well as on pain therapy.

There are studies showing that the NMES induce skeletal muscle microcirculatory function and may create changes in periferic circulation either locally or systemically.

OBJECTIVES. In our study, we aimed to show the systemic effects of high frequency NMES on tissue microcirculation as assessed with near-infrared spectroscopy (NIRS).

METHODS. The study protocol was approved by the Scientific Committee.

Selection of patients: 65 ICU patients(Age18-85), COPD and/or pneumonia, LOS>48 hours; entubated, mechanically ventilated, all minimally sedated, APACHE score< 25, hemodynamically stable (no signs of sepsis -DIC or vasoconstrictor use or any problem interfering with the assesment of the microcirculation); no conditions that limit lower limb mobility.

A single 30-minute high frequency mode NMES session(80-120 Hz) was applied to the lower limbs bilaterally using current of increasing intensity. Current intensity was initially set to the lower

limit that was 80 Hz, then increased to the maximal tolerated level, or until the visible contractions of the quadriceps muscles with or without the minimal knee extention were seen. Peripheral microcirculation was monitored at the thenar eminence of the appropriate hand using near-infrared spectroscopy (NIRS) to obtain tissue O_2 saturation (StO_2), tissue hemoglobin level(tHb), as well as systolic and diastolic blood pressure (SBP, DBP) and heart rate(HR).The recordings were taken before and after the application of NMES.

Comparisons were made using Paired Samples t test for dependent samples and Wilcoxon's signed rank test for independent samples.

RESULTS. High frequency mode was well tolerated in all patients.
Mean age: 63,7±16,9; female/male: 18/47; APACHE II on admission:19±7

StO2: 79,8±8,9 (Before NMES) / 81,7±9,4(After NMES); p=0,012
tHb: 9,7±2,9 / 10,4±2,9 ; p=0,048
SpO2: 96±2,6 / 96,1±2,3; p=0,396
SAB: 135,8±23,9 /134,1±19,9mmHg; p=0,177
DAB:71,1±16,3 / 76,3±13,1 mmHg; p=0,024
HR: 88±15,4 / 94,3±19,1/min; p=0,014

CONCLUSIONS. In our study, a single session of NMES-induced exercise using high frequency current (80-120 Hz) was shown to acutely induce systemic changes in skeletal muscle microcirculation. Although these changes were not clinically remarkable, it may have some beneficial effects in severe ICU patients with serious microcirculatory derengaments

INTRODUCTION. Extracorporeal membrane oxygenation (ECMO) is nowadays a proven therapy strategy for refractory cardiogenic shock (CS) to maximum standard treatment efforts. It can keep the patient alive until the recovery of the disease or the arrival of another definitive therapy, such as heart transplant (HT). However, this invasive mechanical support is not free from complications.

OBJECTIVES. To describe our experience in the management of refractory CS that required venoarterial ECMO (VA-ECMO).

METHODS. We made a retrospective observational study based on a prospectively collected database, which included 65 patients suffering CS from different etiologies admitted in our cardiac ICU from March 2010 to March 2018.

RESULTS. Among the 65 patients, 61% were men, with a median age of 53 (IQR: 43-61). Median APACHE-II score was 15 (IQR: 9-19) and SAPS-II 35 (IQR: 29-49). The most prevalent causes of CS were: refractory end-stage heart failure (35.4%), acute myocardial infarction (24.6%), graft failure after HT (12.2%), postcardiotomy (10.8%), right ventricular dysfunction added to a refractory hypoxemia after pulmonary endarterectomy (10.8%, 1 of which had previously a VV-ECMO) and non-ischemic acute miocardiopathy (6.2%). However, 7 patients required the implantation of a second ECMO: 3 due to graft failure after receiving HT, 3 conversions

from VA to VV (2 due to Harlequin Syndrome and 1 to arterial cannula-related bleeding) and 1 patient with a second VA-ECMO after failing the implant of a left ventricular assistance device; thus making a total of 69 VA-ECMOs (Fig. 1). The most frequent support objective was the bridge to recovery in 45% (n=31), of which 58% survived (16 recovered and 2 received a HT); followed by the bridge to transplant in 33.3% (n=23), of which 74% survived (16 that were transplanted and 1 recovered). About the 15 (21.7%) patients bridge to decision; 9 (60%) died, 3 (20%) were transplanted, 2 (13.3%) achieved recovery and 1 (6.7%) received another assistance (Fig. 2). The median time of ECMO assistance was 190 hours (IQR: 127-312) with a maximum of 960. Peripheral access was chosen in 82,6% of the cases. In total, 49 patients (68%) had complications related to the mechanical support. The most common one was cannula-related bleeding (20), followed by lower limb ischemia (17, of whom two patients required amputation of the ischemic limb), stroke (8), thrombosis (7), and accidental decannulation (1). The median time of mechanical ventilation was 312 hours (IQR: 126-564), being the median length of stay in ICU of 19 days (IQR: 11-36) and in the hospital of 34 (IQR: 17-68). The overall survival during the VA-ECMO support was 61.6% and at the ICU of 46.2%.

CONCLUSIONS. The use of VA-ECMO as a rescue support in patients with refractory cardiogenic shock is an effective therapeutic alternative, although not exempt from complications. In our case series, survival is greater when it is placed as bridge to heart transplantation.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0332

INTRODUCTION. It has been repeatedly shown that extracorporeal membrane oxygenation blood flow (EBF) affects left ventricular (LV) functions in cardiogenic shock by changes in LV preload and especially LV afterload. However, the effect of EBF on LV contractility is not fully understood.

OBJECTIVES. The aim of our study was to assess LV contractility at different EBF levels in porcine model of acute cardiogenic shock.

METHODS. Eight female swine (sus scrofa domestica, 45 kg) underwent implantation of femoro-femoral veno-arterial extracorporeal membrane oxygenation (VA-ECMO). Acute cardiogenic shock with signs of tissue hypoperfusion was then developed using global myocardial hypoxia. Hemodynamic variables including LV dP/dt max as a parameter of contractility were measured using conductance catheter at different levels of EBF ranging from 4.5 L/min to 1.0 L/min.

RESULTS. Decreasing EBF was associated with increasing of LV stroke volume and reduction of end-diastolic volume, end-systolic volume and systolic blood pressure. Left-ventricular dP/dt max was gradually increasing with the reduction of EBF from 833.9 ± 80.8 mmHg/s at EBF 4.5 L/min reaching maximal values of 1119.0 ± 89.3 mmHg/s at EBF 1.5 L/min ($P°0.0001$) with significant linear trend (slope 42.1, $P°0.0001$).

CONCLUSION. The changes of EBF in cardiogenic shock treated with VA-ECMO influence not only LV preload and afterload of severely impaired left ventricle but directly affect also LV contractility.

INTRODUCTION. The second consensus statement on microcirculatory analysis [1] proposes the development of parameters related to physiological function of the microcirculation. We have thus developed a software tool employing advanced computer vision to objectively quantify capillary blood volume and absolute red blood cell velocity (RBCv). Our hypothesis was that (I) advanced computer vision reliably quantifies functional capillary density (FCD) compared to manual analysis while enabling estimation of functional capillary volume (FCV) and RBCv, (II) change in FCV reflects volume contraction of the capillary bed following microcirculatory derecruitment caused by cardiopulmonary bypass (CPB) similar to change in FCD, and (III) RBCv is sensitive to change in microcirculatory convective function induced by CPB that may not infulence microcirculatory flow index (MFI).

METHODS. In 11 patients undergoing coronary artery bypass surgery 3 sublingual capillary microscopy videos were recorded before and after initiation of CPB primed with HES 130/0.4. FCD and MFI were manually assessed using AVA 3.2 software, as well as using a novel advanced computer vision algorithm employing contrast limited histogram equalization and principal curvature-based region detection (Fig 1). FCV was calculated as volume of the microvessels per area (mm3 mm-2) by per-pixel summation of capillary diameter along the centerline.

RESULTS. 5760 capillaries in 66 video clips were analyzed (Fig. 1). Using the software 99357 individiual red blood cells were tracked across 322000 frames. A good correlation was found between algorithm determined and manual FCD (r=0.60, p< 0.001, Fig. 2). CPB resulted in an decrease in FCD from (mean±SEM) 25.6±1.4 to 20.6±0.7 and 35.3±0.7 to 30.9±1.4mm-1 (manual and algorithm), as well as in FCV from 23.8±0.9 to 19.6±1.2mmE-4 (all p< 0.01). An increase in RBCv from 245±7 to 270±7 µm min-1 (p< 0.01) was detected using the algorithm, while MFI remained unchanged at 3.0. An upward shift in RBC velocity distribution before and after initiation of CPB is visualized in Fig. 3.

CONCLUSION. Accurate measurement of FCD is possible using advanced computer vision. It enables quantification of FCV by adding information on capillary volume, reflecting volume contraction of the capillary bed after initiation of CPB similar to FCD. Quantitative estimation of RBCv is sensitive to changes in convective state of capillary perfusion induced by CPB which did not affect MFI. Combined with quantification of capillary hematocrit as recently demonstrated using similar techniques [2] direct insight is given into capillary delivery of oxygen.

A method to derive local blood flow and local vascular resistance from tissue haemoglobin oxygen saturation

C. Smart[1], G. Ward[2], M. Singer[1]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0334

INTRODUCTION. Tissue haemoglobin saturation (StO_2) is distinct from pulse oximetry in that all compartments of the local blood volume are interrogated. Maintenance of the StO_2 depends on the arterial oxygen saturation, and the inflow of blood to the tissue. Higher values of StO_2 require exponentially more flow to maintain as the StO_2 approachs the unsurpassable asymptote of the arterial saturation. If the flow is abruptly occluded, there is a rapid decay in the StO_2 obeying predictable kinetics. Modelling these kinetics allows back-calculation of the arterial inflow. This estimate of flow may be combined with the systemic blood pressure to derive the local vascular resistance. Flow is expressed as an exchange percentage: volume of arterial inflow per second/interrogated blood volume ($\%.s^{-1}$). Resistance is expressed in $mmHg.s.\%^{-1}$.

OBJECTIVES. To validate the algorithm by incremental infusion of noradrenaline, and contrast to the pattern observed in stepwise haemorrhagic shock in an anaesthetised rat model.

METHODS. A bespoke fibreoptic StO_2 needle probe was implanted into the vastus lateralis muscles of the thigh in anaesthetised instrumented Wistar rats. One rat received central noradrenaline in incrementing infusion from 0.1-300 ug/kg/minute increased in half log order steps every 15 minutes. Four rats underwent progressive haemorrhage. Ten percent of initial estimated blood volume (EBV, 66ml/Kg) was withdrawn via an indwelling carotid line every 15 minutes until cardio-respiratory arrest. At this point the withdrawn blood volume was returned, and the animals observed for 20 minutes then euthanased. Tissue saturation and arterial blood pressure were recorded continuously and ABG sampling was performed at intervals.

RESULTS. During incremental noradrenaline infusion computed flow fell stepwise from 70 $\%.s^{-1}$ at baseline to 20 $\%.s^{-1}$ at 30 ug/kg/minute noradrenaline. Resistance rose stepwise from 1.2 to 34 $mmHg.s.\%^{-1}$. Complete flow cessation with infinite resistance occurred beyond 100ug/kg/min.

In the Haemorrhage group, baseline computed flow varied from 40-75$\%.s^{-1}$ with baseline resistance from 1.7-3.7 $mmHg.s.\%^{-1}$. Animals suffered cardiac arrest between 40-60% loss of EBV. In the penultimate step before arrest, flow slowed to 1-6 $\%.s^{-1}$ with resistance from 8.7-48 $mmHg.s.\%^{-1}$. Immediately pre-arrest, flow was universally near zero, and resistance >100 $mmHg.s.\%^{-1}$.

CONCLUSIONS. Imputing tissue blood flow unmasks significant early drops in blood flow that may only produce small decrements in StO_2. Resistance increments in a saw-tooth pattern, with initial vasoconstriction then relaxation. Persistently elevated resistance heralds imminent cardiac collapse. Animals surviving the resuscitation renormalized local vascular resistance to baseline.

INTRODUCTION. Cardiogenic shock (CS) complicating acute coronary syndrome (ACS) is associated with a mortality rate ranging from 40 to 50% despite improvement of early revascularization. The impairment of microcirculation in CS is associated with poor outcome. Early variations of microcirculation reactivity under maximal hemodynamic support including mechanical circulatory support remain unknown in CS.

OBJECTIVES. To describe the hemodynamic, the microcirculation status and outcome in a selected population of severe CS over the first 48h and to evaluate the accuracy of a bed-side estimation of post-ischemic recovery slope (RS).

METHODS. This single-centre prospective observational study, approved by an ethics committee, included patients admitted consecutively the last 2 years to ICU for CS complicating ACS. Inclusion was performed within 24 h of CS onset. Patients with refractory cardiac arrest, older than 75 years or with therapeutic limitation were excluded. The InSpectra™ near infrared spectrometer was used to assess the effect of a vascular occlusion test on thenar eminence tissue oxygenation (StO2). The RS was estimated at bed-side using the average increments per second for the first two values of StO2 after reperfusion. StO2 monitoring data were recorded and analysed using a software for exact calculation of RS. Relevant data were recorded at H0, H12 and H48 and mortality rate calculated at 90 days. We compared survivors (SV) versus non-survivors (NSV) at 90 days using non-

parametric tests with a p< 0.05 considered significant. A Pearson correlation test and Bland-Altman analysis were performed to compare estimated RS (eRS) to calculated RS (cRS).

RESULTS. 14 patients were included (median [interquartile range]: age 63 [59-67] y; SAPS II 62 [58-77]). All patients received catecholamine infusion and required mechanical ventilation under sedation, 10 (71%) were supported by an ECLS and/or Impella CP™ and 2 others by an intra-aortic balloon pump. The 90 days mortality rate was 50%. At H0, lactate (3.2 [2.4-4.3] vs 2.1 [1.5-9.4] mmol/l, p=0.689), RS (3.1 [2.8-3.4] vs 2.9 [1.3-3.1] %/s, p=0.224) and SOFA (9 [8-10] vs 12 [11-14], p=0.077) were not significantly different between SV and NSV, respectively. Unlike lactate, the H12 RS reached a significant difference between groups (4.8 [3.4-5.4] vs 1.9 [1.4-2.7] %/s (p=0.005), which was maintained at H48. The H48 SOFA was lower in SV (6 [5-8] vs 13 [12-15], p=0.022). The mortality was 83% vs 14% for patients with a RS < 3%/s at H12 (p=0.013). The eRS was correlated with cRS (r=0.929, p< 0.001) with a bias at +0.5 %/s (95% CI: 0.3-0.7] between the 2 values.

CONCLUSIONS. The early improvement of microvascular reactivity indicates a good response to treatment with quick decrease of organs failure and better survival. The bed-side assessment of RS overestimates the slope but is well correlated to cRS and may provide an easy monitoring of microcirculation to physicians.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0336

INTRODUCTION. An important part in the treatment of the critical patient is based on establishing adequate tissue perfusion to the organs, a therapeutic goal described has been the optimization of cardiac output (Q) whose components are stroke volume (SV) and heart rate (HR), alterations in any of the components can generate an inadequate cardiac output. Tachycardia is common in critically ill patients, and can cause a decrease in stroke volume by preventing adequate ventricular filling due to a decrease in diastolic time, which can generate ventricular-arterial decoupling and decrease in tissue perfusion.
OBJECTIVE. To observe the changes in tissue perfusion of patients in shock and tachycardia with the use of Ivabradine.
METHODS. Retrospective observational and analytical study conducted in the intensive care unit of the PEMEX Madero Hospital, Tamps. Mexico, records of patients in shock were reviewed and Ivabradina was prescribed for any medical indication, information on hemodynamics and tissue perfusion was collected in a data collection sheet, dividing values prior to the use of Ivabradine and after application.
RESULTS. n: 23. Diagnoses: septic shock (43.5%), cardiogenic shock (21.7%), mixed shock (21.7%), acute coronary ischemic syndrome (4.3%), high-risk pulmonary thromboembolism (4.3%) and severe pancreatitis (4.3 %), 34.8% were under mechanical ventilation. The following average values were reported prior to the use of Ivabradine: HR: 119, mean arterial pressure (MAP): 88 mmHg, dose of Norepinephrine: 24 mcg / min, uresis: 61 ml / h, central venous oxygen saturation (ScvO2) : 67%, lactate: 4.1 mmol / L, cardiac output (Q): 4.1 L / min, systemic vascular resistance (SVR): 1824 dynes and oxygen extraction index (O2EI): 30%. The data reported after the use of Ivabradine were the following: HR: 94, MAP: 83 mmHg, dose of Norepinephrine: 13 mcg / min, uresis 65 ml / h, ScvO2 of 70%, lactate: 1.3 mmol / L, Q: 3.7 L / min, SVR: 2018 dynes and O2Ei of 27%. There was a significant decrease in CR of 21% (p: < 0.0001), a decrease in norepinephrine dose of 46%, an increase in urine of 6.2%, an increase in ScvO2 of 4.3%, a decrease in lactate of 48%, a decrease of Q of 9.8%, an increase of the SVR of 9.7% and a decrease of O2Ei of 10%.

CONCLUSIONS. An improvement in the clinical and biochemical parameters of tissue perfusion was observed with the use of Ivabradine in patients in shock and tachycardia, independently of changes in cardiac output.

Calculating cardiac output during veno-venous ECMO using indirect calorimetry and blood gas analysis

M.C. Müller[1], T. Wollersheim[1,2], N.M. Carbon[1], S. Frank[1], V. Skrypnikov[1], S. Weber-Carstens[1,2]

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0337

INTRODUCTION. Veno-venous extracorporeal membrane oxygenation (vvECMO) is increasingly used for carbon dioxide removal and the treatment of severe hypoxemia. For optimal therapy the knowledge of the cardiac output (CO) is crucial. Conventional methods measuring the CO under vvECMO are either prone to errors by temperature changes (thermodilution), invasive (pulmonal artery catheter) or user-dependent (transesophageal echocardiography).

OBJEKTIVES. Calculate cardiac output (CO) with a new non-invasive method using a new formula including indirect calorimetry and blood gas analysis.

METHODS. We used a new simple equation, a modification of the Fick equation[1], based on basic physiological assumptions to calculate the cardiac output (CO):

$$CO_{modfick} = (Q_{ECMO} \times cO2_{postECMO} - cO2_{preECMO} + VO2)/(cO_{2Art} - cO2_{preECMO})$$

CO: cardiac output; Q_{ECMO}: ECMO blood flow; $cO2_{postECMO}$: Oxygen (O_2) content efferent from the ECMO, $cO2_{preECMO}$: O_2 content afferent to the ECMO; V_{O2}: O_2 consumption by the lung, cO_{2ART}: arterial O2 content

We investigated the equation as part of the MEEP-trial[2] (Measuring Energy Expenditure in ECMO Patients; Charité ethics EA/1/293/13), here shown preliminary data of 22 patients with ARDS and vvECMO and compared the CO results to the CO simultaneously measured by transesophageal echocardiography (TEE). For determination of VO_2 we used indirect calorimetry (Quark RMR, Cosmed), blood gas analysis was done according to clinical routine and O_2 content calculated with a formula by Dash[3].

RESULTS.
CO_{TEE}: Mean 6,34 (SD 2,09), Median 6,11 l/min
$CO_{modfick}$: Mean 7,49 (SD 2,40), Median 7,07 l/min
Relative Error (median, %): 25,1% (IQR -6%/+67%)
Correlation (Pearson): r=0,426*; p=0,048

CONCLUSIONS. While in some cases our new equation shows excellent correlation with the TEE values, other values differed up to 80%. This is a not acceptable error for a clinically relevant parameter. A median error of +21% with and IQR -6%/+67% indicates systemic over estimation and an additional individual error of the CO calculation.

Further research on the cause of these errors and their possible avoidance is necessary.

Correspondence: D. Pérez-Torres

INTRODUCTION. The right ventricle is often subject to an afterload increase in sepsis, mainly due to high pulmonary vascular resistance, leading to and adaptive dilation of the cavity and paradoxical septal motion (acute cor pulmonale). Airway pressures have been described to play a role in these changes, which reflect impairment of the right ventricular systolic function and are associated with worse clinical outcomes. Current guidelines for the assessment of the right heart in adults recommend more reproducible parameters to evaluate right ventricular systolic function.

OBJECTIVES. We aim to assess the impact of airway pressure on the right ventricular systolic function, by using transthoracic echocardiography (TTE), in septic patients undergoing mechanical ventilation.

METHODS. We conducted a single-centre prospective observational cohort study. Patients admitted to the ICU with sepsis over a 20-month period were enrolled, excluding those with ischemic or valvular heart disease and pacemakers. Tricuspid annular plane systolic excursion (TAPSE) and peak systolic velocity at the lateral tricuspid annulus (St) were analysed by comprehensive TTE on Days 1, 3 and 7 of evolution. Right ventricular systolic dysfunction (RVSD) was defined as recommended on ASE/EACVI Guidelines. Positive end-expiratory pressure (PEEP) and plateau pressure (Pplat) were recorded at the same time that TTE were performed. Ventilatory protocol targeted tidal volumes ≤8 ml/Kg predicted body weight, Pplat ≤30 cmH_2O and PEEP adjusted to optimize gas exchange. We explored the effect of Pplat on TAPSE, and the impact of PEEP level on TAPSE and St. Variables are expressed as mean ± standard deviation. Student's T or ANOVA tests were applied as appropriate.

RESULTS. 94 patients were enrolled, 55% male, aged 63±12, APACHE-II 23, 67% mechanically ventilated, ICU mortality 23%, 90-day mortality 29%. 217 TTE were performed, 146 in mechanically ventilated patients. Ventilatory parameters on Day 1: Vt=8.2±1.3, Pplat=22.2±5.0, PEEP 8.6±2.9. Ventilatory parameters on Day 3: Vt=8.0±0.8, Pplat=22.6±5.6, PEEP 9.4±3.1. Ventilatory parameters on Day 7: Vt=7.9±1.1, Pplat=22.8±6.4, PEEP=8.9±2.9. We did not find any difference in PaO_2, $PaCO_2$ and Vt between patients with and without RVSD (p>0.05). The results are shown in the Tables.

CONCLUSIONS. We found high plateau pressure (>30 cmH_2O) in septic patients was significantly associated to RVSD. However, PEEP level did not influence the presence of RVSD, as assessed by TAPSE and St.

Table 1 (abstract 0338). Differences in TAPSE, based on Pplat level

	Pplat ≥30 (n=13)	Pplat <30 (n=133)	p

The quality improvement of unplanned extubation among patients with mechanical ventilator in a medical center

C.-M. Chen[1,2,3]
[1]Chi Mei Medical Center, Intensive Care Medicine, Tainan, Taiwan, Province of China; [2]Society of Emergency and Critical Care Medicine, Taipei, Taiwan, Province of China; [3]Chia Nan University of Pharmacy and Science, Recreation and Health-Care Management, Tainan, Taiwan, Province of China
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0339

INTRODUCTION. It has been considered as an important quality indicator of care in the intensive care unit (ICU) among mechanically ventilated (MV) patients experienced unplanned extubation (UE). It is recognized as the most common airway adverse event in the ICU and might be associated with increased morbidity and mortality.

OBJECTIVES. A continuous quality improvement (CQI) concept has been promoted in reducing the incidence of UE since the year 2001 in a Medical center in Southern Taiwan.

METHODS. The CQI concept was initiated since year 2001 and was promoted in all 6 ICUs (96 beds) in Chi-Mei Medical center in southern Taiwan. The CQI concept, focusing on serial intervention tools including standardization of procedures, improvement of communication, revision of sedation and weaning protocols, changing strategy for physical restriction, establishment of task force for identification and management of high-risk patients, implementation of quality improvement models including Breakthrough Series (BTS) and Team Resource Management (TRM), was launched to reduce the incidence of UE in MV patients.

RESULTS. With the promotion of this CQI concept, the overall incidence rate of unplanned endotracheal extubation (defined as number of new UEs per total amount of MV patients during the same period) decreased gradually from 6.82% (188/2785) in the year 2001 to 0.61% (14/2309) in the year 2017 during a 17-year period.

CONCLUSIONS. The promotion of CQI concept in the ICU is effective in reducing the overall incidence of UE and subsequent reducing the morbidity and mortality, as well as evidenced in other literatures.

Collecting family feedback by digital survey

J.H. Coobs, A.M.M. Duijn, T. van Galen
VU University Medical Center, Intensive Care, Amsterdam, Netherlands
Correspondence: J.H. Coobs
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0340

INTRODUCTION. The ICU handles protocols, guidelines and standards to maintain quality of care[1]. With feedback from family or close contacts it is possible to create insights in the level of satisfaction and it can be used for improving ICU care[2, 3, 4]. Until 2016 we evaluated experienced care through a phone interview, performed by an ICU nurse[5, 6]. This post hospital interview took up to 30 minutes at a time. In 2017 it was decided to gather information a different way, using a digital survey.

OBJECTIVES. Is it more effective to collect feedback by digital survey compared to a phone based interview?

METHODS. An adjusted version of the Consumer Quality Index for family at the ICU is used[7]. The questions are gathered by a digital survey. This is send by mobile text link to all first contacts of ICU patients that were admitted for more than 48 hours 4 weeks after the patient is discharged. To increase response rate, no more than 20 questions are asked. The list of names of the first contacts is derived from our PDMS. This procedure of searching and sending takes approx. 2 ½ hours a month and is performed by the ward clerk.

RESULTS. In one year 243 surveys were sent with a 28% response rate (N=68). This is 35% higher than the response rate of the general hospital survey. It provides us information about the level of satisfaction. Alternate connections can be made. For example: does the time spent in the ICU influences the level of satisfaction? Are partners more or less satisfied than children of the patient? It takes approx. 4 minutes to fill in the survey.

No differences were found between respondents based on relation, age, length of stay or other. 80% is satisfied with current visiting hours. Clear communication with nurses and doctors is also rated positive. Handing out ICU information leaflets and diaries still deserves attention. The results are shared frequently with the team through presentations causing a higher level of involvement to improve overall quality care.

CONCLUSIONS. Sending the digital survey by text message improved effectiveness. It increases our chances to achieve a high response rate and creates an objective profile of experienced care. The effort is minimal for ICU and the respondent. Due to the results, we have insights in the level of satisfaction and areas that need attention or improvement.

Geographic distribution of intensive care audit in Europe

J.K. Adamski[1], W. Weigl[2]
[1]Satakunta Central Hospital, Department of Anaesthesiology and Intensive Care, Pori, Finland; [2]Uppsala University, Akademiska Hospital, Anaesthesiology and Intensive Care, Department of Surgical Sciences, Uppsala, Sweden

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0341

INTRODUCTION. The multiple-center quality improvement projects appear to be a useful mechanism to facilitate progress amongst individual institutions. Collection and analyzing of relevant data can determine why some units are used more efficiently than others.

OBJECTIVES. The aim of this work was to present the geographical distribution of organizations and initiatives appointed to conduct audits of intensive care units (ICUs) in Europe.

METHODS. We updated the list of national ICU registries listed on the Swedish Intensive Care registry (SIR) website (http://www.icuregs-we.org/en/About-Intensive-Care/registries/) with other registries and initiatives that were found in articles on ICU outcomes available in PubMed. In our search, we used the combinations of terms ("intensive care unit" or "ICU") and ("mortality" or "outcome") published in articles, in all languages until December 31, 2017. The databases were analyzed in terms of accessibility, language and used ICU definitions.

RESULTS. Countries gathering nationwide ICU data in Europe are presented in Figure 1. Most of the ICU registries are located in Western Europe. The definition of an ICU patient and an ICU bed differed considerably among countries. Consequently, types of collected data, the way in which they were analyzed, and finally, the scope of publicly available information were not uniform. A deeper comparison of ICU outcomes between different countries was difficult [1,2]. Only a part of annual reports, which are usually published in native languages, has open access. No national ICU registries were found in eastern part of Europe. However, new initiatives are emerging: regional registry in Poland operates since 2010 [3], Italien project PROSAFE gathers a few participants from Greece, Cyprus, Hungary, Slovenia and Poland. Likewise, 1 unit from Estonia participates in Finnish registry run by Tieto Company and some units from Portugal participate in Austrian registry (ASDI) [4].

CONCLUSIONS. Large part of European countries does not have a national ICU registry. For international comparisons, the introduction of a uniform system of data collection and analysis is required.

Care beyond the ICU - using a novel level of care protocol for critical care support of the terminally ill patient

R. Gupta[1], J. Wang[1], S. Ahmed[1], S. Connolly[1], S. Huprikar[2], R. Kohli-Seth[1]
[1]Mount Sinai Hospital, Institute for Critical Care Medicine, New York, United States; [2]Mount Sinai Hospital, New York, United States
Correspondence: R. Gupta
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0342

INTRODUCTION. Traditionally, critical care has been intrinsically linked to the Intensive Care Unit (ICU) due to the need for close monitoring and titration of therapies. This can create unique challenges for health care systems, staff, patients and families especially when outcomes are anticipated to be poor.[1] In this regard, respect for a patient's desire for critical care can be met through a protocoled approach, where bedside critical care support is provided outside of the physical ICU.

OBJECTIVES. We developed a level of care (LOC) protocol to identify and manage critical care for terminally ill patients outside the ICU. We analyzed the impact of our LOC protocol used by the rapid response team (RRT) on the delivery of critical care at our 1171 bed quarternary care center.

METHODS. The RRT is an intensivist led critical care consult service designed to evaluate, manage, and triage acutely ill patients. We integrated our LOC protocol into the RRT consult, to help identify patients that have a terminal illness, who were now critically ill and were anticipated to pass away despite ICU support. Once identified, anticipated prognosis and goals of care discussion were held with patient and family. For patients requesting supportive care, comfort

care plan were instituted in collaboration with the palliative service. If patients desired critical care, care was initiated at the bedside independent of triage to the ICU. A critical care plan was devised within defined limits anticipating vasopressor, ventilator, sedation and vascular access requirements. Operational details and concerns were discussed with floor staff and the care plan was distributed amongst hospital management, nursing and palliative services. The RRT team continued to provide close support for the primary team and family members. Over 12 months, we reviewed the performance of this protocol and its impact on observed mortality, hospital triage and hospice discharges.

RESULTS. Over 12 months RRT saw 10234 consults, of which 908 patients (8.9%) were triaged to the ICU and 619 patients (6%) were triaged to the stepdown unit. 185 consults were identified as level of care consults and 84 unique patients received bedside critical care support. Amongst these, 46 patients (54.8%) expired during their hospital stay, 15 patients (17.9%) were discharged to hospice, 13 patients (15.4%) were discharged to nursing facilities and 10 patients (11.9%) were discharged to home.

CONCLUSIONS. Our level of care protocol enabled critical care support to be provided to the terminally ill patient outside the ICU in a manner that balanced expectations, resources and end-of-life care. Through close cooperation of all stakeholders including families, nursing and support teams, it helped service patient autonomy, improve care and enhance resource utilization.

INTRODUCTION. Intra-hospital transport is associated with worse outcomes and adverse events, especially on critically ill patients.
OBJECTIVES. Our study's objective was to evaluate safeness profile of transport after specific group implementation for this purpose.
METHODS. In a period from October 2016 to September 2017 all critical patients transported were assessed, inside a large hospital, after implementation of specific group consisted by intensive care specialist physician, one nurse, and one physiotherapist. Complications, clinical and non-clinical, were evaluated to establish relation to transport.
RESULTS. The institute performed 1,559 transports, being 54.7% males and 60.9% were hospitalized patients. Use of vasoactive drugs was present in 19.8% and mechanical ventilation in 10.6%. Clinically stable patients comprehended 78.8% of our sample.
Clinical complications happened in 7.5% of the sample, more frequently in hemodynamically unstable patients (n=43) and respiratory failure (n=21). Eight percent of the sample (n=125) presented nonclinical complications. Occurrences were attributed to communication failures in 79.2% of cases.
CONCLUSIONS. Specialized group implementation to in-hospital transport made safer the process with lower rates of complication, including current literature data and guaranteed quality of care.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0344

INTRODUCTION. The Early Mobilization program during intensive care hospitalization has a number of benefits related to the outcome of the patient, including delirium reduction incidence, PICS, IMV and NIV time, risk of infections, vascular and length of hospital stay, and improved functional status at hospital discharge.
Progressive therapeutic activities, with application of additional facilitating resources, started immediately after hemodynamic and neurological stabilization. It requires adequate evaluation to determine the functional diagnosis, listing in the order of priority and its interrelation with the function to be worked.
OBJECTIVES. To evaluate the safety of implementing an Early Mobilization protocol within the first 24 hours of admission and the impact on the functional status of ICU discharge.
METHODS. Total patients admitted to the neurological ICU (Mar / 13 to May / 17). N = 11.219 Patients enrolled in PMP < 24 h of admission. N = 9,873
Excluded: Contraindication for PMP application < 24h; Impossibility to determine GFM at admission; Deaths; Clinical worsening after onset of monitoring; Non-adherence to PMP. N = 1.346
The patients were submitted to sessions with a mean duration of 30 minutes, 2x day, according to the tolerance, from admission serially monitoring hemodynamic, respiratory and neurological parameters.
RESULTS. There were 296 adverse events (3%), 97 of which were temporarily suspended. All events were reversible after discontinuation, with no clinical impact and resumed therapeutic activities within 24 hours.
CONCLUSIONS. The application of an Early Mobilization program within 24 hours of patient admission was shown to be safe, positively influencing the rehabilitation of neurological patients. Knowledge of the effect of postural changes and exercise, physiological and hemodynamic stability, type and intensity of activity need to be considered for the implementation of a PMP.
Effective communication, teamwork, planning and transparency in the therapeutic goal are essential for the implementation of the Early Rehabilitation program.

The effects of music therapy on the level of depression and anxiety in family caregivers of critically ill patients

K. Jeong Min, N. Sungwon
Yonsei University College of Medicine, Department of Anesthesiology and Pain Medicine, Seoul, Korea, Republic of
Correspondence: K. Jeong Min
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0345

INTRODUCTION. Families of seriously ill patients are reported to experience severe caregiving and financial burdens, as well as serious emotional and psychological distress including anxiety, depression, and post-traumatic stress disorder. It has been studied that these experiences of negative emotions would affect caregivers in a long term after the ICU patients are discharged from their hospital. Recently, family centered care has received much attention in intensive care medicine, and there is an increasing interest in practical strategy of how to reduce the psychological difficulties of family caregivers.

Music has been applied in many clinical situations and its effect on pain, sleep, anxiety, stress response is well documented. It can be adapted to an individualized way at different levels in various musical activities. Thus, music therapy can help reduce the emotional burden of caregivers with varying degrees of depression and anxiety.
OBJECTIVES. The purpose of this study is to examine the influence of music therapy on depression, anxiety, and emotional states of family caregivers of ICU patients.
METHODS. Intervention: Subjects completed a consent form to participate in the study and completed a questionnaire on basic emotional state. Then, the family participated in an individual music therapy for 1 hour. Single session music therapy was composed of the following sequence (1) progressive muscle relaxation with utilizing music, (2) listening to participants' preferred music and confirming the emotional states, (3) emotional changes through singing, (4) confirming changed emotional states and discussing the way to adapt in everyday life. After the session, the subjects had an interval of 10 minutes and then completed the post - emotional state questionnaire.
Measures
Depression, anxiety, and emotional states are assessed using Center for Epidemiologic Studies Depression Scale(CES-D), State Anxiety Inventory(STAI), 100mm Visual Analogue Scale for emotional states (happiness, comfort, sad, anger, fear). Before and after variables are analyzed by repeated measures ANOVA, using Subjective Caregiving Burden Scale as a covariate.
RESULTS. A total of 24 caregivers enrolled in this study (13 spouses, 9 children, 1 parent, 1 sibling). After intervention, there were statistically significant differences in depression, anxiety, happiness, sadness, comfort items. On the other hand, music therapy interventions did not have statistically significant differences in fear and anger.
CONCLUSIONS. This study has identified that music therapy has an emotional improvement effect to family caregivers of critically ill patients. The main weakness of this study is this is a pilot study with a relatively small number of subjects. Another limitation is that music therapy is only a single session, and its long term effects are unknown. In spite of its limitations, this study showed the potentiality that music therapy can be used in family-centered care in ICU.

INTRODUCTION. Guidelines for the Provision of Intensive Care Services (GPICS), compiled by the Faculty of Intensive Care and Intensive Care Society state, 'Patients must be reviewed in person by a consultant in Intensive Care medicine within 12 hours of admission to intensive care (ICU).[1]' Increasing comorbidities and complex medical health needs of the population highlight the importance of meeting these targets to ensure safe patient care.
OBJECTIVES. Ascertain whether the use of standardised admission clerking pro formas led to an improved number of patients receiving consultant review within 12 hours of admission to ICU across two moderate-sized ICUs in district general hospitals. Comparison was made to assess whether medical or surgical patients were more likely to meet the above guidelines.
METHODS. A retrospective analysis of patient admission notes across two ICUs was performed over a total of 4 months. Patient admission notes were reviewed before and after the introduction of an 'admission pro forma', which provided written prompts for staff to note when patient admission and consultant review occurred.
RESULTS. In total 262 patient notes were analysed; from February 2017 before admission pro formas were introduced and from September-November 2017, after their introduction. There were 131 medical patients and 131 surgical patients in total. Before introduction of admission pro formas, 46% of patients received consultant review within 12 hours of admission to ICU, compared to 51.8% of patients after pro forma introduction. 25.8% of surgical patients received a consultant review within 12 hours of admission, compared to 35% after pro forma introduction. 65.6% of medical patient were reviewed before pro formas were introduced, compared to 66.7% afterwards. Subjectively, data gathering was easier after pro forma introduction.
CONCLUSIONS. The use of admission pro formas correlated with a moderate improvement in the proportion of patients being reviewed by a consultant within 12 hours of admission to ICU. Medical patients were more likely to be reviewed compared to surgical patients, regardless of whether an admission pro forma was used. The pro forma had no effect on improving consultant reviews of medical patients but more surgical patients were reviewed within 12 hours after the introduction of the pro forma. This indicates there are other factors contributing to consultants being able to review patients. We speculate that these factors could include the detail of discussion between consultant and junior before admitting a patient and the level of care the patient required upon admission to ICU. This audit has highlighted that the use of standardised admission pro formas when clerking patients in ICU improves compliance with GPICS standards, as well as opportunities for further development.

Influence of an open-door policy on the noise generated in an intensive care unit (ICU)

A. Touceda, M. Segura, B. Porral, A. García, E.M. Menor, M.J. Rodríguez, D. Vila
Hospital Alvaro Cunqueiro, Intensive Care Unit, Vigo, Spain
Correspondence: A. Touceda
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0347

INTRODUCTION. The policy of visits in ICUs of our country have been generally restricted so far, only 3.8% have an open visiting schedule (24 hours a day), 9.8 % open only daytime, although in the majority the duration remains equal to or less than one hour (95.7%) (1). On the other hand, noise pollution in an ICU whose usual average levels (52-84 dB) are above those recommended by WHO (35-40 dB), represents an important problem with negative consequences for the staff and for the patients (2).
OBJECTIVES. Study if an open-door policy, allowing families to be present between 12:00 and 23:00 may have contributed to reduce the noise level of our Unit.
METHODS. Descriptive and retrospective study, analyzed the data of a Class 1 sound level meter placed in a polyvalent unit, with 15 beds, during a pre and post open-doors period (January and February 2017 and 18, respectively). We analyzed the number and characteristics of admissions (age, average stay and pathology) in these periods to know if the degree of activity could be comparable. The data have been analyzed with SPSS statistics.
RESULTS. The activity and characteristics of admissions in the two periods was similar: 89 patients entered in 2017 and 93 in 2018, without significant differences with respect to age (Mean 58.2 ± 16.0 and 60.6 ± 14.6 years respectively) nor in their average stay (8.8 vs 7.6 days) or type of pathology. When analyzing the data of the sound level meter, we have observed an overall decrease of the noise generated in ICU during the months in which it has been most permissive in the visiting schedule (Median 59.9 ± 3.7 dB in 2018 vs 60.7 ± 3.5 dB in 2017), which although it has been statistically significant, for sound effects, represents a very slight decrease. When comparing the data according to the time slot, we see that this decrease is maintained even in the period in which the families are found within the Units, from 12 to 23h (60.4 ± 1.6 dB in 2018 vs. 61.2 ± 1.7 dB in 2017; IC 95% -0.85;-0.60).

CONCLUSIONS. According to the existing literature, it is known that high levels of noise in ICU have a direct impact on the evolution of patients, modifying their circadian rhythm and directly influencing the sleep-wake cycle, in addition to a higher incidence of delirium and an increase in the need for sedation. Besides the intrinsic noise to the different machines and devices existing in an ICU, the main cause of this is that derived from human activities (2). Different strategies such as opening doors to families with a more permissive schedule, as we have seen in our study, seems to be able to contribute, although it is paradoxical, to reduce the noise in ICU.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0348

INTRODUCTION. The use of social media (SoMe) in modern society has expanded tremendously. Platforms such as Twitter, Facebook and Instragram have revolutionized communication. This change has extended into medical education, including conferences, where it has become part of the way we learn and keep abreast of the latest developments. Healthcare professionals and societies have responded by having dedicated teams promoting the utilization of such platforms as a way of disseminating information and encouraging discussion beyond physical boundaries. Sceptics argue that this is an unsustainable fad and does not translate to meaningful educational content and discussion. The quality of content placed online has also been questioned.

OBJECTIVES. To quantify and qualify the use of SoMe at critical care conference in the last 3 years.

METHODS. The largest ICM conferences were identified by group consensus. Hashtags unique to the individual conferences were isolated and analysed using proprietary Symplur algorithms. Quantitative/qualitative measures were collated, with comparisons made across the various conferences (2015 - 2017).

RESULTS. The annual conferences of five main societies/organisations were identified between 2015 to 2017. These were the Society of Critical Care Medicine's Critical Care Symposium, European Society of Intensive Care Medicine's LIVES Congress, the International Symposium on Intensive Care and Emergency Medicine and the UK's Intensive Care Society Congress. Compared to 2015, the number of tweets and Twitter users during conferences increased in 2017. The average increase was 149.4% (range 63.5 - 267.7%). Analysis of the tweets during the conference showed an increase in the utilisation of media such as images and video clips. There was also a trend for tweets to contain hyperlinks so that contents/references could be accessed easily. There were more tweets with replies, confirming that such online platforms have the ability to generate online discussions.

CONCLUSIONS. This is the first attempt to quantify and qualify the educational content generated on SoMe over a prolonged period at critical care conferences. The analysis shows that the increasing use of SoMe has been sustained across international conferences examined. The increase use of multimedia content, users and interactions confirms that SoMe has matured as a platform and has gained credibility amongst healthcare professionals. The use of multimedia content has been shown to increase the educational value and impact to learners[1]. In conclusion, the use of SoMe at conferences has shown a sustained quantitative and qualitative increase at critical care conferences. It has a role in 21st century medical education but like all tools, has its benefits and limitations.

Evaluation in the hospitalary management of the high commitment human resource practices from the perspective of the ICU healthcare personnel

P. Vega Ocaña[1], J.D. Martín Santana[2], L. González Bautista[1], C. García del Rosario[3], L. Santana Cabrera[1], R. Lorenzo Torrent[1]
[1]Hospital Universitario Insular de Gran Canaria, Intensive Care Unit, Las Palmas de Gran Canaria, Spain; [2]Universidad de Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain; [3]Hospital Universitario Insular de Gran Canaria, Quality Unit, Las Palmas de Gran Canaria, Spain
Correspondence: P. Vega Ocaña
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0349

INTRODUCTION. Proper management of human resources is critical in providing a high quality of health care. The staff's perception of good high-commitment human resource practices and organizational management affects directly to their job and satisfaction.

OBJECTIVE. To evaluate the level of commitment of the management team in a Spanish public hospital towards the high performance work practices (HPWPs) from the perspective of the healthcare personnel in the Intensive Care Unit (ICU) and to analize the differences in the evaluation according to different profesional categories.

METHODS. Information was collected from August to November 2017 through a survey adapted to each professional category. The questionnaire included a 7-score Likert scale including 24 items aimed at assesing different aspects related to high-commitment human resources management.
The multidimensional nature of the scale required the completion of a Confirmatory Factorial Analysis (CFA) to corroborate the dimensions

traditionally published in the literature on high-commitment human resource practices. In spite of the statistical significance of the model [χ^2=107.87, p=0.000], results showed that othat other adjustment indicators were within the value ranges recommended in the literature (CFI=0.97, NFI=0.94, RMSEA=0.08). Regarding internal consistency measurements of every dimesion composite reliability (CR) reached values over 0.70 and average variance extracted (AVE) reached values over 0.50. The Cronbach's alpha values verifies those observed in composite reliability. These results indicated that the measurement model was valid and reliable.

To analyze the existence of differences of averages in the evaluation of the HPWPs according to the professional category of the ICUs healthcare personnel, an ANOVA analysis was used.

RESULTS. Based on the results of the CFA, we proceeded to create four new variables, which correspond to the weighted average of the items that shape each dimension, weighted by the regression weights of each of them in the CFA. The following table shows the average values for each dimension according to the assesments of the ICU healthcare personnel, globally and according to the professional category.

CONCLUSIONS. We may conclude that the ICU healthcare personnel evaluates, in a global way, with low score the high-commitment human resource practices. Internal promotion is the worst valued aspect by the staff, and on the other hand, participation is the aspect that has received the best assessment.

There are statistically significant differences in the evaluations according to the different professional categories. Nursing assistants has been the category with the best perception of HPWPs and, on the contrary, doctors award the worst assessment.

Change of hospital and critical care unit - does it influence outcome?

M. Strube, J. Oras, C. Rylander
Sahlgrenska University Hospital, Anaesthesia & Critical Care, Göteborg, Sweden
Correspondence: M. Strube
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0350

INTRODUCTION. Centralization and increased subspecialisation of care result in an increased need for interhospital transports during ongoing intensive care. The majority of these patients are transferred with continuous need of organ support but in a stable condition. Studies have repeatedly shown that interfacility transport has no significant impact on morbidity and mortality. However, a preliminary report has shown that change of hospital is associated with an increased risk of adverse outcomes for ICU patients (1).

OBJECTIVE. The aim of this study was to explore if the change of hospital and critical care unit influenced health care results. Our hypothesis was that interhospital transfer to another intensive care unit does not affect patient outcomes.

METHODS. This was a retrospective case-control study. After ethical approval, data from local and national ICU-registries was obtained regarding patient characteristics, ICU length of stay and survival.

All patients >18 years being transported from the critical care unit at Sahlgrenska University Hospital, an 18-bed tertiary care ICU, to other intensive care units during 2012 to 2016 were matched to non-transported patients as to ICU days before transfer, age, diagnosis and illness severity according to SAPS 3. Ninety-day mortality was chosen as the primary outcome.

RESULTS. 827 patients were transferred to other ICUs, with diagnoses predominantly cardiovascular (24%), pulmonary (16%) and traumatic (11%). The majority of patients were transported within the Region of Western Sweden (95%), but almost half of them to other hospitals in Gothenburg (46%). Mortality at 90-days was lower for patients transported vs controls (31,1% vs 36,1%, respectively; p=0.02). Patients moved within Gothenburg had no significant difference in 90-day mortality in comparison to the control group (39,7% vs 36,1% respectively; p=0.60). Compared to all non-transported and non-matched patients treated in our ICU during the study period, 90-day mortality was higher in patients exposed to interhospital transportation (p< 0.001).

CONCLUSIONS. Interhospital transfer had no negative impact on 90-day mortality compared to non-transported matched patients. The lower mortality in patients moved to hospitals outside Gothenburg may be explained by the fact that such transports are initiated after the termination of need for tertiary care, while patients moved within Gothenburg presumably represent a general ICU population transferred in times of limited ICU-bed availability. Still, transfer within Gothenburg was not associated with increased mortality as opposed to what has been reported earlier (1). This may be explained by our use of a matched control group and we conclude that interhospital transfer between ICUs in the Swedish Western Region appear safe.

Challenges associated with critically ill patients admitted to the intensive care unit following international repatriation: retrospective case study and analysis

D. Johnpillai, C.J. Fong, A.J. Cadamy, F. O'Sullivan
Queen Elizabeth University Hospital, NHS Greater Glasgow & Clyde, Intensive Care Unit, Glasgow, United Kingdom
Correspondence: D. Johnpillai
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0351

INTRODUCTION. The Queen Elizabeth University Hospital (QEUH) in Glasgow hosts Scotland's largest critical care unit and accepts patients who have developed critical illness abroad. As in other UK units such repatriations are infrequent, but they can be associated with particular logistical and clinical challenges. There is a perceived need to develop systems, at a local, national, and international level, which optimise care and mitigate the inherent risks to critically ill patients from international transfer.

OBJECTIVES. This project describes local workload and identifies common issues affecting level 3 patients admitted following international repatriation. It aims to inform protocols and governance systems at a local and national level.

METHODS. A retrospective case review was conducted of level 3 patients internationally repatriated to the QEUH intensive care unit (ICU) from June 2015 to January 2018. Cases were identified by a systematic search of the local Wardwatcher database. Clinical notes, imaging, and laboratory results were reviewed, including those provided from the originating hospital where available. Challenges surrounding transfer were recorded as 'errors' and coded by category: information, pressure sores, tracheostomy or other clinical. These were further described by established definitions designed to illustrate type, severity and preventability. Microbiology tests were also reviewed.

RESULTS. In the 31 months since opening, QEUH ICU has admitted 10 level 3 patients as a result of international repatriation: 7 from Spain, and 1 each from France, Italy, and Romania. The most common presenting diagnoses were trauma and pneumonia. Patients spent between 4-77 days in hospital before repatriation, with discharged after 11-20 days in ICU. 9 out of 10 admissions experienced errors related to transfer, most commonly due to information handover. No severe errors were identified, although 2 patients required a tracheostomy change, as extra inner tubes had not been provided. All errors were probably or definitely preventable. 2 of 10 patients grew carbapenem resistant organisms with 2 further growing intermediately-resistant organisms resulting in prolonged isolation. 6 were transferred with officially translated documentation, while only 2 were transferred with electronic imaging compatible with UK systems.

CONCLUSIONS. Every 3 months, the QEUH ICU admits a level 3 patient repatriated from overseas. Many transfers are complicated by poor information handover, complex microbiology, or incompatible imaging. Complications could potentially be avoided by developing clear guidance at a local, national or international level.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0352

INTRODUCTION. Guidelines on ICU admission define that potentially unstable patients could be admitted to intermediate care units (IMCUs) with later transference to intensive care units (ICUs), if necessary (step-up transferences). However, the safety of such approach is not well established in the literature.

OBJECTIVES. We aimed to analyze factors associated to such step-up transferences.

METHODS. Retrospective cohort in a tertiary hospital in Brazil. We analyzed consecutive unplanned step-up transferences from January 2013 to December 2015. Relationship between reason for admission in the IMCU and reason for transference to the ICU was assessed as a categorical variable.

RESULTS. In the study period, there were 815 admissions to the IMCU, of which 99 (12.1%) were transferred to the ICU (step-up transferences). Overall mortality was 10.7%, with a mortality of 4.4% for patients that were not transferred to the ICU and of 45.5% for step-up patients (p< 0.001).

Of the 99 step-up patients, 93 (93%) were admitted for monitoring, while 6 (6%) were admitted for active intervention. Median number of days from admission in the IMCU to step-up transfer was 2 (1-6). Transferences were rated as probably or definitively related to original admission in 81 (82.6%) cases.

CONCLUSIONS. Step-up transference to the ICU occurred frequently in this cohort and was associated to increased mortality. Most transferences were early and were rated as related to the reason for the original admission.

Audit of oral cavity assessment for patients with endotracheal tube in Neuro ICU

A. Kwan[1], V. Ventura[1], S. Shah[1]

[1]St. Georges University Hospitals NHS Foundation Trust, Neuro ICU, London, United Kingdom

Correspondence: A. Kwan

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0353

INTRODUCTION. Mouth assessment represents a significant role in standardising and implementing effective oral care (Baker and Shipway, 2017). A thorough assessment must be carried out as this provides the staff with accurate baseline information regarding the condition of the patient's oral cavity. It also enables the healthcare professional and wider multi-disciplinary team members (MDT) to observe the progress or deterioration of the patient's oral condition hence, allowing for appropriate treatment plans (Wilson, 2011). An application of tool is important for an adequate mouth assessment and therefore the delivery of appropriate and efficient holistic care.

OBJECTIVES. To determine how beside nurses review the state of the oral cavity, particularly for those individuals with EndoTracheal Tube (ETT) and ensure documentation correlates with the TONGUES tool assessment (Neuro Intensive Care Unit, 2008).

STANDARD. 100% of individuals with ETT should receive an appropriate mouth care assessment at the start of the shift.

METHODS. A retrospective analysis was initially done on 24 individuals with ETT. 98 nursing care plans were reviewed to a mouth condition checklist.

A questionnaire survey was given to trained nurses to determine the type of assessment they used in evaluating the oral cavity and there were 45 respondents.

RESULTS. Data shows that 96% (n=94) of care plans had forms of written mouth condition assessment and 4% (n=4) had none. The survey results revealed 42% (n=19) of respondents stated that they follow the ICU guideline in assessing the patient's mouth condition, whilst 58% (n=26) reported that they use their own system or unsure which guideline to follow.

CONCLUSIONS AND ACTIONS. The audit had shown nurses have consistently assessed the mouth condition of patients with ETT. However, most of the assessments were not thorough to cover the whole area of the oral cavity. In order to enhance the practice with minimal disruption to work routine, a standardised mouth condition pre-assessment checklist was designed in the care plan to easily carry out initial and on-going oral evaluations. The guide will prompt the staff to report the result to the rest of the MDT and provide best evidence based practice on mouth care in which will result to patient's having best outcome.

Figure 1. Mouth assessment section of ICU care plan.

Mouth condition

tongue: pink moist dry cracked coated

Yeast in the urine predicts longer hospitalization in liver transplant patients

Q.G. Chen[1], Q.C. Chen[2], W.M. He[1], L.S. Zhang[1], S.H. Ge[1], M. Zeng[1]
[1]First Affiliated Hospital of Sun Yat-sen University, Medical Intensive Care Unit, Guangzhou, China; Sun Yat-sen University, Zhongshan School of Medicine, Guangzhou, China

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0354

INTRODUCTION. Little information is available about the association between yeast detected in urine culture and clinical outcomes of liver transplant patients.

OBJECTIVES. The aim of this study is to evaluate whether there is an association between yeast cultured from urine and poorer clinical outcomes for liver transplant patients.

METHODS. We performed a retrospective cohort study using a modifiable data mining technique applied to the publicly available Medical Information Mart for Intensive Care III (MIMIC III) database (v1.4). The primary endpoint was 90-day mortality. Hospital mortality and length of hospitalization were secondary outcomes. Propensity score matching (PSM) was performed and multivariate regression analysis was used to adjust for potential confounders. Survival curves were constructed according to Kaplan-Meier.

RESULTS. 273 liver transplant patients were included finally with 29 patients isolated yeast from urine. 21 patients with yeast-positive culture were successfully matched with 63 yeast-negative controls using PSM and no statistically significant difference was found between the two groups on age, gender, Elixhauser Co-morbidity Index (SID30), and Simplified Acute Physiology Score II (SAPS II) (p> 0.05). Kaplan-Meier curves analysis of the PSM cohort found no difference on 90-day survival between the two groups (log-rank test, p= 0.43). The median length of hospitalization of yeast-positive patients was significantly longer than that of the yeast-negative controls (55.92 days versus 20.25 days, p< 0.001) but there is no difference on hospital mortality between the two groups (p= 0.259). Results of multivariate regression analysis indicated that isolated yeast from urine was independent risk factor of longer hospitalization (difference 36.64 days, 95% confidence interval [CI] 27.24- 46.04, p < 0.0001) but not for 90-day mortality (hazard Ratio 1.79, 95% CI 0.43-7.50, p= 0.4242) and hospital mortality (odds ratio 2.47, 95% CI 0.59-10.34, p= 0.2154). Analysis of all patients showed similar results.

CONCLUSIONS. Isolated yeast from urine might predict longer hospitalization for liver transplant patients, but whether this was a causal or associational finding cannot be determined.

INTRODUCTION. In 2015, Catalonia began to require hospitals to follow protocols for the identification and early treatment of sepsis. However, there is controversy over whether a faster treatment of sepsis improves outcomes in patients.

OBJECTIVES. To evaluate the early recognition of patients with sepsis and septic shock in a Spanish university hospital.

To evaluate the compliance of the resuscitation bundle in the first 3h from the activation of the system and its association with hospital mortality.

METHODS. Prospective observational study in a tertiary hospital in Catalonia. The data were collected from December 2015 to December 2017 of patients with criteria of sepsis and septic shock at all levels of the emergency department (ED). Initial 3 hour bundle (lactate, cultures, and antibiotics) completion was evaluated as well as

fluid administration within the first 6 hours in those patients who presented hypotension or lactate >4 mmol/L.

RESULTS. 295 patients were collected with the activation system, 59.1% were male; 63.4% were activated at the advanced medical, 6.1% at the advanced surgical level, and 31.2% at the basic ED level. Patients were mostly medical (67.3%), respiratory sepsis as the first cause with 40%, followed by urinary sepsis 26.3%. 87.8% of patients required hospital admission, overall 22% at the intensive care unit (ICU). The average SOFA score was 8±2. Septic shock was developed in 22.5% of patients. Regarding compliance with the 3-hour bundle, in 80% of the patients lactate was obtained within the first 3 hours (overall mean time 174±422 minutes (min)), cultures were obtained within the first 3h (and previous to antibiotics) in 73% (overall mean time 314±1820 min), and antibiotics were started within the first hour in 27.7% with a (overall mean time 213±408 min). The complete bundle (3 measures) was completed in 82% of patients (mean time 307±830 min) and was performed in less than 3h in 61.4% of them. 64% had hypotension±lactate> 4mmol/L, 51% of them receiving correct fluid therapy (30mL/kg), with 32% of them finally requiring vasoactive support. Among patients who had the 3-hour Bundle completed within the first 12 hours from emergency admission, a longer time to complete the Bundle was not associated with higher in-hospital mortality. A linear association was observed between the delay in lactate determination within the first 12 hours and in-hospital mortality (p < 0.02), as well as an association between higher crystalloid administered within the first 6h (p < 0.001) and in-hospital mortality.

CONCLUSIONS. The measurement of early serum lactate seems to improve in-hospital survival. Patients with higher amounts of crystalloids administered with the first 6 hours seem to present a worst outcome. No survival improvement was observed in those patients who early completed the 3 hour bundle.

Impact of assignment of stroke specialist to the stroke care system on reducing in-hospital delay in reperfusion therapy

H.-K. Park[1], H.-J. Bae[2]
[1]Inje University Ilsan Paik Hospital, Goyang-si, Korea, Republic of; [2]Seoul National University Bundang Hospital, Seongnam, Korea, Republic of
Correspondence: H.-K. Park
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0356

INTRODUCTION. Efficacy of reperfusion therapies for acute ischemic stroke patients diminishes with the delay of time from symptom onset. However, the effect of the intervention with highly-skillful stroke specialist throughout the acute stroke treatment process on reducing the time delays in the hospital has not been evaluated yet.

OBJECTIVES. We evaluated the association of the assignment of the stroke specialist to the stroke care system with time intervals in stroke patients receiving reperfusion therapy.

METHODS. From a total of 7,358 patients who admitted to single tertiary referral stroke center in Korea between July 2007 and September 2015, we selected the subjects who arrived at hospital within 4.5 hours from symptom onset (N=2,100) with image-documented ischemic stroke cases (N=1360). We excluded cases who received reperfusion therapy at local hospitals and transferred to our hospital (N=10). The study hospital was designated as the regional cardiocerebrovascular center by the Ministry of Health and Welfare of Korea since January 2008. In addition to the pre-existing Stroke Critical Pathway Protocol that has been used for the quality improvement of stroke care, a stroke specialist was arranged to the acute stroke patients for immediate assessment and acceleration of whole process for stroke treatment. Included patients were divided into two groups according to the admission date [before 2008 (B2008) versus from 2008 (F2008)], and time intervals of study groups were compared.

RESULTS. Among the 1,350 included patients, 546 (40%) patients were treated with any reperfusion therapy [230 for intravenous thrombolysis (IVT), 73 for endovascular therapy (EVT), and 243 for both IVT and EVT (CMT)]. Compared with the B2008 group, the median door-to-needle time was shorter in the F2008 group in both patients receiving IVT alone (50 [40-73] vs. 31 [25-47], p< 0.01) and patients receiving CMT (50 [38-61] vs. 29 [24-39], p< 0.01). Door-to-puncture times were also significantly shorter in the F2008 group regardless of the use of IVT prior to EVT (116 [89-151] vs. 85 [66-110] in patients treated with EVT alone, and 113 [95-133] vs. 82 [68-98] in patients with CMT, all p-values< 0.01). Needle-to-puncture time in CMT showed 14 minutes reduction in the F2008 group (65 [48-81] vs. 51 [30-65], p< 0.01).

CONCLUSIONS. With intervention via immediate arrangement of stroke specialist and acceleration of the treatment process, it is possible to reduce the in-hospital waste of time.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0357

PURPOSE. Analyze clinical profile, complications and results of elderly patients, age equal to or older than 80 years, admitted to our unit with an acute ischemic stroke receiving reperfusion treatment.

MATERIAL AND METHODS. Prospective observational study of patients aged 80 years or older, admitted to our unit with an acute ischemic stroke with reperfusion treatment (thrombolysis, endovascular therapy or both) from December 2016 to December 2017.

Demographic data, cardiovascular risk factors, previous Rankin, baseline NIHSS, baseline ASPECTS, reperfusion treatment and times will be collected. If there is endovascular therapy, sedation management will be used, endovascular technique, TICI score, will be collected. As results: NIHSS at 24 hours and at hospital discharge, RANKIN at hospital discharge, symptomatic intracranial hemorrhage and in-hospital mortality. Statistical analysis with a basic descriptive with absolute and relative frequency, qualitative, mean and standard deviation, quantitative ones of normal distribution, and median and interquartile range otherwise; Comparisons with ANOVA.

RESULTS. We included 206 patients with stroke and reperfusion treatment in our unit, of which 61 (29%) were 80 or older. 74% of this elderly population were women, age 84.14 ± 3.28 years, cardiovascular risk factors in 96%. Basal NIHSS 14.31 ± 6.5. Basal ASPECTS ≥ 7 in 89.4%. Reperfusion treatment was only thrombolysis in 39%, thrombolysis plus thrombectomy in 20%, and only thrombectomy in 41%. The thrombectomy was performed in 62% under mechanical ventilation; combination of aspiration plus stent retriever was the most common technique used (58%), with a good flow as result in 80% (TICI 2B or 3). Symptoms / thrombolysis time 3 h ± 1 h 30 min and symptoms / reperfusion by thrombectomy 4 h 55 min ± 1 h 46 min. NIHSS at 24 hours after ICU admission was 7 [2, 12]. Length of stay in ICU was 1 day [1, 2], and hospital stay 13 [7, 19]. Results at discharge: RANKIN ≤ 2 in 11 patients (18%), RANKIN 3, 13 patients (21%), RANKIN 4-5, 30 (49%), mortality of 11% (7 patients). Symptomatic intracerebral hemorrhage occurred in 4 patients (6 %). There is a relationship between RANKIN at discharge, baseline NIHSS and NIHSS at 24 hours; thus, patients with RANKIN at discharge 0-2 had baseline NIHSS of 8.9 ± 4.3 and at 24 hours 3.36 ± 5.8; Patients with RANKIN

at discharge 3 had 10.6 ± 5.8 and 3.8 ± 3.15, respectively; patients with RANKIN at discharge 4-5, had 16.5 ± 5 and 10.9 ± 6.12, respectively; the deceased had 20.14 ± 7.4 and 20.6 ± 3.5, respectively. There is no relationship between RANKIN at discharge and time between onset of symptoms and administration of fibrinolysis or reperfusion with thrombectomy.

CONCLUSIONS. The results of ischemic cerebrovascular disease in the elderly population are still poor, although the introduction of endovascular treatment techniques offers an alternative treatment that allows to rescue and improve results in some of them.

Selective cerebral hypothermia is an effective component of neuroprotection in patients with ischemic stroke

B. Torosyan, A.V. Butrov, O.A. Shevelev, D.V. Cheboxarov, O.P. Artukov
RUDN University, Moscow, Russian Federation
Correspondence: B. Torosyan
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0358

INTRODUCTION. Ischemic stroke (IS) is one of the main causes of death and disability of the Russian working population and at present there are no known drugs with a proven neuroprotective effect.

OBJECTIVES. The purpose of our study was to evaluate the clinical efficacy of selective cerebral hypothermia(SCH) in the complex therapy of IS and its effect when used in long-term therapy.

METHODS. 113 patients were treated, which were divided into the experimental group (SCH administered) and control group (without SCH). Special helmets were used, which provides selective cooling of the head, while the core temperature did not decrease below 36 °C. To evaluate the temperature of the brain, a non-invasive microwave thermometer was used that could record the average temperature in a given tissue volume. The degree of neurologic deficiency was evaluated using the NIHSS scale, the degree of disability on the 90th day from the onset of the disease - according to the modified Rankin scale.

RESULTS. In the experimental group, there was a marked decrease in the level of neurologicaldeficit in the acute period after 24 hours of CCH (p < 0.01). Also, there was a decrease in the degree of disability by 0.6-0.9 points in groups with CCH. The mortality on the 90th day from the onset of the disease in the group of patients with severe and extremely severe neurologic deficit decreased by 28% (p < 0.01), in the group of patients with a deficit of less than 13 points according to the NIHSS scale, there were no significant differences. SCH has a pronounced therapeutic effect when applied in combination with standard treatment. It can be assumed that this effect is a consequence of the decrease in brain edema and the protection of the penumbra zone.

CONCLUSIONS. SCH can be considered as an effective technique for treating patients with IS and isrecommended for use in its complex therapy.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0359

INTRODUCTION. Aneurysmal subarachnoid hemorrhage (aSAH) patients may be exhibit neurocardiac injury (NCI) evidenced by elevated cardiac troponin I (cTnI), but the association between NCI and impact on early hemodynamics as evidenced by blood pressure (BP) monitoring parameters over the first day after admission is not well

established. Such information could help to inform about the consequences of elevated cTnI in these patients.

OBJECTIVES. We aimed to determine blood pressure trajectory groups in the first 24 hours after aSAH admission, and the relationship between systolic BP (SBP) and cTnI.

METHODS. Prospective analysis of 65 patients with aSAH. Inclusion criteria: age 21-75 years, spontaneous aneurysm rupture, Fisher grade ≥ 2 and/or Hunt and Hess grade ≥ 3, cTnI levels and recorded blood pressures in the first 24 hours after aSAH. Exclusion: traumatic SAH, and recent myocardial infarction. All blood pressures recorded in the medical record at the type (peripheral or intra-arterial) and frequency recorded were collected. The hourly peak (maximum) and hourly nadir (minimum) SBP obtained for each patient in each of their first 24 hours of admission was used in the trajectory analyses, performed with Proc Traj in SAS. The peak cTnI obtained on the first day of admission was utilized. The relationship between SBP and cTnI was performed using mixed model linear regression for the independent variable of cTnI to predict the dependent variable of hourly peak or nadir SBP.

RESULTS. From the 65 patients, two trajectory groups for each of hourly peak and nadir SBP were identified. The lower SBP trajectory group (Group 1) for both peak SBP (n=31) and nadir SBP (n=38) had higher mean cTnI levels (1.09±2.8ng/ml and 1.01±2.6ng/ml) respectively, while the higher SBP trajectory group (Group 2) for both peak SBP (n=34) and nadir SBP (n=31) had lower mean cTnI levels (0.47 ±1.1ng/ml and 0.49±1.1ng/ml respectively). The results of the mixed model linear regression revealed an inverse relationship between cTnI and SBP, with higher cTnI predicting both a lower hourly peak SBP (estimate -1.52, SE 0.6, p=0.24) and hourly nadir SBP (estimate -1.90, SE 0.62, p=0.003).

CONCLUSIONS. There is an inverse relationship between cTnI levels and SBP in the first day of aSAH admission, and patients with higher cTnI exhibit lower SBP trajectories. Clinicians should closely observe patients with elevated troponin to evaluate for potentially impaired perfusion.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0360

INTRODUCTION. Acute ischemic stroke (AIS) is one of the leading causes for both death and disability worldwide, and its prevalence increases with age.

OBJECTIVES. To compare mortality and neurological status at 6 months of three different age groups ($\leq$65, 66-79 and >80 years) of acute ischemic stroke (AIS) patients and to study if there are any disparities regarding thrombectomy application and destination upon discharge.

METHODS. Retrospective and observational study in a Spanish tertiary university hospital (October 2013 to September 2016). We included all AIS patients admitted to our ICU who received either intravenous thrombolysis (IVT), endovascular thrombectomy (TRB) or both. Neurological status was assessed at six months with the modified Rankin scale (mRS), defining good outcome as a mRS of 0-2, and functional dependency as a mRS $\geq$ 3.

Statistical analysis: χ^2 test (categorical) and logistic regression or ANOVA (multivariate analysis).

RESULTS. During the period of study, a total of 164 patients with an AIS diagnosis and treated either with IVT and/or TRB were admitted to our ICU. After subdividing by age, 42% (69) were $\leq$65, 37% (60) between 66-79 and 21% (35) $\geq$80 years old. *Table 1* describes demographic data and general characteristics.

Crude six-month mortality according to age group was 6.7% (4), 25% (14) and 21% (7) respectively (p = 0.02), an association that was lost after adjusting by APACHE II (OR 1.6; IC95 0.81-3.22; p=0.179)

When analysing the neurological outcome at six-months, 70% (42) of our younger patients had a good outcome (mRS 0-2), decreasing to 54% (30) in the 66-79 years-old group and to 29% (10) in those > 80 years (p=0.01; *Graph 1*). This association was maintained after adjusting by initial NIHSS and previous mRS [(OR 2.5; IC95 1.52-4.32; p< 0.001).

We found no differences in TRB rates regardless of age group (p=0.154).

The percentage of patients who required an admission in a rehabilitation facility upon discharge was significantly higher for the $\geq$ 80 years-old group than for the $\leq$ 65 [55% (17) vs. 25% (16); p=0.011].

Results are summarized in *Table 2*

CONCLUSIONS. In our series, after adjusting by severity index, age did not act as a risk factor for mortality. However, it was associated with a poorer neurological outcome at six-months, a higher disability rate and, consequently, an increased need for admittance in a rehabilitation facility upon hospital discharge.

According to our results we think that age should be taken into account as a prognostic factor when treating patients with AIS, especially those above 80 years of age.

Frequency of brain death in acute cerebrovascular disease related mortality

M.A. Qureshi, M.R. Afzal, R. Khatri, P. Piriyawat, A. Maud, G.J. Rodriguez, S. Cruz-Flores, A.R. Vellipuram
Texas Tech University Health Sciences Center, Neurology, El Paso, United States
Correspondence: A.R. Vellipuram

BACKGROUND. Despite the frequent occurrence of brain death in intensive care unit, the prevalence rate of brain death in ischemic stroke (IS), intracranial hemorrhage (ICH) and subarachnoid hemorrhage (SAH) is not known at national level. In addition the prevalence of cardiac arrest in these patients is not established.

DESIGN/METHODS. From 2012, ICD-9-CM includes a specific code for brain death (348.82). Brain death patients were identified from the nationwide in-patient sample database for the years 2012 to 2014. Associated in-hospital cardiac arrest patients were also identified under each category. Demographics, medical comorbidities, in-hospital complications, procedures, length of stay and hospital charges were compared.

RESULTS. Rate of brain death was highest in SAH related mortality (21.8%, 3190 brain deaths/ 14620 in-hospital mortality), followed by ICH,

(11.5%, 6950 brain deaths/ 60475 in-hospital mortality) and ischemic stroke (3%, 1790 brain death/62285 in-hospital mortality). Majority of the patients had brain death secondary to neurological insult (ICH n=5260, 91.3%; SAH 2625 (80.6%) and IS n=1640, 89.1%) without any secondary diagnosis of in-hospital cardiac arrest.Length of stay was shorter in patients with SAH and ICH (mean 2.92 ± 4.1 days and 2.57 ± 4.2 days respectively) compared to IS patients (mean 4.93 ± 10.2 days, p < 0.001) suggesting brain death is an early event in hemorrhagic stroke.

CONCLUSION. Brain death in the majority of cerebrovascular patients occurs as a result of primary neurological insult without associated cardiac arrest. It occurs much earlier in hemorrhagic stroke compared to ischemic stroke.

Impact of hyperoxia and hypocapnia on neurological outcome in patients with aneurysmal subarachnoid hemorrhage

K.C. Li, C.W.Y. Tam, H.P. Shum, W.W. Yan
Pamela Youde Nethersole Hospital, Department of Intensive Care, Hong Kong, Hong Kong, China
Correspondence: K.C. Li

INTRODUCTION. Aneurysmal subarachnoid hemorrhage (SAH) accounts for 80% of non-traumatic SAH and has high rates of death and complications.Hyperoxia and hypocapnia are associated with poor outcomes in critically ill patients with brain injuries or post-cardiac arrest status due to the independent cerebral vasoconstrictive effect. Yet, the impact of hyperoxia and hypocapnia on neurological outcome in patients with aneurysmal SAH has not been well studied.

OBJECTIVES. We aim to evaluate the impact of hyperoxia and hypocapnia on neurological outcome in patients with aneurysmal SAH.

METHODS. Patients with aneurysmal SAH who were admitted to intensive care unit from January 2011 to December 2016 were included into this retrospective single center study in a regional hospital in Hong Kong. Patients' demographics, comorbidities, radiological findings and clinical grading of SAH, PaO_2 and $PaCO_2$ level, Glasgow Outcome Scale (GOS) at 3 months were recorded. Logistic regression analysis was performed to assess independent predictors for poor neurological outcome, which was defined as GOS 1-3 at 3 months after initial insult.

RESULTS. Among 244 patients with aneurysmal SAH, 50% (122 patients) had poor neurological outcome at 3 months. Compared with those patients with good neurological outcome (GOS 4-5 at 3 months), patients with poor neurological outcome were older, had higher APACHE IV score, WFNS grade and Fisher grade, lower Glasgow Coma Scale (GCS) on day 1 and more likely to have intracranial or intraventricular hemorrhage (ICH/IVH). Hyperoxia (PaO_2 >200mmHg) and hypocapnia ($PaCO_2$ < 30mmHg) were more common among those with poor neurological outcome at 3 months. Logistic regression analysis indicated that hyperoxia (OR 3.698, 95%CI 1.167-11.718, p=0.026), APACHE IV score > 50 (OR 5.172, 95%CI 2.348-11.393, p< 0.001), age > 55 (OR 4.113, 95%CI 1.871-9.039, p< 0.001), presence of ICH/ IVH (OR 3.812, 95%CI 1.658-8.764, p=0.002), aneurysm involving posterior circulation (OR 3.643, 95%CI 1.454-9.172, p=0.006), Fisher grade > 2 (OR 3.555, 95%CI 1.472-8.586, p=0.005), and WFNS grade > 3 (OR 2.986, 95%CI 1.282-6.955, p=0.011) independently predicted poor neurological outcome at 3 months. On the other hand, patients who had underwent interventional radiological procedure treatment was shown to have better outcome (OR 0.375, 95% CI 0.167-0.843, p=0.018).

CONCLUSION. Hyperoxia but not hypocapnia was associated with poor neurological outcomes at 3 months in patients with aneurysmal SAH.

INTRODUCTION. Mortality in acute stroke patients requiring ICU admission is high and seems to occur in the short-term (1, 2). Recent studies have limitations that may impact accurate identification of indicators of outcome, including single-center design and lack of adjustment for early decisions to forgo life-sustaining treatment (DFLST).

OBJECTIVES. To determine the predictive value of clinical parameters upon ICU admission for 30-day mortality in acute stroke patients admitted to the ICU and requiring invasive mechanical ventilation.

METHODS. We conducted a retrospective analysis of the French prospective multicenter OUTCOMEREA database over a 20-year period (1997-2016). We included all adult stroke patients admitted to the ICU who required invasive mechanical ventilation at any time during ICU stay. Patients with traumatic brain injury or cerebral thrombophlebitis were exluded. Primary outcome was mortality at 30 days after ICU admission. Clinical predictors of 30-day mortality were investigated using a Cox proportional hazard model. Data are presented as median (interquartile range) or numbers (percentages).

RESULTS. We identified 444 patients (age 68 (58-76) years, male gender 264 (59.5%) patients) from 14 ICUs. On ICU admission, the Glasgow coma scale score (GCS) was 6 (4-9) and the Simplified Acute Physiology score 2 (SAPS 2) score was 58 (46-71). Overall, 425 (95.7%) patients were intubated during the first 48 hours. Patients required vasopressors in 211 (47.5%) cases, and renal replacement therapy in 28 (6.3%) cases. DFLST occurred 3 (1-8) days after ICU admission in 152 (34.2%) patients. Withholding of care and withdrawal of care were observed in 69 (15.5%) and 83 (18.7%) cases, respectively.

At day 30, 285 (64.2%) patients had died, 133 (46.7%) of which had had a prior DFLST. Day-30 mortality according to stroke subtype was 34/52 (65,4%) for SAH, 139/187 (74.3%) for hemorrhagic stroke and 112/205 (54.6%) for ischemic stroke.

Univariate and multivariate analyses of factors associated with mortality are presented in Table 1. Factors independently associated with 30-day mortality were hemorrhagic stroke and SAH as compared to ischemic stroke, a lower GCS score on admission and a higher modified SAPS 2 (calculated without the neurological component).

CONCLUSIONS. In this large cohort of mechanically ventilated patients with acute stroke, prognosis was poor, with one third of the patients alive at day 30. Early mortality seems mainly driven by the type of stroke, neurological presentation and the intensity of non-neurologic organ failure, irrespective of DFLST. Functional outcomes in survivors should investigated in further studies.

Incidence, diagnosis and burden of sepsis on subarachnoid haemorrhage

B. Gonçalves[1], R. Turon[1], N. Melo[1], P. Lacerda[1], T. Santos[1], M. Prazeres[1], F. Miranda[1], P. Kurtz[1], F. Bozza[2], C. Righy[1]

Correspondence: F. Bozza
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0364

INTRODUCTION. Aneurysmal subarachnoid haemorrhage (SAH) is an acute, and often catastrophic, cerebrovascular event, with high mortality and morbidity. One characteristic of the disease is the intense systemic inflammatory response, occurring in up to 83% of patients. There are few studies regarding the prevalence of systemic inflammatory response syndrome (SIRS) and sepsis and its association with outcomes.

OBJECTIVES. Our goal is to describe the outcomes on septic and non-septic group of patients with SAH, and the role of biomarkers on the diagnosis of sepsis.

METHODS. From April 2016 to January 2018, all consecutive patients admitted to the Neuro ICU of Paulo Niemeyer State Brain Institute with aneurysmal SAH were enrolled in our cohort. Clinical and laboratory data were collected during the first 14 days of hospital stay. The primary endpoint was mortality, dichotomized functional outcome (poor outcome defined as Modified Rankin Scale 4-6) at hospital discharge, and the diagnosis of SIRS and sepsis, according to the most recent criteria (Sepsis 3). We also analyzed the incidence of sepsis discarding the neurological component of the SOFA score, since SAH itself can be the cause of neurological dysfunction. Numeric were assessed using Mann-Whitney U-test and endpoints assessed with Chi-square test.

RESULTS. A total of 128 patients were enrolled in the study. Demographic characteristics are detailed on table 1, and baseline characteristics on table 2.
Among all patients, 106 patients (85%) developed SIRS. The incidence of infection was 82% (102 patients).
Using the current definitions (Sepsis 3), 65 (51%) patients had the diagnosis of sepsis. Excluding neurologic SOFA, the incidence of sepsis was 44%.
Mortality was 25% on the septic group and 5% on the non-septic group (p=0.001). Poor outcome occurred on 71% of the septic group and 10% of the non-septic group (p=0.00001).
Both analyzed biomarkers, procalcitonin and C reactive protein, were higher on the septic group on days one and three after admission. Results are detailed on table 3, expressed as mean (range).

CONCLUSIONS. Our data confirm the hypothesis that SAH is a highly inflammatory disease, with a large proportion of patients developing SIRS. In this cohort of patients with SAH, mortality, and mainly poor-outcome were more frequent in the sepsis group. Both procalcitonin and CRP were higher in septic patients, which could aid the differential diagnosis and prompt early treatment of patients at high risk of sepsis.

The effect of daily fluid balance on mechanical ventilation in the subarachnoid hemorrhage patient population in the ICU

A.B. Kumar[1], O.K. Katan[1], S.R. Mehr[1], Y. Shi[2], M. Shotwell[2]
[1]Vanderbilt University Medical Center, Anesthesiology and Critical Care, Nashville, United States; [2]Vanderbilt University Medical Center, Biostatistics, Nashville, United States
Correspondence: A.B. Kumar

INTRODUCTION. A net positive fluid balance is associated with less ventilator free days and worse outcomes in intensive care patients especially in ARDS. The fluid prescription in post intervention aneurysmal subarachnoid hemorrhage (SAH) deviates from fluid management strategies of the general postoperative patient. Hypovolemia is a known risk factor for severe symptomatic vasospasm and frequently hypothalamic dysfunction and cerebral salt wasting syndromes compound fluid management in SAH patients.

OBJECTIVES. To evaluate the effect of daily fluid balance on pulmonary status and MV in the SAH population.

METHODS. This is an IRB approved retrospective cohort study of 726 ICU admissions for subarachnoid hemorrhage at Vanderbilt University Medical Center, a level-1 trauma and stroke referral center, between Jan 06 -Dec, 2012. We followed the patients for 14 days (vasospasm risk window) or discharge, whichever came earlier. The majority of patients had aneurysmal SAH of all Hunt and Hess Classifications. The primary outcome was the effect of fluid balance in the past 24 hours on mechanical ventilation (MV) the following day. We fitted a transition model using logistic regression to examine the association between MV and net fluid balance from the previous day conditional on patient age, gender, body mass index, diabetes mellitus, daily minimum sodium level and mechanical ventilation. All analyses were implemented using R 3.3.0 (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS. Out of 726 admissions with SAH, 399 (55%) required MV. 275 (69%) of patiets presented on MV at admission. Those requiring MV were more likely to have traumatic SAH at presentation (22% vs 13%, $p < 0.002$), were more likely to have a lower Glasgow Coma Score (11 vs 15, $p < 0.001$), and were more likely to have acute kidney injury (12% vs 5%, $p < 0.001$). The cumulative fluid intake for those requiring MV was significantly higher than for those not requiring MV (33,665mL vs 20,518mL, $p < 0.001$), although the net fluid balance was lower (-680mL vs 0mL, $p=0.03$). For patients that were not on MV, each additional 1000mL of fluid loss was associated with 25.8 percent (95% CI: 17.4 - 33.4, $p < 0.001$) reduction in the odds of needing mechanical ventilation the following day. For patients already requiring MV, there was no significant effect of fluid loss on continuing to require MV the following day, likely highlighting the neurological status as a key determinant in the evaluation of extubation.

CONCLUSIONS. The effect of fluid balance is more pronounced in the non-intubated SAH patient with a negative fluid balance decreasing the odds of requiring MV the following day.

Perimesencephalic subarachnoid haemorrhage: is there enough evidence to change our attitude?

S. Dias[1], R. Moreno[1,2]
[1]Hospital de São José, Centro Hospitalar Lisboa Central, Unidade de Cuidados Intensivos Polivalentes Neurocríticos, Lisboa, Portugal; [2]Nova Medical School (Universidade Nova de Lisboa), Lisboa, Portugal
Correspondence: S. Dias

INTRODUCTION. The heterogeneity of angiogram negative subarachnoid haemorrhage (SAH) patients is well established after Van Gijn et al (1985) first described the "benign" perimesencephalic (PM) form. Since then several studies have shown distinct prognoses for different forms of SAH. Nevertheless, guidelines focused on angiogram negative SAH are still missing and we treat all SAH patients roughly the same way.

OBJECTIVES. To analyse the outcomes and neurologic complications of PM-SAH and to assess the possibility of differentiated treatment.

METHODS. A systematic literature review was performed using PubMed to search for clinical studies describing outcomes and neurologic complications of PM-SAH patients in the last 6 years. Search terms included "subarachnoid haemorrhage", "subarachnoid hemorrhage", "perimesencephalic", "unknown cause", "unknown origin", "unknown etiology", "nonaneurysmal", "idiopathic", "angiogram negative".

RESULTS. We found 16 relevant studies (repeated cohorts and works that did not analyse separately the subgroups of angiogram negative SAH were excluded), all retrospective, that collected data since 1980, with a total of 727 PM-SAH patients.

The proportion of PM-SAH (*versus* diffuse) patients is highly variable (graph 1) which may be explained by inconsistency in establishing the diagnosis in different centres.

All studies report at least 95% of World Federation of Neurological Surgeons grading of I-III or 83,3% of Hunt and Hess I-II for PM-SAH patients.

Different definitions of vasospasm are used: 3 studies use Doppler measured velocity, 6 studies use angiography with variable and subjective criteria, and the others did not clarify the criteria used. 10 studies add clinical criteria but these are also variable. Prat *et al* reported the largest proportion of patients with radiological vasospasm (42,9%) but 0% of clinical vasospasm. Konczalla *et al* reported the largest proportion of patients with clinical vasospasm (12%) but only 1% of vasospasm dependent infarction.

Hydrocephaly was diagnosed using clinical criteria in some studies and radiological criteria in others. The largest proportion of patients with hydrocephaly requiring treatment is reported by Sahin *et al* (20,8%).

None of the studies reports seizures in PM-SAH patients.

The only two studies (Lin et al, Sprenker et al) that focused on the protocol of treatment of these patients suggest early discharge of the ICU.

CONCLUSIONS. Although several studies address the outcomes of PM-SAH patients, they lack consistency and neurologic complications may be overestimated. Nevertheless, in most studies the PM form of SAH seems to be a benign subtype and thus it could probably be treated outside the ICU. Prospective multicentric studies are needed to establish the correct prognosis of this disease to avoid medical complications in these patients and for a better use of limited resources.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0367

OBJECTIVE. In-hospital complications following acute neurological injury has been a topic of extensive research to help reduce the morbidity and mortality among the patients. However the incidence and prevalence of in-hospital infections following acute neurological injury at the national level has never been studied. The aim of our study is to determine the frequency and prevalence of in-hospital complications among different patient groups admitted following acute neurological injury.

DESIGN/METHODS. We identified patients with primary diagnosis of ischemic stroke (IS), subarachnoid stroke (SAH), intracerebral hemorrhage (ICH), status epilepticus (SE), meningitis, encephalitis and traumatic brain injury (TBI) from nationwide inpatient database (2011-2014) through using the respective ICD- 9 codes. Common in-hospital complications among the above mentioned diagnoses through using their respective ICD-9 codes

RESULTS. Patients with primary diagnoses of IS (n=1855297), SAH (n=101576), ICH (n=254758), SE (n=190701), Meningitis (n=46067), Encephalitis (n=23839), TBI (n=1142155) were identified. In-hospital events such as myocardial infarction (MI), sepsis, pneumonia, deep venous thrombosis (DVT), pulmonary embolism (PE), urinary tract infections (UTI), and GI bleed were identified and compared among different patient groups. Patients with SE were noted to experience higher systemic complications, MI (3.6%), sepsis (11.2%), pneumonia (8.6%), DVT(1.7%), UTI (16.2%), GI bleed (0.41%). Patients admitted with meningitis had higher incidence of sepsis (20.5%), pneumonia (9.0%), DVT (2.2%), PE (1.5%) and UTI (12.7%) compared to the other groups. UTI was the most common in-hospital complication observed.

CONCLUSIONS. Based on our analysis, we report higher incidence of urinary tract infections among all patients admitted following acute neurological injuries. Patients with primary diagnosis of status epilepticus experienced more systemic complications compared to the other diagnoses.

Some characteristics of hormonal status in patients in the acute period after spontaneous intracerebral hemorrhage

L. Tsentsiper, N. Dryagina, A. Kondratyev
Russian Polenov Neurosurgery Institute, Aneasthesiology and Intensive Care, St Petersburg, Russian Federation
Correspondence: L. Tsentsiper
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0368

INTRODUCTION. The incidence of spontaneous intracranial hemorrhage (SICH) in the world according to different authors is between 1.5 and 2 million a year. SICH is associated with an increased risk of endocrine dysfunction. In our opinion, the determination of neuroendocrine disorders in the acute period of various Genesis of SICH will allow to assess the adequacy of the therapy, including aimed at neurovegetative stabilization, timely correction of hormonal insufficiency and improve the quality of life of patients.

OBJECTIVES.
1. To assess hormonal disorders in patients in the acute phase of spontaneous intracranial hemorrhage.
2. A comparative evaluation of hormonal status during and post sedation.
3. To identify their prognostic significance revealed neuroendocrine changes.
4. Comparative analysis of hormonal status in patients after rupture of arterial aneurysm, AVM genesis and spontaneous hypertensive intracerebral hemorrhage.

METHODS. This study included 58 patients aged 13 to 72 years. We studied the levels of ACTH and cortisol in the morning and the evening, TSH, FT3 and FT4, prolactin, GH, men determined LH, FSH, testosterone. GCS; rating on a scale of Hunt and Hess patients with arterial aneurysm rupture were consistent with points 2-4, 2-4 class Fischer scale. All patients were subjected to sedation and analgesia (further in this article "sedation") as therapeutic narcosis - opioid analgesic fentanyl 0.5-1 µg/kg/ h, alpha 2-adrenergic agonist clonidine 0.2-0.5 µg/kg/ h, sodium thiopental 2.4 µg/kg/ h. for the duration of 3 to 9 days.

RESULTS. The endocrine status of the patient was estimated depending on the functional state of the patient at the sedation and post sedation period. Our results indicate lower activity of the PAS, PTS for patients under sedation. Our studies conducted within 28 days after a SICH revealed no signs of hormonal deficiency requiring correction in the acute period.
Therapeutic sedation limits the severity of the stress response indicating that patient in sedation period had ACTH and cortisol levels lower than in post- sedation period.

CONCLUSIONS.
· The hormone response to intracerebral hemorrhage is different in patients after aneurysmal SAH and intracerebral hemorrhages of hypertensive genesis and caused by AVM rupture, the latter had more pronounced HP activation.
· Patients with acute spontaneous intracerebral hemorrhage were diagnosed with pituitary-adrenal system hyperfunction with daily secretion rhythm irregularities.
· Patients with negatiTve outcome in both groups during post-sedation period had more evident pituitary-adrenal system hyperfunction than those with positive outcome.
· Patients with negative outcome in both groups had FT3 level reduction (34-45%).
· After SICH men developed hypogonadotropic hypogonadism.

INTRODUCTION. The development of stress hyperglycemia is one of the manifestations of the severity of the critical state. It is also known that the presence of diabetes mellitus is one of the aggravating factors affecting the course of ischemic stroke and its outcome.
OBJECTIVES. To assess the incidence of 1 and 2 types of diabetes mellitus and the frequency of development of stress hyperglycemia in patients with ischemic stroke.
METHODS. A prospective observational study was conducted in patients with ischemic stroke, who were admitted to the NICU of the Krasnoyarsk Regional Hospital during one month (the month was randomly selected). The 88 patients were included in the study. the patients were divided into 2 groups: 1 group - surviving patients (78 patients) and 2 group - died patients (10 patients). The age of patients in 1 group was 66.1 ± 10.9 years and 2 group 71.5 ± 14.8 years ($p \leq 0.05$). Patients were assessed the presence and type of diabetes mellitus in history, the level of glycemia determined by an emergency team of Ambulance, in the 1st, 3rd and 5th day. Control of blood sugar was carried out at least 6 times a day with its correction by the introduction of Insulin.
Data are given in the form M [25%; 75%], absolute values and percentages. A statistical check for the parametric data was carried out using the Mann-Whitney criterion, non-parametric χ-test data using the IBM STSS v.20 program. The changes were considered statistically significant at $p \leq 0.05$.
RESULTS. Patients of the 1st group had a history of diabetes of type 2 in 18 patients (23%), there was no data for type 1 diabetes. In the 2nd group of patients, there was not history of the presence of diabetes so 1 type as 2 type ($p \leq 0.05$). The number of patients with elevated blood sugar levels than the reference values was higher 1 in group - 25 (32%) patients and in 2 group - 4 (40%) patients ($p \leq 0.05$). The values of blood sugar at the study stages are presented in the table (Table 1).
The patients in 2 group had a statistically significant higher level of blood sugar at all stages of the study compared with patients in 1 group, although there were no patients in the 2nd group who had a history of diabetes.
CONCLUSIONS. The development of stress hyperglycemia is typical for patients with severe stroke. At the same time, we did not find the effect of having a history of diabetes mellitus on the outcome of the disease.

Table 1 (abstract 0369). Blood sugar level, mmol/l, M [25%; 75%

	Ambulance	1 day	3 day	5 day
1 group	8.3 [4.1; 10.3]	4.1 [3.9; 5.1]	5.1 [4.8; 5.6]	5.2 [4.8; 6.8]
2 group	10.2 [5.8; 12.1]	5.3 [4.5; 7.4]	7.6 [5.9; 9.1]	7.7 [6.1; 9.5]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0370

INTRODUCTION. Inflammation plays a central role in secondary brain injury. Neutrophil-to-lymphocyte ratio (NLR) is an inflammation marker.
OBJECTIVES. The aim was to assess the relationship between NLR and poor outcome.
METHODS. Between January 2007 and October 2017, 102 patients with supra-tentorial ICH within 24 hours of onset of symptoms were admitted. On admission we recorded patient characteristics, clinical and laboratory findings, radiologic features and functional neurologic outcome. Poor outcome was defined as a Glasgow Outcome Scale (GOS) ≤3 at hospital discharge.The logistic regression model was used to identify if NLR was independently associated with poor outcome, including variables which showed a p value ≤0.2 and NLR regardless of the value of p.
RESULTS. From 102 patients admitted to intensive care unit due to acute ICH, 71 presented a poor outcome. Multivariate model was constructed by: APACHE II (p = 0.01), age (p = 0.05), Glasgow Coma Scale (p< 0.001), white blood cells counts elevated (p= 0.02), hyperglycaemia (p< 0.001), hipomagnesemia (p= 0.17), NLR (p= 0.34) and normal pupils (p= 0.04). There was no relation between NLR and poor outcome (p=0.55) in the multivariate model. Instead, we found an association between hyperglycaemia and older age with the end point (p=0.02 and 0.04, respectively).
CONCLUSIONS. We found no relationship between NLR and poor outcome in patients with ICH.

INTRODUCTION. Hyperventilation and hypocapnia lead to a cerebral vasospasm. Severe hypocapnia may be accompanied by a disturbance of cerebral blood flow in critically ill patients with non-traumatic subarachnoid hemorrhages (SAH)
OBJECTIVES. To determine the effect of severe hypocapnia on the outcomes in critically ill patients in acute period of non-traumatic SAH after cerebral aneurisms rupture
METHODS. 85 patients in acute period of SAH who required invasive mechanical ventilation for more than 6 hours after operations enrolled in the study. Mean age was 51±12 years, male/female - 44/41. The patients with grade II on Hunt-Hess scale were 18 (21.2%), grade III - 47 (55.3%), grade IV - 16 (18.8%), grade V - 4 (4.7%). 17 patients (20%) were with grade III on the Fisher scale, 68 patients (80%) - grade IV. Good outcomes on Glasgow Outcome Scale (GOS 1-2) were in 43 patients (50.6%), severe neurologic deficit (GOS 3) - in 7 patients (8.2%), poor outcomes (GOS 4-5) - in 35 patients (41.2%).
RESULTS. Medians of the $PaCO_2$ levels did not differ between the groups of patients: GOS 1-2 - 32 (28.1;36.2) mmHg, GOS 3 - 33.1 (28.8;34.5) mmHg, GOS 4-5 - 32.2 (28.6;36.4) mmHg. Episodes of $PaCO_2$ reduction to 33 mmHg and less were detected in 29 patients (67.4%) in the GOS 1-2 group, in 5 patients (71.4%) in the GOS 3 group, in 26 patients (74.3%) in the GOS 4-5 group. Severe hyperventilation ($PaCO_2 < 30,1$ mmHg) in 1-2 days after surgery were most often observed in patients with poor outcomes (GOS 4-5), in 21 patients (60%). Severe hypocapnia was noted in 18 patients (41.9%) in the GOS 1-2 group and in 3 patients (42.9%) in the GOS 3 group.
CONCLUSIONS. Frequency of severe hypocapnia ($PaCO_2 < 30.1$ mmHg) in 1-2 days after surgery in patients with SAH with poor outcomes (GOS 4-5) higher on 18.1% compared patients with good outcomes (GOS 1-2). Severe hypocapnia in acute period of SAH is one of predictors of poor outcomes in patients with high risk of cerebral vasospasm.

Correspondence: M. Wepler

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0372

INTRODUCTION. A major cause of TBI in particular in the elderly and/or cardiovascular co-morbid patient is acute subdural hematoma (ASDH) [1]. Therefore, we established a long-term, resuscitated porcine model of ASDH-induced TBI in human-sized pigs comprising brain multimodal monitoring.

METHODS. Eleven adult, anesthetized, mechanically ventilated and surgically instrumented pigs (body weight 65±8 kg) with human-like coagulation [2] underwent TBI induced by trepanation above the left parietal cortex and subdural injection of 20 mL of blood [3]. After induction of ASDH swine underwent intensive care therapy according to the guidelines of TBI management [4] for up to 54h. Monitoring included measurement of carotid flow (Doppler ultrasound probe), intracranial (ICP) and cerebral perfusion pressure (CPP), cerebral tissue O_2 partial pressure ($PtcO_2$) and intracerebral tissue metabolites (micro-dialysis for glutamate, lactate, pyruvate, glucose) together with systemic hemodynamics, gas exchange, acid-base status, and metabolism. Crystalloid fluid resuscitation and continuous i.v. norepinephrine was titrated to maintain mean arterial pressure (MAP) at pre-ASDH levels and CPP > 75 mmHg. Every 12h, after reduction of anesthetic depth, the veterinary modified Glasgow Coma Score (MGCS, range 3-18) [5] was used for neurological assessment. Immediately post-mortem, the brain was harvested for immune blotting, histology, and immunohistochemistry.

RESULTS AND CONCLUSION. In n = 9 of n = 11 swine, experiments could be carried out for 54 h and maintenance of target MAP and CPP was associated with normal tissue metabolite concentrations and, ultimately, normal MGCS (13 ± 2). In 2 animals, secondary cardiovascular failure unrelated to the neurosurgical instrumentation caused a marked drop of CPP resulting in neurological failure, ultimately necessitating termination of the experiments.

Hygiene and safety for both your patient and yourself: how to improve the compliance with three of the five moments of hand hygiene on the ICC unit of the VU Medical Centre?

R. Al, A. van Wijk, S. Evelein-Brugman, T. van Galen

VU University Medical Center, Intensive Care, Amsterdam, Netherlands

Correspondence: R. Al

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0373

INTRODUCTION. Healthcare related infections have a severe negative influence on morbidity and mortality rates in intensive and Critical Care(ICC) units. The most simple and effective way to prevent cross-infections is by practicing hand hygiene[1]. Guidelines[2]for hand hygiene have been available for years, yet compliance remains poor. Recent studies [3]show that healthcare workers practice hand hygiene in less than 40% of the 5 moments for hand hygiene. This suggests that healthcare related infections can be lowered by 40-50% if compliance improves. Over the years '14-'17 we conducted surveys on healthcare workers in the ICC unit of the VUmc where the mean compliance with the 5 moments rose from 39%('14) up to 54%('16). The goal of VUmc is a mean compliance of >80%.

OBJECTIVE. Which barriers are present for achieving > 80% hand hygiene compliance with the 5 moments at our ICC?

METHODS. We performed a multimodal approach. Firstly, we trained the healthcare workers regarding the 5 moments for hand hygiene. We organized an Hand Hygiene Day(HHD) on the ICC unit, in which we made the healthcare workers aware of the 5 moments for hand hygiene. We monitored the compliance with 3 of the 5 moments by scoring on an application and giving direct feedback. In follow-up compliance of hand hygiene was measured by one hour of weekly floor surveillance. In addition to the HHD and surveillance, we also conducted quantitative research of the population of intensive care nurses by handing out surveys regarding their opinion and work flow on hand hygiene.

RESULTS. We found that even with an optimum in support and coaching, compliance with the 3 surveyed moments for hand hygiene during the Hand Hygiene Day was 89% among the healthcare workers in the ICC unit. The ongoing monitoring after the HHD indicates that compliance with moment five is the best, whereas moment one is poor and hand hygiene before a clean or aseptic procedure and requires attention.

The mean compliance with the five moments a month after is 64%, which is a 10% increase compared to the results obtained prior to the HHD.

CONCLUSIONS. Improving compliance with the 5 moments of hand hygiene can be achieved by implementing multimodal strategies[4,5] such as actively addressing compliance, increased awareness by education, instruction and coaching. These to help healthcare workers gain insight into workflow barriers and imperfections in compliance. A striking observation is the impossibility for achieving 100% hand hygiene even with 1 to 1 supervision. We would suggest additional likely beneficial measures. These include easier access to proper material as well as using a combination of general hygiene measures and isolation guidelines per patient.

The question remains, can we maintain this compliance with our strategy?

Effects on oral intake by supporting HDU patients with a nutrition assistant

A.J.M. Dobber-Lambalk, A.P. Bouterse-Dekker, T. van Galen

VU University Medical Center, Intensive Care, Amsterdam, Netherlands

Correspondence: A.J.M. Dobber-Lambalk

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0374

INTRODUCTION. Malnutrition is a problem for 25% up to 40% of patients. Therefore a good nutritional status is important for reducing complications, LOS and mortality[1, 2]. At the intensivist led HDU we agreed all (ICU step down) patients are at risk of malnutrition due to disease, metabolic need, muscle atrophy and reduced oral intake or disturbed appetite. Although feeding guidelines are clear, achieving an optimum nutritional status in daily practice is difficult[3, 4]. Due to a busy workflow HDU nurses are not always able to prioritize oral nutrition above other tasks.

OBJECTIVES. To clarify if oral intake improves by embedding a nutritional assistant (NA) at the HDU ward.

METHODS. Most HDU patients start with tube feeding at the ICU. Often HDU patients receive tube feeding balanced with oral

intake. HDU nurses perform daily screenings and evaluate this with the doctor and dietitian. The NA makes multiple rounds per day, provide meals/snacks that are as close to the patients flavor and appetite and stimulates the patient to eat or drink. Before the NA started, oral nutrition was served by the HDU nurse, but usually without structured stimulus or checking of actual intake.

Two periods were selected: one year before and after start of the NA. Registration methods stayed the same. Because the NA only works during daytime (8:00-16:00), we only included meals and snacks that were consumed during these hours. The collected data was cleared up from all with exception of protein containing meals or snacks with a minimum of 5 grams of protein. Providing at least 5 grams of protein per meal or snack is one of our basic nutritional goals. For all energy and/or protein deficit that remains, there is supplemental (nightly) tube feeding.

RESULTS. With no major changes in HDU casemix and no major changes in staffing as well as nursing workflow, the oral protein intake increased with almost 30% after embedding the NA.

CONCLUSIONS. We believe embedding a nutrition assistant contributed strongly to our increase in oral protein intake. Although most of the energy intake is provided by tube feeding, the increase in oral intake is tangible. With an increased protein intake, we think it's plausible that the overall oral energy intake increased, although in this study we only focused on protein intake. We did not measure an improved nutritional status for all admitted HDU patients, but this study showed us that a dedicated assistant is able to stimulate patients to eat more and/or better in a way that also supports nurse care.

INTRODUCTION. Patients in the intensive care unit are at increased risk of potential drug interactions due to the complexity of pharmacotherapy and the restriction of routes of administration.

OBJECTIVES. This study aimed to determine whether immediate improvements in knowledge of incompatibilities and drug interactions in ICU are maintained at 3 and 6 months after training for nurses with different levels of experience.

METHODS. Twenty-six ICU nurses from different levels of experience completed a training course on incompatibilities and drug interactions in intensive care by resuscitators and pharmacists. This training included lectures, experimental lab sessions and clinical case analysis. Each nurse was assessed before, after, at 3 and 6 months using a previously validated scale. The clinical impact of this training was judged from the register of pharmacovigilance declarations.

RESULTS. Nurses´ knowledge scores improved after training (42% vs. 94%, p < 0.05). Three months after the training there was an apparent decline in knowledge but an overall improvement over the baseline test (42% vs. 79%, p < 0.05). The group of novice nurses showed the greatest improvement in knowledge after training. At 6 months, the rate of correct answers was stable compared to the evaluation performed at 3 months (79% vs. 76% p = 0.4). No pharmacovigilance declaration was made after the training and during the study period.

CONCLUSIONS. Nurses´ knowledge of incompatibilities and drug interactions in ICU improved immediately after our training program. Although decreasing 3 months after it remains stable at 6 months. The novice nurses had the greatest benefit.

Predictors and outcomes of delirium within a multi-specialty United kingdom based ICU: a single centre retrospective cohort study

D. McWilliams[1], F. Howroyd[1], C. Snelson[2]
[1]Queen Elizabeth Hospital NHS FT, Birmingham, United Kingdom,
[2]Queen Elizabeth Hospital NHS FT, Critical Care, Birmingham, United Kingdom

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0376

INTRODUCTION. Incidence of delirium ranges from 45-87% in ICU, with higher levels seen in specialised ICU's and patients mechanically ventilated [1]. When present, ICU related delirium is an independent predictor of mortality and morbidity and is associated with a prolonged hospital and ICU length of stay [2]. Early, structured rehabilitation in the ICU has been found to improve delirium status, functional mobility and length of stay [3]. We recently completed a trial of early and structured rehabilitation within our ICU demonstrating a greater intensity of physical rehabilitation than that provided as standard care in other previous trials [4].

OBJECTIVES. To evaluate the incidence of delirium in a critical care unit with an established and effective early rehabilitation service and identify associated risk factors and short term outcomes.

METHODS. We performed a retrospective analysis of patients recruited to a previous trial of early and structured rehabilitation between June 2016 and September 2017 and surviving to hospital discharge. We defined delirium as having a positive CAM-ICU assessment at any point during the ICU stay. Data was analysed using the students t-test.

RESULTS. 87 patients were included in the analysis, of which 32 (34%) developed delirium within the ICU. Age and sedation were significantly associated with the incidence of delirium (see table. 1) and patients who developed delirium were slower to mobilise (10.8 vs 8.9 days, p< 0.05), ventilated for longer (15.5 vs 11.4 days, P< 0.05) and had lower Barthel scores at hospital discharge (76.6 vs 89.6, p=0.015). (table. 2).

CONCLUSIONS. Despite an established and effective rehabilitation service, delirium remains a common complication in our ICU. Older age and longer periods of sedation are significantly associated with development of delirium. When present, delirium is associated with restrictions to early mobilisation, prolonged periods of mechanical ventilation and reduced function at the point of hospital discharge. Further work is required to explore strategies to prevent or minimise the impact of delirium within rehab active ICU´s.

INTRODUCTION. Survivors of critical illness frequently experience muscle weakness and relevant functional impairment after intensive care unit (ICU) discharge. This study aimed to evaluate current of mobilization practice in ICU patients with more than 72 hours of mechanical ventilation.

METHODS. Unicenter prospective observational study from September 2016 to July 2017. We enrolled patients under MV longer than 72h and measure the baseline functional level, ICU-acquired weakness (ICUAW) and functional status at hospital discharge. We recorded the mobilization related adverse events.

RESULTS. We recruited 30 patients (63±12 years; 70% men), mean Acute Physiology and Chronic Health Evaluation II (APACHE II) 16±5. Mean time of ICU stay and hospital stay were 23 and 32 days respectively. Mean time to ask for rehabilitation evaluation was 8±4 days after ICU admission. Finally, rehabilitation began 10±5 days after admission to the ICU. 11 (37%) patients were mobilized with an endotracheal tube and 19 (63%) with endotracheal tube initially and after with tracheostomy tube. Strength was assessed at ICU discharge and 23 patients (80%) had ICU-acquired weakness (Medical research Council Manual Muscle Test Sum Score (MRC-SS) score 48< 60).

The functional level obtained during sessions was sitting at the edge of the bed (n= 24, 80%), standing at the bedside (n=10, 33%) and walking (n=5, 17%). Not adverse effects during rehabilitation therapy were reported. ICU and hospital mortality were 27% and 33% respectively.

The myopathic patients discharged from the ICU had higher mortality at day 90 ($p = 0.002$).

CONCLUSIONS. Early mobilization was uncommon in our ICU. Most of our patients discharged from the ICU had developed ICU-acquired weakness with higher mortality at day-90 in most severe myopathic ones. Implementation of an early mobilization protocol is urgent and requires a cultural change.

Worldwide qualitative investigation of nursing after death rituals

J. Benbenishty[1], M.B. Bennun[2], R. Lind[3]
[1]Hadassah Hebrew University Medical Center, Jerusalem, Israel, [2]Belinson Medical Center, ICU, Petuch Tikva, Israel, [3]Norges Arktiske Universitet, Campus Harstad Institutt for helse- og omsorgsfag, Health Sciences, Tromso, Norway
Correspondence: J. Benbenishty
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0378

INTRODUCTION. Worldwide, both religious and non-religious groups have developed rituals to help provide structure and support to those who mourn and to mark the death of the deceased. Care of the dying is a significant component of nursing practice particularly in hospitals. Nurses who work in certain areas like oncology, intensive care unit (ICU) face the care of the dying, more so than other units. No literature was found regarding country multi culture review of nursing care in the after death practices.
OBJECTIVES. Worldwide investigation of ICU nursing care during after death rituals
METHODS. Multi country nurse investigators researched by using Prospective qualitative interviews of ICU nurses describing the after death care of their patients and delivery of bereavement care to family as well as the reasoning behind the ritual.
RESULTS. 15 nurses from 18 countries from Scandinavia through Mediterranean to African regions were interviewed. Themes found included much about the physical care of the bodies, emphasis on dignity; Family presence and composure of nurse regulating the ritual;Follow up care was described in Northern European ICUs; Spiritual care was provided in diverse fashions including bible reading, insuring a religious leader was present and others. Protocols directing specific care policies were discussed;
Introspective feelings and beliefs were exposed.
CONCLUSIONS. This is the first examination of after death rituals investigated in Europe. Nurses can learn from other cultures in order to be empathetic and sensitive to others at this challenging time. This work can demonstrate several models of after death care

Freedom from physical restraints in ICU: result from a scoping review

E. Mattiussi, M. Danielis, A. Froncillo, A. Palese
Università degli Studi di Udine, Udine, Italy
Correspondence: E. Mattiussi
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0379

INTRODUCTION. Physical restraint (PR) has been defined as "any action or procedure that prevents a person's free body movement to a position of choice and/or normal access to his/her body by the use of any method that is attached or adjacent to a person's body and that he/she cannot control or remove easily". To date several studies have been performed in acute and chronic settings but little data is available on ICUs.
OBJECTIVES. To map all the relevant literature focusing on the use, prevention ad avoidability of PR inside ICU setting.
METHODS. A systematic scoping review was performed.

1) The following databases were examined: PubMed, Scopus, the Cochrane Library, CINHAL and TripDatabase.
2) Different key words were matched to find any other relevant literature.
3) All references were considered to find other studies of interest.
4) Two independent reviewers screened all eligibile articles to meet inclusion criteria.
5) All studies were individually analysed and all data extracted by using a semi-structured form. 6) Literature selected was summarised with both qualitative and quantitative method to find out cathegories and themes.

RESULTS. On a total of 44 studies identified the main areas explored by literature were:

a) *prevalence* of PR in ICU;
b) *policies and guidelines* focusing on actual strategies aiming at preventing the use of PR in ICU;
c) the *determinants* and the *consequences* of PR use;
d) patients, caregivers and healthcare professionals' *perceptions*.

The prevalence ranges from 0% to 100% depending on the definition of PR considered and on organizational aspects of ICU (i.e. nurse/patient ratio). There were few policies across countries guiding the use of PR in ICUs. The main determinants of the PR use aimed at assuring patients safety: the risk of device removal, the cognitive state of patients and the risk of fall. The consequences of PR were: direct damages (i.e. skin sores) and indirect damages (i.e. patient's agitation and device removal). Most of patients admitted in ICU reported that PR determined anxiety and frustration; some others did not remember or understood its use. Personnel's perception varied on their knowledge and skills about PR use.
CONCLUSIONS. As a novel approach for mapping relevant literature on a topic, we focused in performing a broad study of literature concerning the use, prevention and avoidability of PR in ICUs. The results confirmed that there should be a continuous updating of knowledge about PR in ICU, both to ensure patients' outcomes and to improve knowledge and skills of health care personnel.

The effect of an informatics system on use of informal/ad hoc critical care nursing notes as an adjunct to formal systems of communication, work flow support and documentation in a central London teaching hospital

H. Rook, R. West, C. Bell, F. Master, R. Mehta, I. Salako, S. Shah, P. Hopkins
King's College Hospital, London, King's Critical Care, London, United Kingdom
Correspondence: H. Rook

INTRODUCTION. We have conducted a mixed methods observational analysis of communication, work flow and information recording within an adult critical care service before and after the deployment of a 'best of breed' informatics system (Intelliview Critical Care and Anaesthesia-ICCA, Philips HealthCare). Here, we describe the impact of ICCA on the format and content of informal transient hand written notes by critical care nurses outside the formal medical record and the attitude of nurses to such notes.

OBJECTIVES. To assess the impact of a clinical information system on the use of informal notes made by critical care nurses.

METHODS. Centralized HRA approval for non-participant observation, surveys and recording of anonymised data was obtained ICU bedspaces were reviewed sequentially on each of three critical care units until 250 had been reached, recording the presence of informal notes and asking the allocated nurse whether they were utilising such notes. Notes were analysed for content and nurses surveyed to record their attitude to such notes. On two units, the exercise was repeated 6 months after deployment of the ICCA system, with a third ´control´ unit remaining on paper.

RESULTS. 1500 bed spaces were successfully reviewed at handover on three intensive care units before and after the deployment of an informatics system. The commonest form of informal documentation were a paper hand towel (52%), paper medical continuation sheets (24%), the back of other paper documentation or blood gas slips (20%) or by personal note books (8%). Common types of information recorded included task lists; listing questions and information for handover (table 1). Patient identifiers were present on 8% of informal notes. Informal notes were present in 72.7% of bed spaces before ICCA implementation and in 49.2% of bed spaces afterwards. The content of informal notes also changed after ICCA deployment, with less recording of medication/administration reminders; information for handover and metadata, In a survey of attitudes to informal notes, nurses listed speed of notation, immediate availability of informal notes, deficiencies in paper based/electronic systems; control of visibility and personal reassurance as the main benefits of informal notes. The main disadvantages were risk of breach of confidentiality; risks of wrong patient identification; and invisibility of information in the investigation of adverse events or errors.

CONCLUSIONS. To our knowledge, the use of informal and transient notes for communication and work flow support has not previously been reported. Further work on the use of informal communication systems is needed to better understand deficiencies in more formal methods of documentation and workflow support whether electronic or paper-based and to assess the risk-benefit through use of such notes.

Table 1 (abstract 0380). Content Analysis of Informal Nursing Notes

Information	Before ICCA	After ICCA	Control
Task listing/support	407/545 (74.6%)	179/246 (72.7%)	143/179 (79.9%)
Queries to ask NIC/TL	211/545 (38.7%)	107/246 (43.5%)	89/179 (49.7%)
Queries to ask other professions	366/545 (67.2%)	185/246 (75.2%)	122/179 (68.2%)
Medication/administration support	108/545 (19.8%)	11/246 (4.5%)	47/179 (26.3%)
New information pending formal documentation	42/545 (7.7%)	3/246 (1.2%)	41/179 (22.9%)
Key metadata	56/545 (10.3%)	12/246 (4.9%)	23/179 (12.8%)
Handover	301/545 (55.2%)	92/246 (37.4%)	122/179 (68.2%)
Other	29/545 (5.3%)	22/246 (8.9%)	19/179 (10.6%)

Sedation assessment and management in ICUs in Australia and England

C. Green[1], A. Jackson[2], A. Macey[1], C. Boulanger[2], V. Plummer[3,4], R. Endacott[3,5]
[1]Peninsula Health, Intensive Care Unit, Frankston, Australia; [2]Royal Devon and Exeter Hospital, Intensive Care Unit, Exeter, United Kingdom; [3]Monash University, School of Nursing and Midwifery, Melbourne, Australia; [4]Peninsula Health, Frankston, Australia; [5]Plymouth University/Royal Devon and Exeter Hospital, Clinical School, Exeter, United Kingdom
Correspondence: R. Endacott

INTRODUCTION. The goal of sedation, with regular orientation, is often not achieved in ICU (1,2) despite evidence that sedation stops are safe (3). Careful assessment and management of sedation is essential in order to enable timely weaning and extubation. Responsibility for sedation decisions is different in England and Australia; it is unclear whether this influences achievement of optimal sedation.

OBJECTIVES.

1. To examine documentation of sedation and extubation plans in similar ICUs in England and Australia
2. To explore factors associated with assessment and management of sedation in ICU patients.

METHODS. Point prevalence survey to review sedation plans for all adult patients (n=234) in two ICUs at 1600hrs 3 days per week in January, April, July and October. Patients with a tracheostomy, receiving short-term ventilation, intubated less than 24 hrs previously or paralysed for therapeutic cooling were excluded. Data collection instrument was designed to capture workload, skill mix and sedation management. The primary outcome measure was sedation hold.

RESULTS. Mean age was 59.09 years (SD 16.38); mean ICU length of stay was 6.34 days (SD 5.97) and mean ventilation time was 118.19

hours (SD 136.97).A RASS target was documented for 54.7% of patients (n=128) and 46.6% of patients (n=109) did not have a sedation hold. Sedation hold was significantly associated with site (x^2 58.3, df 1, p=0.00), and presence of an extubation plan (x^2 66.20, df 2, p=0.00). Sedation hold was significantly correlated with ventilation hours (r=+0.27, p=0.00) and ICU length of stay (r =+0.13, p=0.00), with sedation hold more likely for patients who had longer ventilation hours and longer ICU stay. There were incidents of sub-optimal sedation in both countries.

CONCLUSIONS. Pilot study using the instrument with patients in both countries has demonstrated utility in detecting factors associated with sub-optimal sedation. The next stage of the work is to refine the instrument to detect more subtle differences, particularly relating to nurse skill mix. The final stage will be to use outcomes to plan an intervention study.

Early mobilisation of critically ill patients in Singapore - a quality improvement project

D. Sani[1], K.K. Myint[2], J. Taculod[3], A.Y. Li[4,5], H.S. Yip[4,5]
[1]National University Hospital, Department of Rehabilitation, Singapore, Singapore; [2]National University Hospital, Department of Nursing, Singapore, Singapore; [3]National University Hospital, Division of Critical Care, Respiratory Therapy, Singapore, Singapore; [4]National University Hospital, Division of Respiratory and Critical Care Medicine, University Medicine Cluster, Singapore, Singapore; [5]National University of Singapore, Department of Medicine, Yong Loo Lin School of Medicine, Singapore, Singapore
Correspondence: D. Sani
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0382

INTRODUCTION. Survivors of critical illness may experience post-intensive care syndrome (PICS) [1], where physical, cognitive and/or psychological impairments persist after discharge. Early mobilisation (EM) in intensive care unit (ICU) has been shown to be safe, feasible and may help to ameliorate the incidence of PICS [2]. Well-designed studies have shown that EM improves quality of life, physical function, muscle strength, increase ventilator-free days, and decrease length of stay (LOS) [2]. In Singapore, the mobilisation practice in ICU and its effects on clinical outcomes are unknown.

OBJECTIVES. This is a six month pre-post quality improvement (QI) pilot project in a single-centre medical ICU (MICU) to (1) investigate the feasibility of EM, (2) hasten mobility and (3) evaluate effects on clinical outcomes.

METHODS. Patients admitted to MICU were recruited if they were >18years old, admitted for ≥48 hours and premorbidly able to ambulate ≥10m independently. Patients were excluded if they had lower limb amputation or fractures limiting mobility, neurological conditions or actively dying.

Prior to QI implementation, MICU operated on a blanket-referral system for physiotherapy. Suitability for EM was not clear.
A multidisciplinary team implemented multifaceted changes which included

1) improving visibility on the mobility status of patients,
2) implementing a sedation and mobilisation protocol,
3) training staff to assess suitability for EM, and
4) implementing functional outcome measures. Waiver of informed consent was granted by the institutional review board.

RESULTS. 107 and 92 patients were recruited in the pre-QI and post-QI group respectively.
Compared to patients in the pre-QI project, patients in the post-QI group had a reduction in sedation (11.2 vs 18 hours, p=.029), intubation duration (38 vs 73 hours, p< .001), sat out of bed earlier (2 vs 4 days, p= .013), and ambulated earlier (4 vs 6 days, p< .001). There was no significant difference in ICU delirium days. ICU and hospital LOS decreased in the post-QI group (4 vs 5 days, p=.079) and (13.5 vs 15 days, p=.12) respectively, but this did not reach statistical significance. ICU Mobility Scale (IMS) scores achieved at ICU discharge were higher in the post-QI group, with 56.5% of patients in the post-QI group ambulating (IMS ≥ 7) at ICU discharge compared to 28% in the pre-QI group (p<.001).

CONCLUSION. EM in ICU is feasible and improves clinical outcomes and functional status. Impact on patient's long-term outcomes is unclear, and warrants further research.

Trauma outcome - quality of life, Injury perception, dream recall and symptom severity over time trajectory from 2 weeks to 5 years post hospital discharge

J. Benbenishty[1], L. Churi[2]
[1]Hadassah Medical Organization, Jerusalem, Israel; [2]Hadassah Hebrew University Medical Center, Orthopedics, Jerusalem, Israel
Correspondence: J. Benbenishty
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0383

INTRODUCTION. Injury is a leading cause of preventable mortality and morbidity worldwide, with approximately 10% of trauma patients admitted to intensive care. Trauma patients experience significant ongoing physical and psychological burden after discharge; however, the patterns of recovery and the subgroups of intensive care patients who experience the greatest burden are not described. Prospective studies have not succeeded in proving enough long-term follow up data, therefore a 6-month prevalence design was chosen.

OBJECTIVES. Understand the relationship between symptom severity, injury perception, quality of life, ICU dreams and health status in revered trauma patients over trajectory of time.

METHODS. Prevalence study; 6-month follow up clinic of all trauma patients in one tertiary referral hospital city of 1million. After IRB approval, all trauma patients in follow up clinic were invited to join study. Questionnaires included quality of life, injury perception, symptom severity, dream recollection, health status and demographics.

RESULTS. 223 participants. 11% of patients recovered from ICU, 20% were more than 1-year post trauma, 20% were over 60 years of age. Range of injuries included multiple trauma multi-organ injuries to limb fractures, solitary rib fractures and soft tissue damage. Length of Hospitalization ranged from 1-90 days. The trend of symptom severity changed significantly over time ranging from severe pain and mobility limitations immediately post hospital discharge to Distress/feeling upset and insomnia severity after 1 year. Over 60 year olds described their health status as very low, but their quality of life as very high. Dreams ranged from recalling psychedelic experience to feelings of calmness and floating sensations. Those injured over 6 months scored highest in feeling that injury affected emotional stability and the perception that the injury will continue for the rest of their life. Women scored their health status and QOL significantly lower than men. No association was found between injury severity, ICU stay and longevity or severity of symptoms. More than 10% had not year returned to work 1-year post injury; 15% returned part time. Those recovering from complex ankle fracture share the same perception of injury severity as those after multi-trauma.

CONCLUSIONS. It is important that we raise awareness about the healing process of recovery among the post trauma population. Patients do not forget their ICU dreams. The complexity and severity of trauma injuries does not affect the long-term perception of this life-changing event. Nurses can instruct patients and the families of the trajectory journey of post trauma.

0384

Better estimation of height in ICU is essential for effective lung protective ventilation

R.S. Millington, V. Edwards, C. Soanes, A. Wong, B. Borgatta
[1]Oxford University Hospitals NHS Trust, Adult ICU, Oxford, United Kingdom
Correspondence: V. Edwards
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0384

INTRODUCTION. Inaccurate height recording negatively impacts delivery of lung protective ventilation as tidal volume (TV) targets are derived from patient height. In our unit, a 1m tape is expected to be used to measure recumbent patient height. This can be challenging and error prone[1]. Furthermore we suspected it was often not done. Validated anthropometric methods for height estimation in ICU include patient measurement with a 2m tape or ulna-length measurement. The latter is a simple method and amongst the most accurate[12].

OBJECTIVES.

1. Evaluate how height is recorded in our ICU.
2. Assess the impact of discrepancies on TV targets between recorded heights (from the electronic record) and predicted heights (via the ulna-length method).
3. Adopt ulna-length as standard if significant discrepancies exist.

METHODS. Prospective data collection included height entered into the electronic record and measured ulna-length using the Malnutrition Universal Screening Tool from the British Association for Parenteral and Enteral Nutrition[3]. Significant discrepancies in TV were defined as ±0.2 ml/kg. After finding a high rate of visual estimation, a nursing staff survey was used to identify barriers to accurate height recording in ICU.

RESULTS. 50 patients were included. 56% were female and 50% < 65years. 78% were unplanned admissions and 50% were postoperative. Height recording methods: 26% visually estimated, 36% from medical records, 8% GP/pre-admission, 24% self-reported and 6% other.

In 22% of patients recorded-height TV matched the ulna-length derived TV of 6±0.2 ml/kg with 52% below and 26% above. The difference in recorded and predicted height ranged from -17 to 20cm (IQR: -5 to 5cm), equating to TV difference ranging from -2.16 to 1.6 ml/kg (IQR: -0.48 to 0.23 ml/kg). Certain subgroups showed greater differences: females, age < 65years, non-postoperative, unplanned admissions, visual height estimation.

37 nurses were surveyed. 30% visually estimated >60% of the time despite 75% viewing accurate height measurement as very/extremely important. Key barriers to physical measurement were: needing help (24%); time taken locating a tape (19%); perceived difficulty (13%); task prioritisation during admission (22%). Nursing preference was equal for both ulna-length and 2m tape measurement.

CONCLUSIONS. There is no consistent method for recording height on ICU and there is a high rate of visual estimation. This negatively impacts TV targets as compliance to 6ml/kg ventilation is < 25%. To improve this, where erect height is unavailable, we recommend ulna-length measurement as the standard for height prediction as it can be done without help and more easily than the 2m tape. All bed spaces should have a 1m tape. Mandatory completion of height recording should be within the admitting shift rather than immediately on admission.

0385

Physiotherapy outcome measure use on adult intensive care units in the United Kingdom (UK)

C. Purkiss
Royal Brompton and Harefield NHS Trust, Rehabiltation and Therapies, London, United Kingdom
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0385

INTRODUCTION. Standardised, validated outcome measures are an essential tool when measuring quality and efficacy of therapy interventions.

NICE guideline CG83 recommends assessment with an outcome measure to assess physical function at regular intervals during critical illness, however does not recommend a specific tool with which to do so.

A 2015 review identified inconsistency in tools used to measure physical function in survivors of critical illness and there is currently no consensus regarding which tools best assess physical impairment in this cohort.

OBJECTIVES. To review outcome measure use throughout Adult Intensive Care Units (AICU's) in the UK, and benchmark the use of outcome measures at the Royal Brompton Hospital against other UK AICU´s.

METHODS. A questionnaire regarding outcome measure use was posted to 247 AICU's across the UK taken from the Intensive Care National Audit Research Centre (ICNARC) in 2016.

RESULTS. 36.8% (n=91/247) of surveys were returned. 79.1% (n=72/91) of responding trusts were using outcome measures, with a range of 27 different outcome measures reported.

Of those using measures the most commonly used was the Chelsea critical care physical assessment tool (66.7% n=48/72), followed by the Manchester Mobility Scale (25% n=18/72), Functional Independence Measure (11.1% n=8/72), Barthel Index (11.1% n=8/72), and the Goal Attainment Scale (6.9% n=5/72). 22.2% (n=16/72) of trusts were using a combination of several measures, hence the sum total of outcomes used exceeds the response rate of the survey. The most sited reasons for choosing a measure were ´ease of use´ (23.61% n=17/72), ´evidence base´ (22.22% n=16/72) and ´appropriateness of the tool´ (20.83% n=15/72).

33.3% (n=24/72) of units completed measures with all patients on AICU, others used set time frame criteria. 12.5% (n=9/72) assessed after >48hrs AICU stay, 11.1% (n=8/72) after >48 hrs ventilated. The longest time frame until patients were assessed was a stay of >2 weeks on AICU (1.4% n=1/72).

The frequency of assessment varied widely with a range from daily, to on admission and discharge from AICU only. The most common intervals for assessment were weekly (22.2% n=16/72) and daily (19.4% n=14/72).

On discharge from AICU, 66.7% (n=48/72) of the trusts using measures continued to do so on high dependency units and the ward.

CONCLUSIONS. The scope of this survey is limited due to the response rate, however it shows a wide disparity of UK AICU outcome measure use. This variance includes the tools being used, which patients are assessed, and the timing and frequency of assessment. This may be due to heterogeneous patient cohorts, staffing levels, patient acuity and a lack of consensus regarding the best outcomes to use. Further investigation into specific outcome measures would be beneficial to provide best quality, standardised care and the creation of a core outcome set to make outcomes translatable for research purposes.

0386
Does functional ability improve for patients in the intensive care unit (ICU) with a structural physiotherapy indication using the patient mobility framework (PMF) protocol?

N.L. O'Sullivan[1], B.I. Cleffken[2]
[1]Maasstad Hospital, Department of Physiotherapy, Rotterdam, Netherlands; [2]Maasstad Hospital, Department of Intensive Care Medicine, Rotterdam, Netherlands
Correspondence: N.L. O'Sullivan
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0386

INTRODUCTION. There are numerous negative side effects associated with an ICU stay, which include immobility, deconditioning and weakness. It is well documented that early mobilization in the ICU is safe and aids in reducing the negative effects of an ICU hospitalization. The aim of this study is to evaluate the effect of the patient mobility framework (PMF) developed by Castelijn (2012), as a tool to increase patient activity through increased cooperation amongst the intensive care team. The PMF algorithm is divided into 3 alphabetic and 3 numerical categories and offers corresponding mobility advice for nurses and physiotherapists. Each patient receives a single alphabetic and numerical score from the supervising consultant and authorization for therapy daily.

OBJECTIVES. The primary objective was to investigate if the protocol has a beneficial effect on patients' functional ability. Furthermore, the possible difference in mean number of delirium days per cohort was examined.

METHODS. The study is a single center observational study in a Level 3, ICU. It is a retrospective, medical records, cohort study comprising of two cohorts. The PMF protocol was introduced in 2015. The primary cohort included patients admitted between January-July 2014 and was compared to patients after the implementation from January-July 2016. Patients were included 48 hours after ICU admission. Patients were excluded if they categorized as receiving end of life care, thrombolysis, burns patients and multi-trauma patients. All patient's daily activities are recorded in their electronic patient dossier. The measurement point for functional activity is an active transfer from the bed to a chair on discharge from the Intensive Care/Medium Care departments. Early mobilization is a key component in the prevention and treatment of delirium. The primary objective was tested with a

chi-square analysis in the study population. The mean number of delirium days in 2014 and 2016 was assessed by a Wilcoxon rank sum test.

RESULTS. The number of patients included in the 2014 cohort was N=174 and in 2016 N=170. There was no statistically significant difference in baseline characteristics in the study population. There was a 19% increase in the ability to perform an active transfer in the PMF group, however, chi-squared tests revealed no significant distinctions between cohorts. There was a 37% decrease in the mean number of delirium days from 2.5 in 2014 to 1.82 in 2016, however, there was no significant difference between cohorts.

CONCLUSIONS. In order to ease the psychological and physical comorbidities, associated with an ICU stay, a complete multidisciplinary, multi-facet approach to physical activity is needed to reduce the facilitation of a sedentary ICU stay. There is a positive shift in functional ability but further focus on enabling factors such as mobility protocols, the ABCDE bundle and mobility teams are vital for early rehabilitation in the ICU.

The benefits of a specialist physiotherapist in ICU rehabilitation clinic

V. Robinson[1], E. Orme[2], M. Allen[2], M. Dabliz[2], E. Morino[2], L. Ma[2]
[1]Kingston Hospital NHS Foundation Trust, Physiotherapy, Kingston Upon Thames, United Kingdom; [2]Kingston Hospital NHS Foundation Trust, Kingston Upon Thames, United Kingdom
Correspondence: V. Robinson
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0387

INTRODUCTION. Intensive care acquired weakness is a common condition in critically ill patients who have been admitted to ICU for a prolonged period of time (Hodgson and Tippin, 2016) and many patients fail to recover fully within one year (Herridge et a, 2013). As a result the NICE guidelines recommend patients are followed up 2-3 months after discharge. In October 2017, Kingston Hospital was given funding from the CCG (clinical commissioning group) to start an Intensive Care Unit (ICU) rehabilitation clinic. The funding was for a clinic one day a month to include a consultant, a senior nurse, a psychologist and a physiotherapist. There are few clinics in the UK that have a funded physiotherapist at every clinic.

OBJECTIVES. To analyse the number of patients who attended ICU rehabilitation clinic that required specialist physiotherapy assessment, treatment, advice and follow up.

METHODS. Patients were invited to attend the ICU rehabilitation clinic if they had been admitted to the ICU for five days or more and all obstetric patients.

A retrospective study was performed, analysing the notes of all patients who attended clinic from October 2017 to March 2018. The physiotherapy needs of the patients in ICU rehabilitation clinic were recorded following specialist physiotherapy assessment.

RESULTS. Twenty six patients attended ICU rehabilitation clinic between October 2017 and March 2018. Seventeen patients (70%) needed physiotherapy input with ten requiring ongoing physiotherapy input due to significant muscle loss and balance impairment. Three patients were already attending community physiotherapy programmes (one at a hospice and two since discharge from a rehabilitation hospital). Two patients refused referral onto community services. Direct physiotherapy input in clinic included taking patients to the physiotherapy gym, teaching of balance and strengthening exercises and advice on exercise at home and education on the effects of ICU acquired weakness.

CONCLUSIONS. The majority of patients who attended the Kingston Hospital ICU rehabilitation clinic had physiotherapy needs which were appropriately assessed and treated by the physiotherapist at

the clinic and ongoing physiotherapy input provided. The waiting time for outpatient or community physiotherapy assessment is more than four months. A physiotherapist in ICU rehabilitation is vital for patients' care following ICU stay.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0388

INTRODUCTION. Swallowing disorders, dysphagia, occur frequently in patients admitted to the intensive care unit (ICU). Dysphagia in the ICU is caused by many factors including drugs, muscle wasting, neuromyopathy, delirium and the presence of nasogastric tubes and tracheostomies. Dysphagia is associated with insufficient feeding and an increased chance of aspiration and associated pneumonia. These effects may cause prolonged length of stay in the ICU and the hospital with inherent worse outcome. We present two cases in which we used surface electromyographic (sEMG) signals as input for an interactive biofeedback game (Rephagia®) to evaluate and train swallowing strength.

CASE DESCRIPTION. Case 1 is a 67 year old woman admitted to the ICU because of abdominal sepsis due to strangulated and perforated stomach. Case 2 is an 82 year old male admitted to the ICU because of abdominal sepsis due to a complicated hemicolectomy because of a sigmoid carcinoma. Both patients suffered from multiple organ failure and severe muscle weakness and received a tracheostomy. Clinical signs of dysphagia (abnormal water swallow-test) were present. Using FEES, both demonstrated severe dysphagia, i.e. they scored a Murray Secretion Score of 3 (Most severe rating - Secretions seen in the laryngeal vestibule. Pulmonary secretions were included if they were not cleared by swallowing or coughing.) and a Rosenbek Penetration-Aspiration Scale (PAS) of 8 for thin ánd for thickened liquid (Material enters the airway, passes below the vocal folds, and no effort is made to eject).

RESULTS. The patients welcomed the interactive training exercise and were actively involved in the game.

Patient 1 trained 8 times in 12 days before she was discharged from the ICU. At the start of the training she had no oral intake (Functional Oral Intake Scale 1). At discharge she had a functional oral intake scale (FOIS) of 3 (tube dependent with consistent oral intake). The average peak swallow values on day 1 increased from mean 33.2μV (SD 8.5) to 59.6μV (SD 11.4) on day 8.

Patient 2 trained 25 times in 47 days. Days of clinical deterioration and/or delirium made daily exercising impossible. Unfortunately he deteriorated further due to a recurrence of his carcinoma and he died at the ICU. During training his FOIS improved from 1 to 3. The average peak swallow values increased from mean 34.6μV (SD 3.8) on day 1 to 74.6μV (SD 8.7) on day 25 (see graph).

CONCLUSION. The swallowing strength and oral intake improves while training with sEMG biofeedback. However studies should compare the use of sEMG biofeedback training with standard optimal care to evaluate its additional value in regaining swallow function.
Making the best of antibiotic use

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0389

INTRODUCTION. Antimicrobial stewardship (AST) aims to improve outcome and reduce resistance through better use of antimicrobials. Its success relies on collaboration between microbiologists, pharmacists, infectious diseases specialists and treating physicians[a]. It is unclear whether AST meetings impact antibiotic therapy decisions.

OBJECTIVES. To assess whether AST meetings impact antimicrobial therapy decisions (initiation, switch and discontinuation of antibiotics) in the ICU.

METHODS. Start and end date of all antibiotic prescriptions for surgical (SICU) and medical (MICU) ICU patients admitted between Jan 2013 and Dec 2017 were recorded using the COSARA software package[b]. Days were categorized based on the availability of results from surveillance cultures (SC), routine microbiological service (weekdays versus weekend) and AST meetings (Table 1, '+' = available and '-' = not available). Based on this classification we assessed the impact of AST meetings by comparing the proportion of antibiotic prescriptions changed (start, switch or end) on days with and without AST meetings and days with and without SC results available.

RESULTS. We reviewed 8848 antibiotic prescriptions, 5487 (62%) and 3361 (38%) in SICU and MICU respectively. Overall, significantly more prescriptions were changed during weekdays (*p*< .001, proportions not shown). Also, significantly more changes in antibiotic prescriptions were noted on days when both SC results were available and AST meetings were organised, when compared to days when SC were available but no AST meetings were organised (*p*< .001). Vice versa, significantly more changes in antibiotic prescriptions were made on days when both AST meetings were held and SC were available when compared to days when AST meetings were held in the absence of SC results (*p*< .001). Of note, we did not find a significant difference in the proportion of changed antibiotic prescriptions when we compared AST+/SC- versus AST-/SC- (p=0.191). Also, we did not find a significant difference between AST-/SC- and AST-/SC+ (Table 2). The absence of a difference between AST-/SC- and AST-/SC+ could be explained by the fact that microbiology results (first day reading) of SC may be reported to the treating physician on days that are classified as SC-.

CONCLUSIONS. Antimicrobial stewardship meetings significantly influence antibiotic therapy decisions when results of surveillance cultures are available.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0390

INTRODUCTION. Methicillin-resistant *Staphylococcus aureus* (MRSA) is a common causative pathogen of nosocomial pneumonia. Although current guidelines recommend vancomycin and linezolid as first-line agents against MRSA pneumonia, in a recent clinical trial[1], telavancin achieved higher curative rates in comparison with vancomycin, specifically in a subset of patients with monomicrobial *MRSA* pneumonia. Nevertheless, studies comparing telavancin with linezolid are lacking.
OBJECTIVES. To compare the bactericidal efficacy of telavancin vs. linezolid in a porcine model of severe MRSA pneumonia.
METHODS. Eighteen pigs (32.11±1.18 kg) were anesthetized and mechanically ventilated for 76 hours. Pigs were challenged with 15 mL of $10^{7\text{-}8}$ cfu/mL of MRSA into each lobe via bronchoscopic inoculation. After onset of pneumonia, pigs were randomized to receive the following intravenous treatments: saline solution (control), 22.5 mg/kg q24h of telavancin, or 600mg q12h of linezolid. At the end of the study, animals were euthanized and tissue samples were harvested from ventral and dorsal sections of each lobe. Microbiology studies then quantified MRSA pulmonary burden.
RESULTS. All animals completed the study. A total of 180 lung tissue samples, 90 from the ventral and 90 from the dorsal pulmonary regions were analysed. Overall, MRSA was found in 46.7, 43.3, and 26.7% of all lung tissue samples treated with control, linezolid and telavancin, respectively (p=0.013), yielding mean±SD MRSA lung concentration of 1.86±2.30, 1.58±2.38 and 0.79±1.60 (p=0.015). Figure 1 depicts MRSA colonization of the ventral and dorsal lung samples, corroborating augmented bactericidal effects of telavancin, specifically in the dorsal regions.
CONCLUSIONS. In a porcine model of severe MRSA pneumonia, telavancin, in comparison with linezolid, exerts higher bactericidal efficacy, specifically hindering colonization of the dorsal pulmonary regions. We are currently evaluating in our animal model pulmonary distribution of telavancin and linezolid to draw inferences on the above mentioned pulmonary colonization. Comparative clinical studies are needed to confirm the benefits of telavancin in the treatment of severe MRSA pneumonia.

Clinical impact of an Antimicrobial Stewardship Program in critical patients based on early antibiotic adequacy

F.S. Amado, A.M. Silva, M.R.G. Freitas, N.S. Silva, F. Spada, L.H.B. Gonçalves, J.R.A. de Azevedo, R.P. de Azevedo
Sao Domingos Hospital, Intensive Care, São Luís, Brazil

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0391

INTRODUCTION. The main goal in treatment of infections in critically ill patients is to provide an effective, early and proper antibiotic therapy and, at the same time, minimize future bacterial resistance, especially in an era of rising antibiotic resistance and lack of new antimicrobial development. Reducing microbiologic time results has been aimed to minimize costs, improve antibiotic adequacy and patient's outcomes. Antibiotic stewardship in the intensive care unit (ICU) encompasses rapid identification of patients with bacterial infections, better empirical treatment selection, de-escalation once culture results become available, shortening therapy duration, and reducing the numbers of patients treated unnecessarily [1].
OBJECTIVES. To evaluate the clinical impact and feasibility of the implementation of an Antimicrobial Stewardship Program (A.S.P.) based on early antibiotic adequacy in critical care patients.
METHODS. All patients, aged above 18 years, admitted to a 45-bed ICU of a tertiary hospital, with positive cultures from November 2016 to August 2017, were included. This program is based on rapid germ identification, effective communication and proper antibiotic adequacy. The germ identification started with gram-staining followed by mass spectrometry (MALDI-TOF MS) and results were sent by an on-line instant messages software (*WhatsApp*®) to ICU care team. The team should answer (closed-loop communication) and adequate the therapy in 2 hours after the message was sent. The antibiotic therapy was chosen in compliance with recommendations aimed to isolated germ by MALDI-TOF MS. Then, final adequacy occurred as soon as susceptibility tests and MIC by E-TEST were available. These final results were sent by daily electronic reports.
RESULTS. We included 209 patients (601 positive cultures). The information sent was confirmed in 2 hours in 88.2% of all exams. The median time to administration of proper antibiotic therapy since the

delivery of information was 90 (56 -185) minutes. Median time to MALDI TOF germ identification was 41 (24-49) hours. The recommendations for empirical antibiotic therapy had accuracy of 98,1% and final adequacy rate after susceptibility tests was 99%. This A.S.P. enabled a de-escalation rate of 76.5%. The early antibiotic therapy had impact on ICU mortality rate (34,2% in the early group against 56% in the late adequacy group; p = 0,034), on hospital mortality rate (35,9% in the early group against 60% in the late adequacy group; p = 0,02) and also on ICU and hospital length of stay.

CONCLUSIONS. As showed by this study results, the adoption of an Antimicrobial Stewardship Program organizes information and consequently facilitate the early and proper antibiotic adequacy, improving outcomes.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0392

INTRODUCTION. Prevalence of staphyloccoci (Staph) in surgical samples of postoperative intra-abdominal infections (PIAI) varies from 4 up to 16% of the cases. Few studies mention these organisms in microbiological samples and their pathogenicity is debated, especially coagulase-negative Staph (CNS).
OBJECTIVES. Our purpose was to compare in a prospective cohort of PIAI patients those with positive cultures of Staph (PIAIS) in surgical samples versus patients without Staph (PIAInS), then to differentiate cases with coagulase-positive Staph (PIAICPS) and CNS (PIAICNS).
METHODS. Between 1999 and 2017, we prospectively included all patients (pts) admitted in ICU for the management of PIAI. Clinical characteristics, severity scores (SAPS II and SOFA on admission), microbiological data (blood cultures and surgical operative samples), empirical antibiotic therapy and outcome (mortality, reoperation, ICU stay) were collected. Results are presented in means and DS or proportions. Statistical analysis used Fisher exact test, Mann Whitney and Kruskall Wallis tests(significance $p< 0.05$).
RESULTS. 380 pts were analysed, including 87 PIAIS (23%). Clinical and demographic characteristics, were similar in both groups (age, gender, fatal underlying diseases, immunosuppression, cancer, diabetes, initial surgery). Severity scores on ICU admission were lower for PIAIS : SAPS II 44±15 versus 49±18 ($p=0.03$), and SOFA 7±3 vs 8±4 ($p=0.04$) for PIAIS and PIAInS respectively

(without any difference between PIAICPS and PIAICNS). Frequency of bacteraemia was similar in both groups while increased proportions of polymicrobial peritoneal samples were reported in PIAIS cases (94% vs 80% in PIAInS ($p=0.001$)). *Escherichia coli* and *Enterococcus faecium* were less frequently cultured from peritoneal samples in PIAIS vs PIAInS ((36% vs 47% ($p=0.007$) and 8% vs 20% ($p=0.01$), respectively). Proportions of fungi in surgical samples were similar in both groups. Adequate empirical anti-infective therapy targeting all the organisms was only obtained in 54% PIAIS and 72% PIAInS cases ($p=0.0025$), mainly explained by methicillin-resistant Staph. Similar mortality and morbidity (re-operation, duration of mechanical ventilation) rates were observed between PIAIS vs PIAInS and between PIAICPS and PIAICNS.
CONCLUSIONS. Our data suggest that PIAIS marginally differ from PIAInS cases. The prognosis of PIAIS cases is similar to what is reported from other patients. While it is not possible to fully assess staphylococci pathogenicity in the course of PIAI, our data suggest that these organisms should be considered cautiously and probably as authentic pathogens in a majority of the cases.

Incidence and time dependence of inadequate and supratherapeutic vancomycin levels in critically ill: a retrospective study
J.E. van der Mast[1], M.W.N. Nijsten[2], D.J. Touw[1], W. Bult[1]
[1]University Medical Center Groningen, Clinical Pharmacy and Pharmacology, Groningen, Netherlands; [2]University Medical Center Groningen, Critical Care, Groningen, Netherlands

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0393

INTRODUCTION. Timely adequate antibiotic treatment is paramount in critically ill patients with severe infection. In case of suspected or proven infection with Gram-positive bacteria, vancomycin is often the appropriate first line treatment. Since 2011 our protocol in is to use continuous vancomycin infusion with therapeutic drug monitoring (TDM) with daily or less frequent measurements. We evaluated how effective our policy was in achieving the required concentrations, i.e. 20 to 25 mg/L.
OBJECTIVES. Determine the incidence and time dependence of inadequate or supratherapeutic vancomycin levels.
METHODS. Retrospective analysis of vancomycin levels in all adult patients admitted to our ICU over a 64 month interval who were treated with vancomycin bolus followed by continuous infusion. Levels were classified compared with the desired range of 20 to 25 mg/L. Only vancomycin levels determined within 30 days of ICU admission were included.
RESULTS. We included 472 patients with a mean ±SD age of 61 ±14, 62% male and an acute physiology and chronic health evaluation score (APACHE-IV) of 76 ±30. Hospital mortality was 32%.
The mean number of vancomycin measurements was 5.0 ±4.8. Per patient the percentage of vancomycin levels < 15, < 20, within range, >25 and >30 was 22%, 43%, 26%, 31% and 12%, respectively. The percentage of within range levels did not differ between survivors and non-survivors, although non-survivors had a higher fraction of levels >25 mg/L (< 0.001). Moreover, only at two days after ICU-admission more than 50% of the vancomycin levels were in the therapeutic range.
CONCLUSIONS. Timely target attainment vancomycin is difficult with our current TDM-protocol. Protocol changes and more frequent vancomycin sampling appear to be mandatory.

Prevalence and role of respiratory viruses in ICU patients with community acquired-pneumonia (CAP): a one-year retrospective single center study

M. Giry, A. Chefdeville, M. Gueudin, D. Boyer, A. Baron, G. Beduneau, S. Skallil, D. Carpentier, C. Girault, B. Misset
CHU de Rouen, Rouen, France
Correspondence: M. Giry
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0394

BACKGROUND. Pneumonia is the most frequent community-acquired infection responsible for ICU admission. Multiplex PCR enables early diagnosis of viral infection in daily practice. Few series have been described since this technique has been made available in routine.
OBJECTIVES. We aimed at assessing the prevalence and distribution of viruses among ICU patients with CAP and their relationship with severity and outcome.
METHODS. Retrospective analysis of the consecutive viral multiplex PCR (Eplex™, Genmark Dx) between November 2016 and October 2017 in a French 21 bed medical ICU admitting around 1,000 patients per year. Patients' nasopharynx was sampled within 72 hours following their ICU admission. We selected those patients with a diagnosis of CAP and split them into 4 groups according to causal agent: none, viruses, bacteria, combination of both. Comparisons were made with non-parametric Kruskall-Wallis and Fischer's exact tests.
RESULTS. 223 patients were sampled, of whom 109 had CAP, 38 aspiration or opportunistic pneumonia, 22 non-pulmonary infections, 11 pulmonary edema, 19 exacerbations of chronic lung disease, and 24 other diagnoses.
Patients with CAP had the following characteristics: age 59± 16 y, male sex 60%, SAPS 2 score 40 ± 18, ICU length of stay (LOS) 8.7±9.0 d, mortality 11 %. No infectious agent was found in 33 (30%), a virus in 27 (25%), bacteria in 33 (30%) and both a virus and bacteria in 16 (15%). The main bacteria were *S. pneumonia* (23%) and *H. influenza* (6.5%). The main viruses were Rhinovirus/Enterovirus (13.8 %), Influenzae A (11 %) and Parainfluenzae (4.6%). The most frequent virus-bacteria association was *S. pneumoniae* and Influenzae A (3%) and *S. pneumoniae* and Rhinovirus/Enterovirus (3%).
The SAPS 2 score was higher in the mixed group (p = 0.02). The ICU-LOS was 5.2 (no agent), 7.8 (virus), 10.1 (bacteria) and 14.8 (mixed) days respectively (p = 0.04). Mortality was similar among groups.
CONCLUSIONS. In our ICU population, respiratory viruses were present in 39.5 % of CAP. Patients with mixed infection had higher severity at admission and longer ICU-LOS.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0395

INTRODUCTION. Bacterial resistance is a global problem. It can influence the outcome of critical patients.
OBJECTIVES. To find out the risk factors (RF) that can predict which patients are carriers of multiresistant bacteria (MRB) on admission or during their stay in the ICU, including infection and colonization as well as the type of BMR.
METHODS. Prospective, multicenter cohort study (ENVIN registry) that included patients admitted> 24 h in ICU from 2014 to 2016. The MRB studied were: Meticillin resistant *S aureus* (MRSA), *P aeruginosa A baumannii*, Enterobacteria producers of extended beta-lactamases (ESBL) and carbapenemase-producing Enterobacteriaceae (CBP). We included as intrinsic data: age, gender, severity (APACHE II, GCS and neutropenia), origin (community, another ICU, ward, and long-stay centers), pathology (medical, trauma, coronary, scheduled and emergency surgery), comorbidities (diabetes, chronic renal insufficiency, COPD, cirrhosis, immunosuppression, neoplasia, solid organ transplantation (SOT) and malnutrition); previous hospital stay (before ICU admission).
The chi square test was applied and the Odd ratio (95% IC) was calculated. The p < 0.05 and the OR ≥ 1.1 were considered significant.
RESULTS. Among the 69,741 patients registered, the presence of some MRB was diagnosed in 4.830 (6.4% of the total). Of these, in 3024 patients (4.3%) the identification was on admission and in 1.940 (2.8%) during the stay.
The MRB at admission / during ICU stay were 1,508 / 870 ESBL, 1020/ 265 MRSA, 448/505 *P aeruginosa,* 227/281 CBP and 154/297 *Acinetobacter.*
When comparing the RF of the pts with BMR at admission or during ICU stay, some differences were observed: APACHE ≥15: OR (95% IC) 1.8 (1.7-2.0) vs 2.6 (2.4- 2.9); previous hospital stay ≥10 days: OR (95% IC) 3.7 (3.5-4.0) vs 34.2 (29.1-40.2); long-stay center: OR (95% IC) 3.4 (2.7-4.4) vs 0.5 (0.0-3.0); coronary disease: OR (95% IC) 0.2 (0.2-0.2) vs 0.2 (0.2-0.3); traumatic: OR (95% CI) 0.5 (0.4-0.6) vs 1.8 (1.5-2.1); Emergency surgery: OR (95% IC) 1.4 (1.3-1.6) vs 4.1 (3.7-4.5); Neutropenia: OR (95% CI) 3.4 (2.8-4.2) vs 2.5 (1.9-3.3), Chronic Kidney Ins: OR (95% IC) 2.3-2 , 1-2.6) vs1.19 (1.0-1.3), Cirrhosis: OR (95% IC) 1.9 (1.6-2.2) vs 1.4 (1.2-1) , 8), COPD: OR (95% IC) 1.8 (1.7-2.0) vs 1.5 (1.3-1.7), malnutrition: OR (95% IC) 3.5 (3.1-3.8) vs 2.5 (2.2-2.9) and ORT (95% IC) 3.3 (2.8-4.0) vs 1.2 (0.8-7.0) 1,7)
In addition, the stay in ICU> 10 d had the highest OR in the acquisition of MRB 43, 4 (37.9-49.6) and also the exposure to extrinsic RF such as MV, CVC, UC
CONCLUSIONS. RFs vary when considering the acquisition prior to admission or during the stay in the ICU. The type of MRB also varies, predominantly ESBL and MRSA in the previous ones, and *P aeruginosa*, CBP and *Acinetobacter* during.

Diagnostic performance of a rapid detection test (PCR) for multiresistant bacteria (MRB) in patients admitted to the ICU

A. Carranza Pinel, O. Moreno Romero, I. Cruz Valero, J. Tejero Aranguren, M.E. Yuste Ossorio, M. Colmenero Ruiz, M. Muñoz Garach
Hospital Universitario San Cecilio Granada., Intensive Care Unit, Granada, Spain
Correspondence: A. Carranza Pinel
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0396

OBJECTIVES. To determine the diagnostic performance of a rapid detection test for multiresistant bacteria by PCR in patients admitted to the ICU. The performance of the test is measured in terms of accuracy and agreement with the bacteria isolated in the culture.
METHODS. Prospective observational cohort study during a seven-month period. Patients admitted to a mixed ICU who underwent the PCR test in rectal and pharyngeal swabs and cultures (rectal swab and tracheal aspirate if under mechanical ventilation) at the time of admission, considering this last one as the reference test. Patients screened were those who had at least one risk factor of the six proposed in the "Resistencia Zero" program of Spanish Intensive Care Society for preventive isolation. These are:

1. Hospitalization of more than five days in the three previous months.
2. Institutionalized patients (prison, social health centers, nursing homes, etc.)
3. Colonization or known infection by multiresistant bacteria (MRB)
4. Antibiotherapy >7 days in the previous month (especially cephalosporins of 3rd-4th generation, quinolones and carbapenems)
5. Patients with chronic kidney failure undergoing hemodialysis or continuous ambulatory peritoneal dialysis
6. Patients with chronic pathology and high incidence of colonization / infection by MRB: cystic fibrosis, bronchiectasis, chronic ulcers, etc.

We calculated the accuracy parameters of the test and the concordance values of the PCR test were determined by the Kappa value.

RESULTS. There were 86 patients who met criteria for preventive isolation. There were 28 patients had a positive PCR, 22 of them had also a positive culture, showing concordance between the multiresistant bacteria isolated in culture and the PCR in all cases. There were 58 patients who presented negative PCR at their admission to the ICU. In this group, only 3 showed discrepancy between negative PCR and positive culture. All three had only one risk factor. The values of diagnostic precision were: Sensitivity: 0.88; Specificity: 0.9; PPV: 0.79; NPV: 0.95; LR +: 8.8; LR-: 0.13. The Kappa concordance index was 0.754 with a 95% CI of 0.965-0.544.

CONCLUSIONS. The PCR technique for rapid detection of multiresistant bacteria presents a good agreement with conventional cultures. Preventive isolation could be withdrawn for patients who only had a single risk factor.

INTRODUCTION. Multidrug-resistant (MDR) bacteria (*Klebs spp., Pseud. aerog.,Acinet b.,Staph.MRSA*) account for a significant percentage of health care associated infections in Greek ICU setting .

OBJECTIVES. To establish the incidence of lower inspiratory tract colonization by MDR pathogens and ventilator-associated pneumonia (VAP) , in a 3-years period (2015-2017) before and after implementation of care bundle and furthermore, after incorporation of antimicrobial copper (Cu^{++}) in a general 8-bed ICU.

METHODS. All intubated patients admitted in ICU from 1/1/2015 to 31/12/2017 were examined for MDR colonization, on admission day, every Monday and any day there was a clinical or laboratory deterioration.Non-invasive tracheal aspiration and semiquantitative or qualitative cultures were performed.CPIS score was used for VAP definition. Patients with positive culture on admission were excluded. 2015 was observation year.In 2016 care bundle was implemented including: hand hygiene, elevation of head of bed 30-45°, no scheduled ventilator circuit changes, oral hygiene/8hrs, subglottic secretions drainage.In 2017 Cu^{++} was incorporated in key touch surfaces in ICU as an additional antimicrobial measure.

Colonizations (in the same patient different pathogen was a different colonization),VAP, APACHE II score on admission, total days on ventilator,total days in ICU and day to first detected colonization were recorded.Results were analyzed by SPSS vs.20 using Mann-Whitney U test for median values,Shapiro-Wilk test of normality and Pearson Chi-square for correlation, with significance level p< 0,05.

RESULTS.

CONCLUSIONS. Care bundle for VAP prevention resulted in significant reduction to MDR VAP occurrence during the second semester in 2016 and in 2017 when Cu^{++} was added to standard care.Prolongation to 1st detected colonization was significant. Decrease in pharmaceutical expense was noticable.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0398

INTRODUCTION. The growing adoption of extracorporeal membrane oxygenation (ECMO) into adult intensive care units (ICUs) has lead clinicians to re-evaluate the use of conventional dosing regimens in

this patient population. Neonatal studies have suggested modified antimicrobial dosing regimens are necessary in the presence of ECMO to attain PK/PD targets for optimised bacterial kill and clinical cure. However, due to significant differences in physiology, these findings cannot be safely transferred to the adult population. Empirical antibiotics such as ceftriaxone have no defined titratable endpoint, leading to possible sub- or supra- therapeutic management in this group of critically ill patients.

OBJECTIVES. The aim of this study is to describe the pharmacokinetics (PK) of ceftriaxone in critically ill patients receiving ECMO. Through the improved understanding of ECMO-induced PK effects, propose dosing strategies that are more likely to attain the PK/PD target of 60-70% $fT>_{MIC}$ to optimise therapeutic outcomes.

METHODS. This study was a multi-national, open-label study designed to describe the PK of ceftriaxone over one dosing interval. Critically ill adults with severe cardiac and/or pulmonary dysfunction from six intensive care units in Australia, New Zealand and Switzerland were eligible for recruitment. Serial blood samplings were taken over pre-defined time points over one dosing interval. Centralised bioanalysis occurred at the University of Queensland to determine plasma ceftriaxone concentration through validated chromatographic methods. The concentration-time data were then used to generate pharmacokinetic parameters through non-compartmental methods.

RESULTS. Nine patients were recruited to the study [Table 1]. One patient was excluded from analysis due to incorrect documentation. Non-compartmental analysis yielded a median (IQR) of 0.67 (0.5-0.85) L/h for total clearance and 12.19 (8.72-15.88) L for volume of distribution. Refer to Figure 1 for the total plasma concentration time graph.

CONCLUSIONS. The PK parameters generated by this study were generally consistent with published parameters of critically ill patients not receiving ECMO. It appears that conventional dosing of ceftriaxone in the critically ill population may provide the target attainment of 60-70% $fT>_{MIC}$. It is important to acknowledge the heterogeneity within the results and that further analysis and recruitment is required to produce robust recommendations in dosing antibiotics in adults on ECMO.

The first experience of targeted antibiotics for the regulation of the metabolic activity of the gut microbiota (MAGM) in critically ill patients with pneumonia or abdominal infection

N. Beloborodova, Y. Sarshor
Federal Research and Clinical Center of Intensive Care Medicine and Rehabilitology, Negovsky Research Institute of General Reanimatology, Moscow, Russian Federation
Correspondence: N. Beloborodova
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0399

INTRODUCTION. We suggest that antimicrobial therapy in critically ill patients should be aimed not only at the death of bacteria in the focus of infection, but also at reducing the metabolic activity of gut microbiota (MAGM). The gut is the main reservoir of bacteria and the main source of bacterial metabolites. Serum levels of some aromatic microbial metabolites (AMM) reflect MAGM and closely correlated with the severity of organ dysfunction and mortality: this has been shown previously for phenyllactic (PhLA), p-hydroxyphenylacetic (p-HPhAA), p-hydroxyphenyllactic (p-HPhLA) acids [1, 2].

OBJECTIVES. Try to correct the metabolic activity of microbiota and evaluate its effectiveness.

METHODS. For research purposes, we use enteral antibiotics that prevent protein synthesis in bacteria and/or possess anti-biofilm activity: gentamicin (GEN) 240 mg 2/day plus clarithromycin (CLAR) 500 mg 1/day. Adult patients (pts) with pneumonia or abdominal infection were divided into two groups: group 1 with GENT+CLAR in addition to standard treatment, and group 2 - only standard treatment. The levels of AMM were measured in blood serum using GC-FID [3]. Data of patients, the SOFA scales, serum levels of AMM, their sum (Σ3AMM) were evaluated at admission to ICU and in dynamics, than analyzed by nonparametric methods of statistics (Statistica 10).

RESULTS. The study included 56 pts: 26 pts in 1st group, 30 pts in the 2nd group. On admission, patients of both groups were comparable in age and clinical state (APACHE II and SOFA scales).

The next day, patients of the 1st group had an improvement in the state - a decrease in the SOFA score by 29% (p< 0,05), and tendency towards lower p-HPhLA and p-HPhAA, whereas in the 2nd group were no positive dynamics in SOFA score and tendency towards higher p-HPhLA and p-HPhAA when comparing to baseline (Fig. 1). The correlation between SOFA and AMM exceeded r=0.6 (p< 0.05). The survival rate in 1st group was higher than in in the 2nd group (57% vs 46%, p> 0.05).

Conclusions. Despite the absence of significant differences, the downward trend of mortality in group 1 by 11% is encouraging. Enteric correction of metabolic activity of gut microbiota contributes to the improvement of indicators of organ dysfunction (SOFA). This means that it is advisable to further explore the possibilities of targeted antibiotic use to regulate the MAGM.

INTRODUCTION. Multiresistant bacteria (MRB) are an important Public Health issue as it increases the patient´s morbimortality rates, particularly in the critically ill. The choice of a correct empirical antibiotic is relevant as it may reduce the impact of these infections and the disseminations in our units.

OBJECTIVES. First, to describe the frequencies of MRB infection and colonization from ESKAPE microorganisms in our intensive care unit

(ICU) in a twelve-month period. Second, to define our appropiate empirical antibiotic rate for MRB infections.

METHODS. Analysis of a prospectively collected database (ENVIN-HELICS registry of Spanish Society of Intensive Care) during 12 months (year 2017) in our ICU, 20 bed, mostly neurotraumatologic patients. We registered all positive cultures with ESKAPE germs (Enterobacteriae, SARM, Klebsiella, Acinetobacter, Pseudomona, Enterococcus). Cultures were divided into 2 categories. The first one, "colonization culture", as part of a surveillance program at the admission of patients at risk of harboring MRB (Zero Resistance). The second, "suspected infection", obtained when an infection was clinically suspected at admission or during ICU stay. From all "suspected infection", we registered the empirical antibiotic therapy used. When the microorganism was identified, we analysed if the antibiotic was either maintained, changed or added a second one. Finally, with the antibiogram, we defined whether the empirical treatment was appropriate or not.

RESULTS. 1398 patients admitted to ICU in 2017. 61% male, 49% female. Mean age of 57±11. There were a total of 498 positive cultures, 111 (22.2%) with MRB-ESKAPE in 75 different patients. From these, 78 (70.3%) were "colonization cultures" and 33 (29.7%) "suspected infection". The localization of these infections were: 25 (60%) respiratory, 8 (19%) urine tract, 5 (12%) bacteremia and 4 (9%) other infections.

In these suspected infections (33) an empirical antibiotic was initiated. After the identification of the microorganism: in 22 (66.66%) there were no modifications in treatment, in 7 (21.21%) the antibiotic was changed and in 4 (12.12%) we added a second one. After knowing the antibiogram: in 26 (78.78%) first empirical treatment was appropriate, in 3 (9%) we were right at the second election, and in 4 (12.12%) none of the antibiotic were correct. ESKAPE percentages were: 29% Enterobacteria, 25% SARM, 19% Klebsiella, 16% Pseudomona, 11% Acinetobacter and no vancomicine-resistant enterococcus.

CONCLUSIONS. Most frequent ESKAPE bacteria in our unit is the Enterobacteriae group. Along with SARM they represent more than half of MRB infections. Our ESKAPE MRB infection rate is 7.8% and the appropriate empirical antibiotic rate for these were 79%. In half of the 21% of inappropriate empirical antibiotic treatment was due to an unusual early infection with klebsiella MR in patients with no risk factors for developing infection or colonization with MRB.

INTRODUCTION. Ventilator-associated pneumonia (VAP) is one of the most frequent nosocomial infections in intensive care patients, particularly in traumatic brain injury (TBI), with an incidence ranging from 28 to 67% (1-2). Although its attributable mortality in trauma seems close to zero, reports have emphasized the potential deleterious effect of VAP in TBI patients (3-4).

OBJECTIVES. We aimed to investigate the role of antibiotic prophylaxis (AP) on the incidence of VAP in patients suffering from severe TBI.

METHODS. This post hoc analysis of 2 multicentre double studies extracted and pooled data on severe TBI (Glasgow coma scale ≤8). Patients were differentiated into 2 groups: those who received AP before the occurrence of VAP (AP group) and those who did not receive prophylaxis (control group). The main objective was to

evaluate the impact of AP on the incidence of VAP (early VAP (>2 days and ≤5 days) and late VAP (>5 days)).

RESULTS. A total of 295 patients were included in the analysis (AP group, n=146 and control group, n=149). The global incidence of VAP was 145 (49%), early VAP was 62 (43%) and late VAP was 83 (57%). The rate of VAP was significantly lower in the AP group than in the control group (n=57 [39%] vs n=88 [59%], Relative Risk=0.33, 95% CI, 0.19-0.56, p=0.001) and time to VAP occurrence was significantly reduced (hazard ratio=0.50, 95% CI 0.36-0.69, p< 0.001). The rate of early VAP was significantly lower in the AP group (15 [10%] vs 47 [32%]; p< 0.001), whereas that of late VAP did not differ between the 2 groups (42 [29%] in the AP group vs 41 [28%] in the control group; p=0.811).

The total duration of antibiotic exposure was significantly lower in the AP group. ICU length of stay and mortality in the ICU and at day 28 were not significantly different between the 2 groups.

CONCLUSIONS. In a large population of severe TBI, AP decreased the incidence of early VAP. It remains to be seen whether this treatment has a significant impact on bacterial ecology and late neurologic functional outcomes.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0402

INTRODUCTION. Vancomycin (VCM) has a narrow therapeutic range, therefore, therapeutic drug monitoring is necessary for effective and safe use. At Kagawa University Hospital, starting from April 2016, we assigned a ward pharmacist to the emergency medical center and began intervening for blood level control for VCM administered patients. This research will report what effects have been confirmed through the process of these interventions.

OBJECTIVES. To research the effects of intervention by a ward pharmacist on VCM blood concentration control in the emergency medical center.

METHODS. We compared two sets of data, patients who received VCM in intravenous infusions during a period in which we had not assigned a ward pharmacist (April to October 2015), and during a period in which we had assigned a ward pharmacist (April to October 2016). The data collected included the implementation rate of dosing regimen initiated by a pharmacist, retention rate of blood concentration maintained in the therapeutic range (10-20 μg/mL) and in the toxic range (over 20 μg/mL), duration of administration, survival rate on 28th day after the start of administrations, the number of days stayed in the life emergency medical center, incidence of renal dysfunction and compare them to before and after assigning a ward pharmacist.

RESULTS. There were 15 subjects before the assignment of a ward pharmacist and 12 subjects after the assignment. The implementation rate of dosing regimen initiated by a pharmacist had significantly increased after assignment (20.0% vs 83.3%, p = 0.002). The days spent in the emergency medical center had significantly decreased after assignment (median: 19.0 days vs 9.5 days, p = 0.032). The retention rate of blood concentration maintained in the toxic range decreased after significant resident (45.1% vs 9.1%, p = 0.003).

CONCLUSIONS. Up until now, there was no pharmacist stationed in the emergency medical center of our hospital, and we had only limited intervention in VCM blood concentration management. However, as a ward pharmacist has been assigned, it has become possible to participate in designing proactive administration schedules from an early stage of VCM administration in almost all cases, which is thought to have led to a decrease in the rate of intoxication. In addition, decrease of intoxication rates leads to prevention of adverse events and contributes to the shortening of days in which patients stay within the ward. It is expected that continued active intervention in the blood concentration control of VCM by ward pharmacists will lead to a good therapeutic effect and treatment outcome in the future.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0403

Background: Pre-emptive fungus coverage in patients with secondary peritonitis and sepsis is still controversial. Expert opinion recommends its use in upper gastro-intestinal lesion and in patients with septic shock (1, 2). However, there is still no accurate score to predict fungal infection or when to decide to provide antifungal.

OBJECTIVE. We aimed to evaluate antifungal usage in patients with peritonitis admitted to the ICU and its impact on mortality, as well as to identify factors related to positive culture to fungus.

METHODS. We performed a retrospective study of patients submitted to urgent abdominal surgery due to peritonitis. We analyzed global mortality and its relationship with empirical antifungal treatment and the presence of positive culture for fungus in the blood or products collected during surgery. Statistical analysis was performed using STATA.

RESULTS. We included 188 patients between 2016 and 2017 admitted after gastro-intestinal urgent surgery, in which 77% was the first intervention. Patients were predominantly male (53.7%), with a mean age of 69.1 (±15.2), a mean SAPSII of 51.6 (±19.3), and an admission SOFA of 7.6 (±4.3). Importantly 53.7% had septic shock.

Fungus were isolated in only 8.5% of patients (n=16) during the first 4 days of ICU admission, with a median length of stay in hospital of 4.5 days until isolation. 81% of isolates were Candida albicans or Candida glabrata. All the fungal identification were done in products collected during surgery excepted in one patient that had candidemia. Empirical fungal coverage was provided to 20.7% (n=39), 8 of which had fungal infection documented later on, but mortality was not related to antifungal prescription.

ICU mortality in patients without fungal isolation was 26.1%, and 31.3% in patients with fungal isolation (p=0.66). Significantly, SAPSII,

time in hospital, number of previous surgeries, gender, age and segment of gastrointestinal lesioned were not linked with a high risk for fungal isolation. Of note, there was a trend for septic shock patients to have increased risk of fungal infection (odds ratio 2.8, P=0.08), even when adjusted for SAPSII.

CONCLUSION. There is a need to better define indication for fungal coverage in patients with peritonitis(1). Although limited by the low number of patients with positive cultures, we propose that antifungal coverage is not needed in peritonitis in the first event that leads to ICU admission. These results will be further confirmed in a larger dataset.

BACKGROUND. Target Controlled Infusion (TCI) is a technique of infusing IV drugs to quickly achieve a user-defined drug concentration in a specific body compartment. TCI systems have been widely implemented in the field of anesthetics, but have never been applied for antibiotic dosing. As there is growing evidence that pharmacokinetic/pharmacodynamic (PK/PD) target attainment is related to an improved clinical outcome, TCI seems an attractive tool to accurately achieve target concentrations. In this study we have used TCI to administer cefepime in critically ill patients.

MaATERIAL/METHODS. A previously developed population pharmacokinetic (PopPK) model for cefepime was integrated in Rugloop II software (Demed, Belgium). Rugloop II calculated the amount of cefepime required to quickly achieve and maintain target concentrations. A Fresenius Orchestra syringe pump was connected to Rugloop II for drug delivery. The estimated creatinine clearance (eCrCl) based on the Cockcroft-Gault formula was used as an input variable to calculate cefepime clearance. A cefepime blood concentration of 16 mg/L was targeted and a total of 21 ICU patients were treated using TCI for a median time of 4.5 days. During therapy there were no adaptations based on changes in eCrCl or cefepime concentration measurements. To evaluate the measured versus predicted plasma concentrations, blood samples were taken (median number of samples per patient: 13) and total cefepime concentrations were measured using UPLC-MS/MS. Performance of the TCI system was characterized using the Varvel criteria.

RESULTS. The median prediction error (MdPE) was 21.1%, median absolute prediction error (MdAPE) was 32.0%, wobble was 11.4%, and divergence was -3.72%.h^{-1}. Clinical trial simulation showed that the results for MdAPE, wobble and divergence were as expected by the TCI model. The positive bias (MdPE) was caused by an overestimation of the volume of the central compartment in the TCI model. A combined fit of the original and the new dataset showed that the volume of distribution for cefepime is 12.2 L and not 18.3 L as previously estimated.

CONCLUSIONS. Measured cefepime concentrations were close to those predicted using TCI in critically ill ICU patients. TCI is a promising tool for individualized dose optimization of antibiotics.

INTRODUCTION. Patients developing an AKI episode in the community (known as *community-acquired AKI*, CA-AKI) have been described as having different clinical features and better outcomes from *hospital-acquired* AKI patients (HA-AKI). However, previous studies have included mixed populations of AKI patients. If better outcomes still could be expected once CA-AKI has progressed to severe AKI with renal replacement therapy (RRT) requirements is unclear.

OBJECTIVES. To compare the aetiologies, clinical characteristics, severity and outcomes of critically ill patients with CA-AKI and HA-AKI requiring RRT during ICU stay.

METHODS. From 2006 to 2016, 889 adult critically ill patients older than 18 years diagnosed with severe acute kidney injury with RRT requirements were included and classified into CA-AKI and HA-AKI according to prespecified criteria. Clinical characteristics, RRT dependence, inhospital mortality, hospital and ICU length of stay, and other secondary outcomes were registered. Comparison of baseline and follow-up serum creatinine values was done using analysis of variance (ANOVA) test. Time-to-event distributions (survival curves) were estimated using the Kaplan-Meier method. We performed a Cox regression model to analyse risk factors for RRT dependence and mortality. Robustness of the results was assessed using a sensitivity analysis.

RESULTS. Of the 889 patients with severe AKI, 56.2% (500 patients) had CA-AKI, from which 78% had AKI stage 3 before RRT; 43.7% (389 patients) had HA-AKI and 66% AKI stage 3 before RRT. HA-AKI patients had a higher number of pre-existing medical conditions (Charlson Comorbidity Index) (3.1 ± 2 vs 1.8 ± 2; $P < 0.0001$), than CA-AKI, including chronic kidney disease (CKD) (9.5% vs 4.4%, p< 0.0001) and chronic liver failure (90(28%) vs 81(17%), p=0.001). CA-AKI patients had worse Acute Physiology And Chronic Health Evaluation II (APACHE II) scores and higher baseline sCr values (70 vs 66 μmol/L, p< 0.0001). Peak sCr levels during the first 24 hours of ICU admission were 305 mmol/L vs 207 mmol/L (p< 0.0001). sCr at discharge did not differ between the groups, however, hospital LOS was significantly longer for HA-AKI compared with CA-AKI (63±54 vs 43±37 days, p< 0.0001). Overall in-hospital, 30-day and 90-day mortality was 30.7% vs 23.3% (p= 0.216) in CA-AKI and HA-AKI respectively. There were no differences neither in duration of CRRT, nor in mechanical ventilation free days. Sensitivity analyses were applied in order to confirm the replicability of these findings (p < 0.001).

CONCLUSIONS. This study found no differences on mortality rates between CA-AKI and HA-AKI in a population of critically ill patients with severe AKI with RRT requirements.

INTRODUCTION. Acute kidney injury (AKI) has a high incidence in critical ill patients[1]. Recently, biomarkers have been developed to detect AKI earlier and their implementation could be able to contribute to an early therapeutic approach leading to better outcomes[1].

OBJECTIVES. To evaluate the predictive value of biomarkers TIMP2 and IGFBP7 (NephroCheck™) for early detection of renal replacement therapy (RRT) requirements. METHODS A retrospective study was performed. We enrolled adult patients admitted in the intensive care unit (ICU) whom the NephroCheck™ was tested in a period between February 2015 and June 2017. The predictive value of NephroCheck™ was assessed by a receiver operating characteristic curve (AUC).

RESULTS. 123 patients were analyzed. Agree to KDIGO criteria, 24.4% had AKI I, 46.3% AKI II and 29.3% AKI III. 50.4% patients required RRT.

According to the previous publications, the NephroCheck™ was classified into three risk categories[1]. Table 1 shows the comparison of the variables analyzed by the three groups.

There were no differences in baseline renal function based on estimation of glomerular filtration rate for the three groups. The high-risk patients, had more oliguria 12, 24 and 48 h (p< 0.001) after admission and they took more time to recover diuresis (p< 0.001). The AUC of NephroCheck™ for urine output at 12, 24 and 48h was 0.728, 0.703 and 0.724 (p < 0.001) respectively. And the AUC of NephroCheck™ for predicting RRT was 0.719 (p< 0.001).
CONCLUSIONS: NephroCheck™ is able to predict oliguria and RRT requirements. In the future, this test could be recommended to contribute to therapeutic decisions in critically ill patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0407

INTRODUCTION. Postoperative acute kidney injury (AKI) is a prominent problem in patients undergoing LVAD implantation and associated with increased morbidity and mortality. Although several risk models for the prediction of postoperative renal replacement (RRT) have been widely used in cardiothoracic patients, none of these scoring systems have been validated in patients after LVAD implantation.

OBJECTIVE. Validation of three clinical risk scores for the prediction of AKI requiring RRT after LVAD-implantation.

METHODS. A retrospective analysis of all patients undergoing LVAD-implantation at our institution between 09/2013 and 07/2016 was performed. Primary outcome measure was AKI requiring RRT within 14 days after LVAD implantation. The predictive capacity of the Cleveland Clinic Score (CCS), the Society-of-Thoracic-Surgeons-Score (STS) and the simplified renal index score (SRI) were evaluated using receiver-operator characteristic curve analyses and Hosmer-Lemeshow test.

RESULTS. During the observation period, 76 patients underwent LVAD-implantation, 19 patients were excluded due to preoperative RRT. RRT was associated with a prolonged ventilation time (2.41±5.86 vs. 14.13±18.88 d, p< 0.001), LOS on the ICU (6.12±7.49 vs. 26.78 ±

27.07 d, p< 0.001) and 180 day mortality (14(60.9%) vs. 6(17.6%), p< 0.01).

Patients with postoperative RRT were characterized by a higher serum creatinine (1.86±1.3 vs. 1.36±0.4 mg/dl, p=0.04), a higher Alanine transaminase/ Aspartate aminotransferase (De Ritis-Ratio) (1.45±1.05 vs. 0.89±0.56, p= 0.01), and a higher INR (1.59±1.05 vs. 1.19±0.4, p=0.04).

Whereas the CCS (7.43±1.75 vs. 6.44±1.44, p=0.02) and the STS (28.12±15.08 vs. 21.53±5.43,p=0.02) were significantly higher in patients with RRT than in those without RRT, the SRI did not differ between these groups (3.96±1.15 vs. 3.44±1.05, p =0.08). Using ROC-analyses, CCS, STS and SRI showed moderate predictive capacity for AKI with need for RRT with an AUC of 0.661 ± 0.073 (95%CI 0.518-0.804, p =0.040), 0.637 ±0.079 (95%CI 0.082- 0.482, p =0.792) and 0.618±0.075 (95%CI 0.135 -0.471,p =0.764) respectively with comparable accuracy in the Delong test. Using univariate logistic regression analysis, only the De Ritis-Ratio (OR 2.67, 95% CI 1.08-6.62, p = 0.034) and MELD (OR 1.11, 95% CI 1.01-1.22, p= 0.028) were identified as predictors of postoperative RRT.

CONCLUSION. Our data suggest that risk scores derived from general cardiac surgery cannot predict RRT in patients after LVAD implantation. Therefore, it seems to be necessary to develop a specific risk score for this patient population.

Acute kidney injury after Kasai portoenterostomy for biliary atresia

M.S. Song, J.H. Park
Yonsei University College of Medicine, Department of Anaesthesiology and Pain Medicine, Seoul, Korea, Republic of
Correspondence: J.H. Park

INTRODUCTION. Acute kidney injury (AKI) after surgery is associated with high morbidity and mortality in children. Biliary atresia (BA) is a progressive inflammatory destructive process of the bile ducts. Children with BA are at risk of AKI because of their young age at the time of surgery, long operation time and liver failure.

OBJECTIVES. The aim of this study was to evaluate the incidence and risk factors for postoperative AKI after Kasai operation.

METHODS. We performed a retrospective investigation of 100 children undergoing elective Kasai operation between November 2005 and December 2015. The incidence of AKI was assessed on the basis of Acute Kidney Injury Network criteria. Children were divided into 2 groups depending on the occurrence of AKI. Multivariable logistic regression models were developed to analyze risk factors for AKI.

RESULTS. AKI occurred in 34 of 100 children (34 %). Age older than 30 days of age at the time of surgery was the leading cause for AKI. Lower pre-operative serum creatinine and hemoglobin levels were independent risk factors for AKI. Children born before 37 weeks of gestation had lower incidence of AKI.

CONCLUSIONS. Increased age at the time of surgery had progressive and deleterious effects on postoperative AKI in children undergoing Kasai operation. These finding indicate the importance of early diagnosis and treatment for BA.

Predicting factors of mortality during the first 24 hours of continous renal replacement therapy in patients with acute renal injury stage 3 in an intensive care unit

N.E. Carrillo Molina[1], J. Franco Granillo[1], J.S. Aguirre Sanchez[1], G. Camarena Alejo[2]
[1]American British Cowdray Medical Center I.A.P., Critical Care, México, Mexico; [2]American British Cowdray Medical Center I.A.P., Intensive Care Unit, México, Mexico
Correspondence: N.E. Carrillo Molina

INTRODUCTION. AKI refers to an abrupt decrease in kidney function, established in hours to days. Several consensus definitions of AKI have been developed in order to provide a uniform definition. AKI occurs in more than 50% of critically ill patients, 23% need renal replacement therapy, preferring continuous therapies. However mortality seems not to change with this technology.

OBJECTIVES. Identify factors thay may predict mortality in AKI patients in the first 24 hours of the star of continuos renal replacement therapy (CRRT).

METHODS. Restrospective cohort study in a single center. Included patients with AKI 3 under CRRT. We estimate the global mortality, total free time of CRRT and risk factors for mortality.

RESULTS. 48 patients were included 56.3% were masculine with an average age of 69 years (SD±14.7). Overall mortality during ICU stay was 68% of all patients and the average length of stay was 14 days (IQR 6-28). 85% of all patients required CRRT with 140 hours free of CRRT (IQR 63-221). Creatinine and blood urea nitrogen at the time of diagnosis of AKI was 2.7 mg/dl (SD ±1.6) and 62.6 mg/dl (SD ±31). The average scores severity scores at the time of admission were APACHE II 24 points (SD ±8), SOFA 13 points (SD ±2), SAPS III 70 points (SD ±12). Median lactate levels at the time of admission were 2.3 mEq/L (IQR 1.2-2.7). The variables with best capacity to predict mortality where creatinine and BUN at the time of admission with an AUC of 0.59 (p=0.07) and AUC 0.73 (p=0.01) respectively. Severity scores $AUC_{APACHEII}$=0.56, AUC_{SOFA}=0.51, $AUC_{SAPSIII}$=0.55.

CONCLUSIONS. The variables predictive capacity for mortality at the time of admission or at the time of diagnosis of AKI were creatinine >2.0 mg/dl HR = 2.5 (IC 95% 1.13 - 5.9, p=0.024), APACHE II >= 20 points HR = 2.7 (IC 95% 1.17-6.2, p=0.019). The rest of variables had no predictive capacity at the time of admission and where not associated as independent risk factors at the time of admission for mortality.

Acute kidney injury in a medical ICU: a prospective observational study

M. Simsek, E. Ortac Ersoy, E.K. Kaya, S. Ocal, A. Topeli
Hacettepe University Faculty of Medicine, Medical Intensive Care Unit, Ankara, Turkey
Correspondence: M. Simsek

INTRODUCTION. Acute kidney injury (AKI) is a common and a serious complication among patients admitted to ICUs.

OBJECTIVES. The aim of this study was to describe the incidence, severity and outcome of AKI among patients admitted to a medical ICU; and to compare the characteristics of AKI and non-AKI patients.

METHODS. This is the preliminary report of patients admitted to the medical ICU of Hacettepe University Faculty of Medicine between 1st February and 1st April 2018. All adult patients admitted to ICU except those who died within first 24 hours of admission were included. Re-admitted patients and patients on chronic hemodialysis were excluded, as well. Diagnosis and staging of AKI was based on KDIGO (Kidney Disease Improving Global Outcomes) criteria as any of the following: increase in serum creatinine (Cr) by >0.3 mg/dl within 48 hours, increase in Cr to 1.5 times from baseline which is known or presumed to have occurred within the prior 7 days or urine volume < 0.5 ml/kg/hr for 6 hours. Positive fluid balance was calculated as total fluid intake minus total fluid output divided by body weight (x100) and more than 5% is accepted as positive fluid balance. Variables during the first 15 days after admission are reported.

RESULTS. Fourty-two patients were included. Twenty (47.6%) patients were male and mean age (±SD) was 64.8±19.5 years. Mean APACHE II and SOFA scores were 21.5±8.3 and 6.8±4.5, respectively. Major reasons for ICU admission were respiratory failure (n=16; 38.1%) and sepsis (n=15; 35.7%). Twenty eight (66.7%) patients received invasive mechanical ventilation and total of 25 (59.5%) patients had sepsis during ICU stay. AKI was present in 24 (57.1%) patients according to KDIGO classification (22 AKI cases on admission, 2 during ICU stay). Stage 1 AKI was present in 12 (50.0%) patients, stage 2 in 2 (8.3%) and stage 3 in 10 (41.7%) patients. Mean ICU length of stay was 10.3±12 days. ICU mortality and hospital mortality were 23.8% and 26.2%, respectively. Renal replacement therapy was admitted to 13 (54.2%) patients with AKI. Of them, 11 patients received intermittent hemodialysis, 1 received continuous renal replacement therapy and 1 received both. Statistically significant variables in the comparison of AKI and non-AKI patients are shown in the Table. AKI patients had higher APACHE II and SOFA scores, basal and peak creatinine levels, peak BUN levels, sepsis, shock and positive fluid balance, and they received mechanical ventilation more than non-AKI patients, whereas they had lower albumin levels. AKI patients had higher ICU and hospital mortality rates than non-AKI patients.

CONCLUSIONS. AKI was present in 57.1% of critically-ill patients admitted to the medical ICU. In 91.7% of patients AKI was present on admission. ICU and hospital mortality rates were higher in AKI than non-AKI patients.

Table 1 (abstract 0410). Comparison of AKI and non-AKI patients

	ALL n=42	AKI n=24	Non- AKI n=18	P
APACHE II	21.5±8.3	24.9±7.4	17.3±7.7	0.002
SOFA	6.8±4.9	9.4±3.6	3.2±2.9	<0.001
Invasive mechanical ventilation	28 (66.7%)	19 (79.2%)	9 (50%)	0.047
Sepsis during ICU stay	25 (59.5%)	19 (79.2%)	6 (33.3%)	0.003
Shock during ICU stay	21 (50.0%)	7 (29.2%)	14 (77.8%)	0.002
ICU Mortality	10 (23.8%)	9 (37.5%)	1 (5.6%)	0.017
Hospital Mortality	11 (26.2%)	9 (37.5%)	2 (11.1%)	0.014

Table 2 (abstract 0410). Comparison of Laboratory variables and fluid balance between AKI and non-AKI patients

	ALL n=42	AKI n=24	Non- AKI n=18	p
Basal Creatinine, mg/dl	0.9±0.6	1.1±0.6	0.6±0.2	<0.001
Peak Creatinine during ICU stay, mg/dl	2.16±2.0	3.2±2.0	0.7±0.2	<0.001
Peak BUN during ICU stay, mg/dl	57.2 ±35.7	79.9 ±29.2	27.0±15.1	<0.01
Median albumin during ICU stay, g/dl	2.51±0.5	2.3±0.5	2.7±0.4	0.043
Positive fluid balance during ICU stay, >5% *	26 (61.9%)	19 (79.2%)	7 (38.9%)	0.014

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0411

INTRODUCTION. It is known that the main reasons for admission in different intensive care units are shock followed by cardiac disease, neurologic, respiratory failure and septic conditions. The main studies published so far date from the general population.

OBJECTIVES. To analyze the epidemiology in patients with stage 3-4 chronic kidney disease admitted to intensive care.

METHODS. A single-center retrospective descriptive study. Inclusion period of six years. Qualitative variables are expressed in frequencies, and quantitative variables using mean, median, range and standard deviation, according to the probability distribution. Five groups of patients were established:

1. Cardiac (arrhythmia, acute pulmonary edema, acute coronary syndrome, cardiac tamponade),
2. Septic (endocarditis, abdominal post-operative, others),
3. Cerebrovascular disease(CVD),
4. Hemorrhagic Shock (post-surgery urological, vascular, gastrointestinal bleeding, ...) and
5. Others (pancreatitis, respiratory insufficiency, hepatic failure and cholelithiasis).

RESULTS. 99 patients, 59% female and 41% male, were analyzed. Mean age was 70 ± 12 years old. APACHE II 22.8 ± 9.2 points. The average stay was 7.3 ± 13.4 days. Analyzing these three variables as a cause of admission to the age differences between the septic vs cardiac (73.3 ± 10.3 in cardiology, P = 0.003) were found, and the APACHE between cardiac vs CVD,(31 ± 8.3 in CVD, P = 0.004). In males, the acute coronary syndrome was more frequent (p = 0.012) and in women the acute pulmonary edema (p = 0.058). The main cause of admission was cardiology with 57.6%, followed by 17.2% in septic, 12.1% for stroke, hemorrhagic shock in 6.1% and 7.1% in others. The overall mortality of the population was 34.3% (being higher in CVD group with 91.7% and lower in cardiology in 21.1%, P ≤ 0.001). Mortality was similar between

men and women. When we analyzed by age, APACHE and stay, significant differences were observed for APACHE, being greater in deceased (p $\leq$ 0.001), and stay more days for dead (p = 0.083).In the cardiac group, those admitted for increased incidence of arrhythmia had died (19.4%, P = 0.018). The rest did not reach statistical significance. In the septic group no differences were observed.

Regarding substitutive techniques depurative was observed that 78.9% (n = 79) did not perform any technique in 15.2% (n = 15) and they were performed hemofiltration and 5.1% (n = 5) hemodialysis. Septic were performed more frequently these techniques (52.9%, P = 0.007)

CONCLUSIONS. Cardiac's group was the main reason for admission and presented a high age in admission and APACHE was higher in CVD group. Mortality in cardiac´s group was lower compared to CVD. Deceases presented greater APACHE and average hospital stay. Techniques extrarenal depuration were higher in the septic´s group.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0412

INTRODUCTION. Despite improvements in the quality of medical care, the incidence and mortality of acute kidney injury (AKI) continues to rise. Every year about 2 mln. people worldwide die due to AKI. Such high mortality persists for already several decades, and stimulates to search for the possibilities to reduce it.

OBJECTIVES. The aim of our study was to establish the predictive factors of mortality of the patients with severe dialysis - dependent AKI (stage 3).

METHODS. Single-centre of the largest university Lithuanian hospital Kaunas Clinics within a 2-year period retrospective pilot study was carried out. Inclusion criteria: 1) severe dialysis - dependent AKI stage 3; 2) age $\geq$ 18.

RESULTS. In 573 patients hospital mortality was found to be 51.7% (n=296). For 32.5% (n=186) of the investigated patients the renal function improved, and almost 16% (n=91) of patients remained dialysis - dependent after their discharge from the hospital. Significant prognostic factors of mortality were found to be: age > 85 years (OR 2.356, 95% CI [1.105-5.021], p=0.026), chronic kidney disease before AKI (OR 1.734, 95% CI [1.121-2.682], p=0.013), AKI after a cardiosurgery (OR 3.358, 95% CI [1.564-7.210], p=0.002), sepsis (OR 3.048, 95% CI [2.128 - 4.367] p< 0.001), requirement of vasopressors (OR 17.164, 95% CI [11.306 - 26.056], p< 0.001), mechanical ventilation (OR 7.732, 95% CI [5.268 - 11.350], p < 0.001), administration of aminoglycosides (OR 2.402, 95% CI [1.345 - 4.291], p=0.003), oliguria (OR 3.504, 95% CI [2.430 - 5.054], p< 0.001), alveolar pulmonary oedema (OR 2.018, 95% CI [1.391 - 2.926], p< 0.001), systolic blood pressure (BP) $\leq$ 120 mmHg (OR 8.452, 95% CI [5.784 - 12.352], p< 0.001), diastolic BP $\leq$ 65 mmHg (OR 5.892, 95% CI [4.099 - 8.470], p< 0.001), SOFA score $\geq$ 7.5 (OR 13.149, 95% CI [8.812 - 19.619], p< 0.001), serum sodium > 140 mmol/l (OR 2.206,

95% CI [1.546 - 3.148], p< 0.001), requirement for the combination of renal replacement therapy (RRT) methods (OR 3.410, 95% CI [2.238-5.196] p< 0.001), and multiple organ failure (MOF) (especially when function of 3 and more organs is affected) (OR 19.885, 95% CI [12.956-30.519], p< 0.001). Model of multifactorial logistic regression analysis predicting lethal outcome was significantly forecasted by age $\geq$ 65 yrs, systolic BP $\leq$ 120 mmHg, oliguria, requirement of vasopressors and MOF.

CONCLUSIONS. More than half of patients with severe dialysis - dependent acute kidney injury has died. The prognosis of lethal outcome especially strongly relates with elderly, some limits of systolic blood pressure, oliguria, requirement of vasopressors and multiple organ failure.

INTRODUCTION. Poly-trauma is a condition with $\geq$ 2 trauma in the body that life threatening with Injury Severity Score (ISS) $\geq$ 16[1]. Ischemic-reperfusion injury can happen in these patients that can be caused by hypovolemia, hypoxia and release of inflammatory mediators and cytokines [2,3,4]. These conditions may cause acute kidney injury (AKI) that can be detected by measurement of creatinine and cystatin-C serum. Cystatin-C is cysteine protease inhibitor that filtrated freely by renal tubule and absorbed completed, so it can be used to diagnose AKI[5,6]

OBJECTIVES. This study was to assess that AKI can be detected earlier using cystatin-C than creatinine measurements.

METHODS. Cross sectional study in poly-trauma adult patients, 18-65 year old, with ISS $\geq$ 16 who admitted to Emergency Department. Patients with history of chronic kidney disease, hemodialysis, cardiac disease and malignancy from hetero anamnesis were excluded from this study.

As soon as admitted to the Emergency Department, the patients were given fluid resuscitation and then blood samples were withdrawal for creatinine and cystatin-C measurements. The data were analyzed using chi-square, Kolmogorov Smirnov and Exact Fisher.

RESULTS. In this study we found that the incidence of AKI using cystatin-C more frequent than creatinine (7/23 than 5/23). It can be detected that 11,1% patients non-AKI in creatinine group were AKI in cystatin-C group. Cut off point for creatinine is > 1.3 mg/dl and Cystatin C >354.98 ng/ml. We also found that Sensitivity, Specificity, Positive Predicted Value, Negative Predictive Value and Accuracy of Cystatin C were 100%, 88.9%, 71.4%, 100% and 91.3%

CONCLUSIONS. Cystatin-C can detect AKI earlier than creatinine and accuracy was good

INTRODUCTION AND OBJECTIVES. To compare clinical profile and outcome in patients with Acute Kidney Injury (AKI) with respect to underlying co-morbidities.
METHODS. This is prospective study of 60 patients with AKI admitted to our hospital from July 2017 to December 2017.
Inclusion criteria:

i)   Patients age >18 years.
ii) All admitted patients with AKI as defined by KDIGO guidelines.

Exclusion criteria: Known cases of CKD.
RESULTS. Of the total 120 patients with AKI, 88 had underlying comorbidity (Group A) and 32 had no co-morbidity (Group B). Of the patients with co-morbidities (Group A), 41% had diabetes mellitus, 31% had hypertension, and 23% had chronic liver disease.
Of the patients in Group A, 91% patients were more than 50 yrs old, male: female ratio was 1.5:1, 72.8% were oliguric, 54.5% required dialysis, and 86.4% required ICU management. Of the patients in Group B, 25% were more than 50 yrs old, male: female ratio was 1:1, 87.5% were oliguric, 37.55 required dialysis, and 37.5% required ICU management.
When comparing patients according to the cause of renal failure, 54.5% patients in group A and 75% patients in group B, had pre-renal cause of AKI($p= 0.311$); while 36.5% patients in group A & 25% patients in group B, had renal cause of AKI($p= 0.311$). 9% patients in group A & 0% patients in group B had post renal cause of AKI. ($p= 0.311$).
Morbidity (residual renal disease on discharge) and mortality was 50 % in Group A and 12.5% in Group B .
Patients more than 50yrs of age with underlying co-morbidities had significant risk of developing AKI ($p= 0.0003$). . There was significant association between presence of comorbidies and requirement of ICU management ($p= 0.007$). The outcome was worse in patients with underlying co-morbidities though not statistically significant ($p=0.06$).
CONCLUSION. Patients with AKI and co-morbidities require more ICU care and have worse outcomes than AKI patients without associated comorbidities.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0415

INTRODUCTION. Acute kidney injury (AKI) is one of the most common entities in the intensive care unit (ICU), it can be presented in up to 50% of the admitted patients and shows an independent correlation with higher morbidity and mortality. The usual criteria to diagnose AKI relies on serum levels of creatinine and urine output both in function of time. New methods for early detection of AKI risk have been developed (Discriminant value of Erdfelder et al. 2015 and the AKI predictor of Fletcher et al. 2017) pointing out the relevance of detecting renal angina.
OBJECTIVES. To analyze the performance of two scales in the detection of renal damage progression and renal replacement therapy (RRT) in critically ill adult patients.
METHODS. Retrospective analysis of 95 adult patients admitted to the ICU. Two scales where calculated, Discriminant value at 24 hours from admission and AKI predictor at 0 and 24 hours from admission. Demographic, biochemical, severity and fluid status including urine output also were collected. Receiver Operating Characteristics curves where constructed in order to analyze the performance of the two scales in detecting the need for RRT (decided by the care team) and renal damage progression (increase of ≥0.3mg/dL in 24 hours and/or urine output < 0.5mL/Kg/h at 48 hours).
RESULTS. The AKI predictor at 0 hours showed an area under the curve (AUC) of 0.87 (Sen: 86, Sp: 69.3, $p< 0.05$) for detecting RTT and AUC of 0.74 (Sen:60.9, Sp: 73.6, $p< 0.05$) for detecting renal damage progression. The discriminant value showed an AUC of 0.87 (Sen: 85.7, Sp: 94.6, $p< 0.05$) for detecting RTT and AUC of 0.83 (Sen:673.9, Sp: 83.3, $p< 0.05$) for detecting renal damage progression.
CONCLUSIONS. Both scales showed promising results for the detection of renal angina by using AKI predictor at admission and discriminant value at 24 hours.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0416

INTRODUCTION. Septic shock is one of the leading causes of death in patients admitted to the intensive care unit (ICU). Acute kidney injury (AKI) occurs in almost 50% of septic patients and is associated with significant mortality.

OBJECTIVES. To examine whether the new urinary biomarkers TIMP2 and IGFBP7 can predict progression within 24 hours and 72 hours from mild and moderate (KDIGO 1 or 2) to severe AKI (KDIGO 3) in patients with septic shock.

METHODS. Prospective, multicentre observational study performed in three French ICUs. The urinary biomarkers TIMP2*IGFBP7 were analyzed at the early phase (< 6 hours) of patients admitted for septic shock with mild and moderate AKI.

RESULTS. Among the 112 patients included, 45 (40%) progressed to KDIGO3 level 24 hours after inclusion (KDIGO3 H24) and 47 (42%) 72 hours after inclusion (KDIGO3 H72). The median urinary TIMP2*IGFBP7 at inclusion (baseline) were higher in the KDIGO3 group than in the KDIGO< 3 group at H24 and H72. All covariates with a p value < 0.2 in the univariate analysis were included in a stepwise multiple logistic regression models to identify factors independently associated with the risk of KDIGO3 at H24 and H72. TIMP2*IGFBP7 remained independently associated with KDIGO3 only at H24 but not at H72. Baseline posology of norepinephrine, baseline urine output and baseline serum creatinine remained also significantly associated with progression to KDIGO3 at H24. Baseline TIMP2*IGFBP7 and baseline urinary output had the best AUC ROC. A baseline TIMP2*IGFBP7 >2.0 (ng/ml)^2/1,000 identified the population at high risk of KDIGO 3 H24 (relative risk 4.19 (1.7-10.4)) with a sensitivity of 76% (60-87) and a specificity of 81% (69-89).

CONCLUSIONS. The urinary TIMP2*IGFBP7 concentration and the urine output at the early phase of septic shock is an independent factor to identify high risk population of progression from mild and moderate to severe AKI over the next 24 but not 72 hours. A TIMP2*IGFBP7 concentration > 2.0 (ng/ml)^2/1,000 quadruple the risk of KDIGO3 AKI within 24 hours.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0417

INTRODUCTION. Acute kidney injury, renal impairment and augmented renal clearance are common conditions in critically ill patients making appropriate dosing of renally excreted drugs a challenging task on the intensive care unit (ICU) (1). Close and accurate monitoring of kidney function in daily clinical practice is important to ensure medication safety (2). More than 50 mathematical formulas using biomarkers have been developed to give an estimate of the GFR (eGFR) as a measure for kidney function (3). However, these equations suffer from relevant limitations when applied for patient populations with low muscle mass or otherwise altered body composition like the critically ill (4, 5).

OBJECTIVES. To evaluate the use of Multifrequency Bioelectrical Impedance Analysis (MBIA) to predict 24-hour creatinine-urea clearance (24h CrUCL). A practical formula was developed and its performance was compared with that of established formulae such as Cockcroft-Gault, MDRD and Jelliffe's.

METHODS. An open-label prospective observational cohort study was performed in a twelve-bed intensive care unit at Gelre hospitals. All patients were included with an expected length of stay on the ICU of at least 48 hours. Each patient's body composition was assessed using a validated Quadscan 4000 analyzer (Bodystat® Ltd, UK, CE 0120) by placing 4 electrodes on wrists and ankles. A 24-hour urine specimen was collected and laboratory parameters in serum including creatinine, urea and albumin were obtained at the beginning and end of the collection period.

RESULTS. 151 patients were enrolled in the study over a 2-year period. An equation to predict 24h CrUCL was developed using stepwise linear regression using a training data set (n = 75). This equation was subsequently tested and compared with other relevant predictive equations using a validation data set (n = 76). Serum creatinine ranged from 40 μmol/l to 446 μmol/l. With the predictive model based on estimated body cell mass and a so called "prediction marker" more than 71% of the observed variance could be explained (Fig. 1). Predictive performance was superior to eight other evaluated models (R^2: 0.39 - 0.55) and demonstrated to be homoscedastic (Fig. 2).

CONCLUSIONS. MBIA measurements can be used to predict creatinine clearance with superior performance than currently established prediction models. This rapid, non-invasive method enables correction for influences of a patient's actual body composition and may prove very valuable in daily clinical practice, specifically to ensure adequate dosing of renally excreted drugs.

Postoperative level of urine neutrophilic gelatinase-associated lipocalin (u-NGAL) can predict acute renal injury, MODS and outcome in cardiovascular surgery patients

O. Dymova[1], A. Eremenko[2], N. Minbolatova[2]
[1]Federal State Budgetary Scientific Institution «Petrovsky National Research Centre of Surgery», Scientific and Clinical Laboratory, Moscow, Russian Federation; [2]Federal State Budgetary Scientific Institution «Petrovsky National Research Centre of Surgery», ICU, Moscow, Russian Federation

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0418

INTRODUCTION. As a rule acute kidney injury after cardiovascular surgery in the patients with normal preoperatively renal function occurs as a component of multiorgan failure.
The goal of the study was to evaluate diagnostic and prognostic value of the u-NGAL to detect AKI, MOSF and predict the mortality in patients after cardiac surgery.
METHODS. 117 patients undergoing cardiac and aortic surgery with CPB were included into the study. All of them had no signs of renal failure and MODS preoperatively. 43 of the patients had complicated postoperative period and multiorgan failure (mortality rate among them was 23.3%). The control group consisted from 74 patients. Blood biochemical, hematological and coagulation tests were analyzed before and on the first and third days after operation. Studies of u-NGAL were performed on Abbott Architect i1000sr.
RESULTS. Preoperative concentrations of NGAL in the urine do not allow predicting the risk of developing MODS and the outcome after surgery (AUC 0,636, 95% confidence interval 0,477-0,794).
The main causes of MODS in cardiosurgical patients in the early postoperative period were: prolonged cardiopulmonary bypass, aortic cross-clamp time and a large volume of blood loss.
The most informative for predicting the development MODS and death was the values of the uNGAL in the first postoperative day (AUC 0.957, 95% confidence interval 0.921-0.992).
Interpretation of the results obtained in the first postoperative day, using reference u-NGAL values (130 ng/ml), allows to predict the risk of severe AKI and death in patients with postoperative MODS (sensitivity of 100% and a specificity of 91%).
The levels lower than the reference values more effectively predict uncomplicated postoperative period after cardiac surgery. The cut-off u-NGAl level in the first postoperative day of 23,75 ng/ml had the sensitivity of 74.4%, and specificity of 56.8%, while in case of the level 76,45 ng/ml, the sensitivity was 48.8%, and the specificity was 74.3%.
CONCLUSION. The level of u-NGAl over 130 ng/ml in the first postoperative day after cardiovascular surgery can be used as a predictor of acute kidney injury, MODS and poor outcome.

Investigating the association between in-hospital mortality and age in patients receiving continuous veno-venous haemofiltration during their hospital admission

G. Amaratunga, T. Samuels, J. McLoughlin
East Surrey Hospital, Redhill, United Kingdom
Correspondence: G. Amaratunga
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0419

INTRODUCTION. We assessed whether increasing age is associated with higher in-hospital mortality in patients receiving continuous veno-venous haemofiltration (CVVHF) on the intensive care unit. In other patient groups receiving CVVHF it has been shown that older age is a predictor of both 30-day and late mortality[1]. Acute renal failure is often part of multi organ failure and CVVHF is the most common mode of renal replacement therapy used in intensive care units.[2]
METHODS. From an 8 year period, complete data for 913 patients was analysed. Mean age was 66.3 years (SD 14.8 years) with ages ranging from 16 to 93 years. Patients were separated into two groups based upon age, above and below the age of 75. Data was analysed using the program R 3.4.1 to perform a Pearson's Chi-squared test and produce the fourfold plot.
RESULTS. The association between age and in-hospital mortality was found to be significant (p < 0.001). The odds ratio [95% CI] is 0.52 [0.40 - 0.69] suggesting that the odds of a patient over the age of 75 surviving if they receive CVVH is reduced by nearly 50%.
CONCLUSIONS. Our results demonstrate that patients over the age of 75 that received CVVH are less likely to survive their admission. Limitations include unbalanced group sizes, single centre study and confounding variables. The results do warrant further research into age and its association with in-hospital mortality in patients commenced on CVVH.

INTRODUCTION. In 2011, the Spanish Society of Intensive Care Medicine (SEMICYUC) published an actualization of quality indicators in critical patients.
OBJECTIVES. To analyze the accomplishment of two continuous renal replacement therapy (CRRT) quality indicators that weren´t accomplished in our ICU since then: the correct stratification of acute kidney injury (AKI) and the CRRT monitoring. In addition we analyzed the duration of the filters and the complications of CRRT.
METHODS. Descriptive analysis including all patients admitted from November 2016 to October 2017 in the ICU of a referral hospital for a population of 450000 inhabitants. AKI was diagnosed according to the Acute Kidney Injury Network (AKIN) criteria.
RESULTS. During this period, 913 patients were admitted in the ICU. Mean APACHE-II score was 14.79 and mean days of admission were 4.89.

AKI was present in 27% of the patients. CRRT was needed in 14% of them and 68% were hemodynamically unstable. The reason for admission was mainly medical (50%), followed by surgical (31%) and traumatic (19%). Mean days of admission of patients with AKI was 6.1, mean age was 63 years and 46% of them were men. Mean APACHE-II was 18.5, and 21.9 in those who needed CRRT. 11% of these patients had medical history of chronic kidney disease.

The most frequent indication of CRRT was anuria (80%) followed by hypervolemia (62.9%) and non-responsive acidosis (54.3%). More than a half of our patients presented the combination of anuria and non-responsive acidosis. The main prescribed ultrafiltration dose was 29 ml/kg/h and the real administrated dose was 26 ml/kg/h. With this prescription the blood concentration of urea and creatinine decreased to less than a half of the baseline value and there was no evidence of dialytrauma caused by hyperdyalisis.

The mean duration of the filters was 22 hours, taking into account that only 45.7% of the patients with CRRT received anticoagulation, and only 35% of these patients achieved an optimal range of rPTTA (1.5-1.9). In all cases the filtration fraction was under 25%. Citrate was used in only 2 patients.

The CRRT associated complications were: hypothermia (83%), electrolytic alterations (43%) and anaemia that required transfusion (34%). The main electrolytic alterations were hypokalemia (70%) and hypophosphataemia (21%).

Patients with CRRT recovered an urine output higher than 0.5 ml/kg/h in 30 days. 15% died during their admission in ICU and 37% died after a 30 days follow up.

CONCLUSIONS. Quality indicators have been accomplished. All our patients with AKI have been stratified following the AKIN criteria and, in those requiring TRRC, monitoring was performed following the SEMICYUC recommendations. Mean duration of the filters is similar to that described by other groups, although only 35% of heparin-anticoagulated patients achieved a correct rPTTA. The most frequent adverse effect was hypothermia.

Table 1 (abstract 0420). AKIN of patients with AKI

INTRODUCTION. Nephrotoxicity is the most important side effect of intravenous colistin. With growing incidence of multi drug resistant bacteria and increasing the use of colistin in the intensive care units (ICUs), early recognition of colistin induced acute kidney injury (AKI) in ICUs setting remains a critical problem. Kidney injury molecule-1 (KIM-1) elevations do occur within hours of acute tubular necrosis; then, among the potential advantages of this biomarker are its apparent specificity for ischemic renal injury and the availability of a rapid assay. Using serum creatinine levels to detect renal toxicity has several limitations in clinical practice.

OBJECTIVES. To compare the patterns and the accuracy of urine KIM-1 with that of serum and urine creatinine in critically ill patients receiving colistin.

METHODS. A longitudinal study was performed during 13 months at ICUs of two Hospitals in Shiraz, Iran. Patients > 18 years with no documented history of acute kidney injury or chronic kidney disease scheduled to receive colistin for at least 1 week were recruited. Using the pre-designed form, the clinical information of the population under study was collected and recorded. Urinary and serum levels of creatinine, urea, KIM-1 were measured at 4 time intervals including zero, three, five, seven days of Colistin treatment.

RESULTS. During the study period,18.18% of patients developed nephrotoxicity, with a mean ± standard deviation onset of 7.33 ± 2.25 days.Furosemide co-administration (odds ratio = 0.07, 95% confidence interval = 0.07-0.707, P = 0.024) was significantly associated with colistin nephrotoxicity. The changes in KIM-1 levels during colistin treatment in either group with or without renal toxicity (P < 0.001) and between two groups with and without renal toxicity (P = 0.402) showed a decreasing trend.The accuracy of KIM-1 in renal toxicity was significantly lower than serum creatinine on days 3, 5 and 7.

CONCLUSION. In this study, serum creatinine was more accurate than urine KIM1 in detecting colistin induced nephrotoxicity. More studies with adequate sample size and more frequent sampling times are warranted to elucidate the role of new biomarkers of renal function in the detection of colistin nephrotoxicity.

INTRODUCTION. Deciding when and how to wean the ECMO from the patients represents a significant challenge. The usual weaning process is to switch off the fresh gas flow of the oxygenator for a few hours when pulmonary function is improved.;if the patient can be ventilated with plateau pressure < 30 cmH$_2$O, tidal volume < 6 ml/kg, and PEEP 8 to 12 cmH$_2$O without acute corpulmonale, the ECMO cannula can be pulled out. However, among these weaning criteria, lung function recovery attested by lung reaeration is not taken into consideration. It has been reported that assessment of lung aeration changes during a spontaneous breathing trial could predict postextubation distress.Lung ultrasound has been validated to assess alveolar recruitment induced by PEEP for patients with ARDS, antibiotic-induced lung reaeration in ventilator-associated pneumonia (VAP) as well as loss of lung aeration after fluid loading in patients with ARDS. To date, however, the changes of lung aeration in patients with ARDS requiring VV -ECMO support have never been evaluated by lung ultrasound

OBJECTIVES. Bedside Ultrasound assessment of lung reaeration in patients receiving veno-venous extracorporeal membrane oxygenation.

METHODS. Thirty seven patients with acute respiratory failure who received VV-ECMO treatment of intensive care unit were included in the study.Thirty two patients assessed by transthoracic lung ultrasound at 4 time points as before receiving VV-ECMO (T0),24 hours after the VV-ECMO treatment (T1),before weaning off the VV-ECMO (T2) and the mechanical ventilation(T3). Transthoracic lung ultrasound was performed by an experienced investigator with level-3 certification, using a Siemens Acuson CV70 echograph and a 2- to 4-MHz round-tipped or convex probe were used.

RESULTS. There were 24 patients weaning from the VV-ECMO and ventilation successfully, lung ultrasound score (LUS) of the whole lung decreased 45.6% from T0 to T2 (P < 0.05),and 52% from T0 to T3 (P < 0.05) ;but there was no significantly decreased of LUS after 24 hours VV-ECMO treatment (T0 to T1) and from T2 to T3 (P > 0.05). Lung ultrasound score on right and left lung distubrion from T0 to T2 also had significantly decreased trend (P < 0.05).It is proved there is a close relation between the changes of PaO_2/ FiO_2 and LUS from T0 to T2 was to be positive.

CONCLUSIONS. The transthoracic lung ultrasound may serve as a useful tool for lung aeration assessment on adult patients with severe acute respiratory distress syndrome receiving veno-venous extracorporeal membrane oxygenation. Further studies are needed to evaluate the impact of this screening strategy on the weaning process and patients outcome.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0423

INTRODUCTION. The predictive factors for success of high flow nasal cannula in acute respiratory failure are inconsistent in different studies.

OBJECTIVES. We conducted a retrospective study evaluating the predictive factors for success of high flow nasal cannula in acute hypoxemic respiratory failure.

METHODS. This retrospective study was conducted in the Intensive Care Unit (ICU) of Pamela Youde Nethersole Eastern Hospital in Hong Kong. The hospital records of patients admitted to ICU between May 2012 to April 2017 were retrospectively evaluated, and patients were included if they were given high flow nasal cannula in acute respiratory failure. Patients were excluded if they were

(1) given high flow nasal cannula (HFNC) as a tool to wean from mechanical ventilation,
(2) given HFNC as a palliative management in malignancies,
(3) considered not suitable for enrolment by the investigators.

RESULTS. Among the 124 eligible patients, the majority (77.4%) suffered from pneumonia. Before commencement of high flow nasal cannula, 72 patients (58.1%) , 35 patients (28.2%), 14 patients (11.3%) and 1 patient (0.8%) received nonrebreathing mask, nasal cannula, noninvasive ventilation, and Hudson mask respectively.
Fifty-five patients (44.35%) were defined as success which is defined as no escalation to non-invasive ventilation, mechanical ventilation, extra-corporeal membrane oxygenation or death within 28 days after commencement of HFNC.

Primary Endpoints
Compared with the 69 patients with failure, the 55 patients defined as success with HFNC had higher APACHE IV Score and GCS score upon ICU admission. (p=0.002, 0.024) They had lower heart rate and respiratory rate 1 hour before HFNC high flow nasal cannula (p= 0.011, 0.032) and lower heart rate 1 hour after HFNC (p< 0.001). They had higher platelet count (p=0.012) and serum sodium level (p=0.011) upon ICU admission and lower pH on day of HFNC (p=0.029).
The Respiratory rate-oxygenation (ROX) index which is defined as ratio of SpO2/ FiO2 to respiratory rate was significantly higher in the success group at 1 hour and 12 hours after HFNC.
By multivariate binary logistic regression, success of HFNC is only associated with higher ROX index at 12 hours after HFNC (p=0.01 OR 0.802).
The Receiver's operating curve has its largest area under curve if ROX index at 12 hours is used to predict the success of HFNC in our patients. (AUC=0.653). The sensitivity and specificity would be 0.88 and 0.41 if cut-off value for ROX 12 hour would be 5.626.

CONCLUSIONS. By multivariate analysis, success of HFNC is only associated with higher ROX index at 12 hours after HFNC. Clinical monitoring in the first 12 hours after commencement of HFNC is necessary for prediction of success of HFNC.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0424

INTRODUCTION. High-flow nasal cannula (HFNC) can be used as an initial support strategy for patients with acute respiratory failure (ARF) and after extubation. However, no clear evidence exists to support HFNC use in practice.

OBJECTIVES. We summarized the effects of HFNC compared to conventional oxygen therapy (COT) and noninvasive ventilation (NIV) on important outcomes in adults presenting with ARF and after extubation.

METHODS. We searched four electronic databases (Pubmed, EMBASE, Scopus and Web of Science) to identify randomized clinical trials (RCTs) involving adults, comparing HFNC with COT or NIV, and reporting clinically important outcomes. Primary outcomes were treatment failure, and intubation/reintubation rates.

RESULTS. Eighteen RCTs were included for analysis. Compared to COT-treated patients, HFNC treatment resulted in significantly lower risk of treatment failure (OR, 0.65; 95%CI, 0.43-0.98; *p*=0.04; I^2=32%), but had no effect in preventing intubation (OR, 0.74; 95%CI, 0.45-1.21; *p*=0.23; I^2=0%). For post extubation patients, HFNC (vs. COT) significantly reduced reintubation rate (OR, 0.47; 95%CI, 0.29-0.76; *p*=0.002; I^2=30%) and extubation failure (OR, 0.43; 95%CI, 0.25-0.73; *p*=0.002; I^2=66%). In contrast, when compared to NIV-treated patients, HFNC significantly reduced intubation rates (OR, 0.57; 95%CI, 0.36-0.92; *p*=0.02; I^2=0%) in patients with ARF. However, HFNC was not superior over NIV on treatment failure and on reintubation rates for patients after extubation. There was no difference between HFNC vs. COT or NIV on both ICU and hospital mortality or length of stay.

CONCLUSIONS. HFNC is superior to COT in reducing treatment failure as an initial support strategy and in reducing extubation failure and reintubation rates after extubation. HFNC could reduce intubation rates as an initial use but had similar effects in patients after extubation compared to NIV treatment.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0425

INTRODUCTION. Few data exist on the control of respiratory drive and effort through extracorporeal CO_2 removal in spontaneously breathing early ARDS patients on ECMO [1]. Uncontrolled drive and effort could result in injurious transpulmonary pressure despite ECMO support and this response might be correlated with ARDS severity and clinical outcome [2].

OBJECTIVES. To investigate the spontaneous breathing pattern during nearly total extracorporeal CO_2 removal and its correlation with severity and clinical outcome in early severe ARDS patients on ECMO.

METHODS. Patients with severe ARDS on ECMO since 2-7 days undergoing ultraprotective mechanical ventilation were included. CO_2 excretion from the native lung (VCO_2_NL) was continuously monitored by volumetric capnography. After awakening (Richmond Agitation Sedation Scale value between -2 and 0), patients were switched to pressure support ventilation. Sweep gas flow was increased until reaching minimal VCO_2_NL, so that extracorporeal CO_2 removal (VCO_2_ECMO) corrensponded to nearly total CO_2 production (VCO_2_tot). The waveforms of esophageal (Pes) and airway pressure, flow and volume were continuously recorded to obtain: tidal volume (Vt), respiratory rate (RR), esophageal pressure swings (ΔPes) and driving transpulmonary pressure (ΔP_L). According to the value of RR (below or above the median value), patients were categorized as "responders" and "non-responders".

RESULTS. Median VCO_2_NL was 0 [1-6] ml/min with a VCO_2_ML of 290 [266-321] ml/min (98 ± 3% of $VCO2\_tot$). Responders and non-responders did not differ in terms of baseline controlled mechahical ventilation settings and indexes of lung and systemic severity (Table 1). Despite similar low values of Vt and ΔPes, higher RR was associated with higher ΔP_L in non-responders vs. responders (Table 2). Moreover, time to successful switch to assisted ventilation was shorter in responders, with similar positive trends for ECMO duration and mortality (Table 2).

CONCLUSIONS. In early ARDS on ECMO, failure to decrease respiratory drive and effort during a spontaneous breathing test with "maximized" extracorporeal CO_2 removal might help identifying more severe patients requiring longer controlled mechanical ventilation and ECMO course and with higher mortality.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0426

INTRODUCTION. Non-invasive ventilation and continuous positive airway pressure are commonly used outside the Intensive Care Unit (ICU) for the treatment of respiratory failure due to chronic obstructive pulmonary disease or heart failure. Conversely, the use of these "advanced" respiratory supports in general wards for acute hypoxemic respiratory failure (AHRF) is debated, since delaying intubation results in increased mortality. The use of High flow oxygen therapy (HFOT) outside the ICU is rare. We hypothesized that early application of HFOT in general ward could be safe and could reduce the ICU admission rate.

OBJECTIVES. To assess the feasibility and safety of HFOT for the treatment of AHRF or mixed (hypoxemic and hypercapnic) respiratory failure in patients hospitalized in general wards, under the strict supervision of an intensivist.

METHODS. An ICU physician and an ICU nurse performed 12 educational meetings in 9 wards of Ospedale Maggiore Policlinico in Milan, Italy. The functioning of HFOT was illustrated to both nurses and medical staff members. HFOT was started in case of: a. AHRF with PaO_2/FiO_2 ≤300 and ≥150 mmHg; b. Hypoxemia defined as above and respiratory acidosis (pH < 7.35 and ≥7.30 + $PaCO_2$ >45 mmHg). Patients had to be hemodynamically stable and with preserved mental status. Doctors informed the ICU Outreach Team whenever HFOT was started. Data collected in each patient immediately before HFOT application, after 2 hrs of treatment and then once daily, were: respiratory rate (RR), arterial blood gas, SpO_2, blood pressure, Borg scale and comfort (visual scale). (Fig 1)

RESULTS. From January 1st to April 15th, 34 patients were treated with HFOT in the following Hospital Departments: Haematology (n= 14, 41.2%), General Medicine (n= 6, 17.6%), Neurology (n= 2, 5.9%), Pulmonology (n= 4, 11.8%), Emergency (n= 8, 23.5%). Mean patients age was 64.3 and 18 were male (53%). Patients had a SOFA score of 3.31±1.97. Causes of respiratory failure were: pneumonia 26 pts (76.4 %), sepsis 2 pts (5.9 %), COPD and asthma 2 pts (5.9 %) and others 4 pts (11.8 %).Duration of HFOT was 4.35±1.95 days. After 2 hrs of HFOT, we observed a significant decrease in RR (26.2±7.0 Vs. 23.0±5.2) and Borg scale value (3.8±1.9 Vs. 2.3±1.2) and a significant increase in comfort score (2.5±0.8 Vs. 3.5±0.7). No differences in gas exchange was detected (Table 1). After 24 hrs, data confirmed an improvement of RR, dyspnea, comfort. No worsening of $PaCO_2$ or acidosis was observed in hypercapnic pts; there was a trend toward $PaCO_2$ reduction, but it did not reach statistical significance. After 24 hrs, only one pt needed ICU-admission.

CONCLUSIONS. HFOT in patients hospitalized in general wards with acute hypoxemic or mixed respiratory failure is safe and effective. The patients should be daily monitored by an intensivist, to avoid delayed recognition of clinical deterioration.

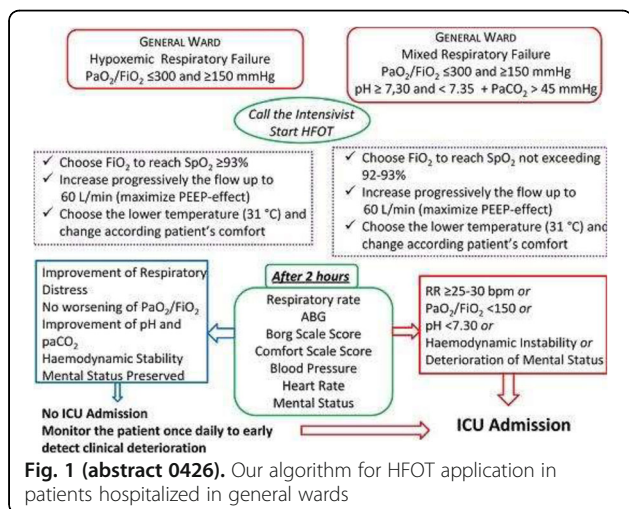
Bedside ultrasound assessment of lung reaeration in patients with blunt thoracic injury receiving high-flow nasal cannula therapy: a retrospective study

L. Xiao, M. Zhang
Second Affiliated Hospital, Zhejiang University School of Medicine, Department of Emergency Medicine, Hangzhou, China
Correspondence: L. Xiao

INTRODUCTION. The purpose of this retrospective study is to describe the use of HFNC in a population of patients with blunt thoracic injury to examine if HFNC was associated with positive patient outcomes such as reduced rates of intubation and decreased ICU days,and use the lung transthoracic ultrasound to assess if the HFNC could improve the lung reaeration in these patients.

OBJECTIVES. The study aims to observe the evolution of lung aeration by "Lung Ultrasound Score" in a chest-injured population treated with HFNC, and to assess the benefit of the HFNC in trauma patients.

METHODS. A retrospective study examined trauma patients with moderate to severe thoracic injury admitted to the ICU at a tertiary hospital between October 2015 and March 2017. The decision to initiate HFNC was made at the discretion of the trauma surgeon and respiratory therapist when supplemental oxygen delivery was required. All patients assessed by transthoracic lung ultrasound everyday after admit into the ICU,we retrospective analysised 3 time points for this study: initial EICU presentation within 12 hours (T1), 24-48 hours after including (T2) and 72-96 hours after including (T3). Transthoracic lung ultrasound was performed by an experienced investigator with level-3 certification, using a Mindray M9 echograph and a 2- to 4-MHz round-tipped were used. Primary outcomes were the need for intubation after HFNC for respiratory failure during the treatment, length of ICU during and mortality.

RESULTS. During the study period, 34 patients with blunt chest trauma were admitted to the study; 16 patients received HFNC therapy and 18 received Conventional oxygen therapy (COT);There was no significantly different of the baseline clinical characteristics between two groups.The length of ICU stay and intubation rate for respiratory failure was significantly different between the 2 groups


(P< 0.05), but without difference for the in-hospital mortality (P=0.78).The lung ultrasound score of COT group had no significantly different from T1 to T2,neither from T2 to T3 (P >0.05).However,the lung ultrasound score decreased significantly by 25% at T2 (P < 0.05) and by 31% between at T3 (P < 0.05) compared to T1 in the HFNC therapy group. LUS of the patients intubated for respiratory failure in the COT group increased from T1 (17±3) to T3 (21±3),and the LUS (21±3) were much higher than the patients not intubated (11±3) at T3;LUS of HFNC group were all above 15 which had no significantly different from T1 to T2,neither from T2 to T3 (P >0.05).

CONCLUSIONS. HFNC may be considered as an initial respiratory therapy for trauma patients with blunt chest injury. HFNC could improve lung aeration through the transthoracic lung ultrasound assessment, it may help the attending physicians identify the useful of HFNC,and decide if continue use the HFNC or have the intubation.

High flow nasal oxygen therapy in patients with acute exacerbations of COPD

P. Hancı, S. Öcal, Ş. Eyüpoğlu, E. Ortaç Ersoy, A. Topeli
Hacettepe University Faculty of Medicine, Medical Intensive Care Unit, Ankara, Turkey
Correspondence: A. Topeli
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0428

INTRODUCTION. Noninvasive mechanical ventilation (NIMV) has been proven to reduce intubation rate and mortality and is being widely used to support ventilation in COPD acute exacerbations. The rate of NIMV failure in COPD patients with acute respiratory failure ranges from 5-40%.[1] Some of these patients cannot tolerate mask or high inspiratory pressure during NIMV.

OBJECTIVES. We investigated the efficacy of high flow nasal oxygen therapy (HFNOT) in addition to standard medical treatment in patients admitted to intensive care unit (ICU) because of acute exacerbation of COPD. Our primary endpoints were changes in respiratory rate and visual analogue scale (VAS) for assessment of dyspnea; secondary endpoints were changes in $PaCO_2$ and PaO_2/FiO_2 within 48 hours.

METHODS. Patients were eligible for the study if they were admitted with an acute exacerbation of COPD with respiratory rate > 20/min, signs of respiratory distress, pH > 7.30 or increase in $PaCO_2 \geq 5$ mmHg from the basal value.

HFNOT was administered on the ICU with Optiflow™ (Fisher & Paykel Healthcare, New Zealand) by using a predefined protocol. Vital signs, VAS, signs of respiratory distress, arterial blood gas parameters were recorded at the beginning and at the 1st, 6th, 12th, 24th and 48th hours of therapy. If deterioration in patient's general condition, vital signs and dyspnea severity were detected, it was recorded as treatment failure and NIMV or IMV was commenced as a rescue therapy. Results are presented using median (25-75 percentile). Friedman test was conducted to test whether there is a significant change in the vital signs, VAS and ABG parameters.

RESULTS. Nine patients have been enrolled between October 2017 and February 2018. The median age was 71 (61-75) and 8 patients were male. Patients GOLD[2] COPD stages were D (n=8) and C (n=1). HFNOT was applied for a median of 100 hrs (50-120). There was not any significant improvement in respiratory rate, pH, $PaCO_2$, PaO_2, PaO_2/FiO_2 ratio within 48 hours. However, there was a decrease in VAS (p=0.010) and heart rate (p=0.024). Seven patients were weaned from HFNOT. HFNOT failure was observed in 2 patients; one of them was intubated and NIMV was applied to the other one. One of the 6 patients was transferred to the ward, but was lost due to cardiac arrest during follow-up. 28th and 60th-day mortality rates were 11%.

CONCLUSIONS. The preliminary results of this ongoing study revealed that HFNOT decreased VAS and heart rate. Therefore, HFNOT might be feasible and reliable for patients with acute exacerbations of COPD.

INTRODUCTION. Indications for Extracorporeal Membrane Oxygenation (ECMO) use in lung transplantation (LT) are: bridge to transplantation, intraoperative extracorporeal respiratory and/or circulatory support and treatment of primary graft dysfunction (PGD) in postoperative period. Several mortality risk factors pre-ECMO initiation has been investigated in ARDS, but not in LT patients. Presence of pulmonary hypertension (PH) before LT is common. If pulmonary vasodilators use pre-ECMO initiation can affect mortality has not been studied.

OBJECTIVES. To estimate if pulmonary vasodilators use before ECMO initiation in patients waiting LT, in the intraoperative phase or for PGD treatment affects ICU mortality.

METHODS. Retrospective, descriptive and observational study between January 2009 to December 2016 in 12 beds intensive care unit (ICU). Inclusion criteria for ECMO entry: bridge to PT, intraoperative support and in PGD. ECMO systems: centrifugal pump and polymethylpentene membrane oxygenation with Bioline® coated circuits and cannulas. Demographic data, APACHE II and SOFA, ECMO indications, type of ECMO support, PH grade, cardiac output (CO), type of vasodilator and inotrope/vasopressor use were collected at the time of ECMO initiation. Pulmonary vasodilators and inotropes/vasopressors use were compared between survivors and non-survivors. Continuous variables, reported as mean ± standard deviation (SD) were compared using the Student t-test. Categorical variables were compared using the X^2 test.

RESULTS. 35 patients (p), 23 males (65.71%) were included with a median age of 49.57±13.14 years. Median APACHE II was 19.85±7.73 and median SOFA was 7.11±3.02. VA ECMO was used in 22 patients (62.85%) and VV ECMO in 13 patients (37.14%). Intraoperative support was used in 54.28% (19 p); bridge to LT in 20% (7 p) and PGD was the indication in 25.71% (9 p). Median CO was 4.74±1.95. Interstitial lung diseases disease (ILD) were the principal indication for LT in 13 p (37.14%), and idiopathic pulmonary fibrosis was the most frequent disease. PH was present in 88.5% (severe in 48.5%). No significant statistical differences were observed between survivors and non-survivors in inhaled nitric oxide use (45% vs 46%; p=0.596), inhaled iloprost (30% vs 33.3%; p=0.560). Continuous intravenous epoprostenol use was significantly higher in survivors than in non-survivors (35% vs 0%; p=0.012). There were not statistical differences in noradrenalin, adrenalin, dopamine, dobutamine and milrinone use between survivors and non-survivors, but a higher use of milrinone was observed in survivors than in non-survivors (50% vs 20%; p=0.07).

CONCLUSIONS. In this retrospective review about ECMO in LT patients, intravenous epoprostenol use before ECMO initiation was higher in survivors than in non-survivors (p=0.012).

INTRODUCTION. Extracorporeal membrane oxygenation (ECMO) requires systemic anticoagulation. Despite technological improvement (i.e. coating of extracorporeal tubing and membranes) international guidelines still recommend full anticoagulation, with a recommended aPTT ratio target of 1.5-2 and ACT target of 180-220 sec. Previous studies by Panigada et al. (1,2) showed that pursuing these targets may lead to excessive anticoagulation, resulting in a high prevalence of "flat line" thromboelastography (TEG®) traces (defined as kaolin R-time >90min), ranging from 38 to 46%. At our institution we manage these patients with moderate anticoagulation, targeting an aPTT ratio of 1.3-1.7 and a ACT of 160-180.
OBJECTIVES. The aim of our study was to retrospectively assess the TEG R-time and other coagulation parameters in a 10-years ECMO patients cohort. We hypothesized that lower anticoagulation target may correspond to a more adequate anticoagulation level when assessed by TEG.
METHODS. Electronic charts, TEG database and a prospective ECMO database were reviewed to assess the level of anticoagulation in ECMO patients.
RESULTS. 110 adult patients were treated with vv-ECMO between 2009 and 2018. Median ECMO duration was 16 days [IQR 10-25], for a total of 2650 ECMO days. Average circuit duration was 7±5 days. Mean aPTT was 1.48±0.24, heparin daily dose was 24,400±11,100 IU. A total of 973 K-TEGs were collected. Median TEG kaolin R-time was 21.6 min [IQR11.8-40 min]. The fraction of TEG tracings with r>90 min ("flat line TEG") was 8.6%.
CONCLUSIONS. An anticoagulation strategy based on moderate aPTT and ACT targets resulted in an adequate level of anticoagulation when assessed by kaolin R-time.

INTRODUCTION. Heated and humidified high flow nasal cannula (HFNC) therapy is a form of non-invasive respiratory support for patients with non-hypercapnic acute hypoxemic respiratory failure[1]. Common indications include pneumonia and respiratory support post-extubation. Studies on outcomes describe the duration of HFNC use before intubation and the ROX index (ratio of pulse oximetry/ fraction of inspired oxygen to respiratory rate) for patients with pneumonia as significant predictors of survival and success[2, 3].
OBJECTIVES. A review of the factors that predict HFNC success in patients with hypoxemic respiratory failure from pneumonia.
METHODS. We conducted a retrospective analysis of our unit's HFNC registry from February 2017 to 2018, for patients initiated with pneumonia. Patient demographics, co-morbidities, ROX index at 12 hours, ICU severity scores (APACHE and SOFA) and mortality outcomes were analyzed.
RESULTS. In total, 22 patients were initiated on HFNC (mean age, 61 ± 16, 68.1% male), of which 50% were immunocompromised hosts (ICH). Twelve patients (54.5%) were successfully weaned off HFNC while 10 patients (45.5%) required intubation and mechanical ventilation. There was no significant difference in baseline characteristics between the two groups, including Charlson Comorbidity Index, severity of hypoxemia based on PF ratio, ICU severity scores and mortality. There was a trend towards a higher ROX index at 12 hours for those who were successfully weaned off HFNC (9.16 ± 4.43 vs 5.97 ± 1.65, p = 0.145). The duration of HFNC was also significantly longer in the successful group (73.7 ± 58.3 hours vs 27.4 ± 29.6 hours, p = 0.034). Between the ICH and non-ICH group, there was no significant difference in baseline characteristics, duration of HFNC and outcomes of successful termination and mortality. The overall ICU mortality and in-hospital mortality was 13.6% and 22.7% respectively.
CONCLUSIONS. In our cohort of patients, HFNC success was associated with a higher ROX index at 12 hours, consistent with the predictive utility of ROX as described in literature[3]. A longer duration of HFNC treatment was also observed in patients who were successfully weaned off HFNC and was not associated with increased mortality. This differs from other studies that have a 48 hour limit to the duration of HFNC usage[1], with concerns that failure of HFNC might cause delayed intubation and worse outcomes[2]. We did not observe any significant difference in HFNC usage and outcomes between the ICH and non-ICH patients. Our findings may be the result of our small sample size, a larger study is needed to further evaluate predictors of HFNC success and to identify specific groups of patients who may benefit from a longer duration of HFNC usage.

Use of prone positioning and airway pressure release ventilation (APRV) for patients with acute respiratory distress syndrome (ARDS) in intensive care units in London and the South-East of England

R.D. Lakhani, A.F. Nwamarah, R. Kumar, A.E. Myers, S. Ranjan, T.L. Samuels

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0432

INTRODUCTION. ARDS carries significant morbidity and mortality (35%-46% in mild to severe forms)[1]. There is good evidence to support prone positioning in the management of ARDS[2]. Evidence is also emerging to support APRV[3]. Despite this, use of both remains inconsistent, with literature suggesting prone positioning is only used for between 8-33% of patients with ARDS[1,2].
OBJECTIVES. To review the use of prone positioning and APRV in the treatment of ARDS in critical care units within one region of the UK.
METHODS. An online survey consisting of 25 questions on ICU demographics, prone positioning and the use of APRV was distributed to ICUs in the South-East Coast and London Critical Care Networks.

RESULTS. There were 18 responses, mainly from mixed medical & surgical ICUs (67%), with a median size of 13.5 beds (total range 2-68). 50% (n=9) reported proning patients on a regular basis, with reasons for not proning being lack of a protocol, lack of experience, risk of complications, the procedure being too labour intensive or rarely clinically required. The median number of patients proned by these units in the last 12 months was 4 (IQR 2-6). 33% (n=6) of respondents had a protocol for when to prone patients. P:F ratio (PaO$_2$/FiO$_2$), PaO$_2$, and FiO$_2$ were the most common variables used to determine when to prone patients. 33% had a protocol for how to prone patients, with common factors including the use of neuromuscular blockade, five or more staff required, and pronation during the daytime, with durations of 12-18 hours. 56% (n=10) used APRV infrequently, with only 17% (n=3) using it frequently. There was a protocol for when to commence APRV in 22% (n=4), and how to start it in 33% (n=6).

CONCLUSIONS. In spite of compelling evidence, only half of the ICUs in this region use prone positioning regularly. The main impediments appear to involve human factors, such as risk of complications or labour intensiveness. However, where pronation does take place, there appears to be some consistency regarding when and how this should be done. APRV is used infrequently and tends to be initiated based upon clinician decision. This may be due to the lack of a large multi-centre trial supporting its use. However, if more convincing evidence does emerge, APRV may represent a valuable alternative rescue technique for ARDS which avoids the risks and difficulties of prone positioning.

A retrospective observational study of prone positioning practices in the management of acute respiratory distress syndrome (ARDS) over a 2 year period in a single adult district general hospital (DGH) intensive care unit (ICU)

INTRODUCTION. Mechanical ventilation in ARDS may contribute to further lung damage due to high ventilatory pressures/volume delivered to a poorly compliant lung. Although various strategies for improving outcomes in ARDS have been tried, the only technique with good supporting evidence is prone positioning [1]. However, it is labour intensive, requires staff training and has potential complications.

OBJECTIVES. To review prone positioning practices within one DGH ICU in terms of demographics, reasons for initiation and outcomes.

METHODS. The electronic patient record database for a single ICU was interrogated for the keywords 'prone', 'proned', 'proning' and 'ECMO' for the period 03/2016 to 03/2018. Cases were reviewed to find the PaO2/FiO2 (PF) ratio and ventilation modes at instigation of prone positioning. Outcomes were recorded in terms of in-hospital and ICU mortality, and whether extra corporeal membrane oxygenation (ECMO) was required. Demographics and Clinical Frailty Scores (CFS) were recorded.

RESULTS. Of the 14 patients placed in prone position, 64.3% met the classification for severe ARDS with a PF ratio of < 13.3 kPa. The mean

age was 61 years (SD 19.3 years), 4 males and 10 females. We observed 50% survival. A higher CFS was associated with a worse outcome. Although 6 patients were referred to an ECMO centre, only 2 were transferred and none received ECMO. 2 of the patients referred for ECMO were not deemed candidates due to increased bleeding risks. The median number of proning episodes was 2 (IQR 1- 2.25) with a mean duration of 14hr10mins (SD 4hrs10mins). There appears to be no correlation between the number of proning episodes and PF ratios. Patients with a lower CFS were found to tolerate a lower PF ratio in comparison to those with a higher CFS. 28.6% deemed CFS 1, were all classified as severe ARDS. 57.1% of patients received a trial of airway pressure release ventilation (APRV) prior to proning; and had a better outcome with 75% survival. 2 patients had documented complications secondary to proning: re-intubation; and facial oedema.

CONCLUSIONS: In this small group, reduced frailty and a trial of APRV, may both be associated with better outcomes in prone positioning for ARDS. Further work should be done to investigate the relationship between CFS and PF ratios, in terms of impact upon survival with proning. It is likely that, during this 2 year study period, other patients with ARDS may have benefited from prone positioning. The duration of proning was intended to be 16 hrs, but there was considerable variation. Introduction of an evidence based protocol for the initiation of prone positioning in ARDS may lead to more frequent instigation of proning in ICU.

INTRODUCTION. Interest in High-flow nasal cannula (HFNC), a non-invasive support for acute hypoxemic respiratory failure (AHRF) patients, is rapidly growing. A major clinical challenge is to avoid delayed intubation by recognition of more severe AHRF patients on HFNC. The ROX (Respiratory rate-OXygenation) index was recently introduced as predictor of the need for mechanical ventilation in patients with AHRF treated with HFNC. However, the variables included in the ROX index can vary significantly with set flow rate.

OBJECTIVES. We analysed the effects of two set HFNC flow rates on the ROX index value in a population of AHRF patients.

METHODS. Fifty-seven non-intubated AHRF patients with PaO$_2$/FiO$_2$ ≤300 supported by HFNC, previously included in two prospective randomized cross-over studies (2, 3) were analyzed. All underwent two steps for 15-20 minutes in randomized order with HFNC delivered at 30 and 60 l/min, leaving FiO$_2$ unchanged. Towards the end of each phase, we collected SatO$_2$ (SO$_2$ in 17 patients (2) and SpO$_2$ in 40 patients (3)), FiO$_2$, respiratory rate (RR), Borg dyspnea scale, heart rate and mean arterial pressure. The ROX index was then calculated as (SatO$_2$/FiO$_2$)/RR. Demographics, number of lung quadrants involved and SOFA score were collected, too.

RESULTS. Patients were 59±14 years old, 25 (44%) were female, clinical PaO$_2$/FiO$_2$ was 199±54.

Increasing set HFNC flow rate from 30 to 60 l/min led to a significant increase of the ROX index values (10.21 [7.15 - 13.33] vs. 11.14 [8.81 -

13.93], median [interquartile range, IQR] p=0.003). Only 4 patients had ROX index < 4.88.

Forty patients showed a change in ROX index between the study phases >0 (+1.04 [0.49 - 2.22]), while 17 had unchanged or decreased ROX index at higher flow (-1.22 [-2.05 - -0.29]); p< 0.001 vs. patients with increased ROX) (Figure 1). The two subgroups showed significant differences in terms of severity of AHRF, SatO2 and RR measured at 30 l/min flow rate, with patients responding to the "flow challenge" showing worse conditions (Table 1).

CONCLUSIONS. Set HFNC flow significantly impacts the ROX index. Increase of this index at higher flow seem to occur in more severe patients.

INTRODUCTION. Although a lung rest strategy is recommended during ECMO in severe ARDS, observational studies show that alternative ventilatory approaches are used, including allowing spontaneous breathing (SB). SB may have some theoretical benefits, but it has been suggested to induce further lung injury in severe ARDS. However, this risk associated to SB may decrease with ECMO due to the possibility of modulating ventilatory drive.

OBJECTIVES. To compare the effects of spontaneous breathing versus near-apneic ventilation with neuromuscular blockade (NMB), on lung injury, in a porcine severe ARDS model assisted by ECMO.
METHODS. Ten pigs (30±5kg) were anesthetized, mechanically ventilated and monitored. Lung Injury was induced by repeated lavages (30 ml/kg of warm saline) until PaO_2/FiO_2 dropped below 100, followed by a 2-hour injurious ventilation (PEEP 0 cmH_2O, PInsp 40 cmH_2O, RR 10/min, I:E 1:2). After completing lung injury (time 0, T_0) animals were connected to an ECMO circuit by inserting an AVA-LON 23F double-lumen cannula through the right jugular vein. Blood flow was set at 60-70 ml/kg/min and sweep gas flow adjusted to $PaCO_2$ 30-50 mmHg. During the first 3 hours, all animals were ventilated with near-apneic ventilation (PEEP 10, driving pressure 10, RR 5/min, I:E ratio 1:2) and NMB. After T_3, animals were randomized into 2 groups: i) Near-apneic ventilation, which continued with the same settings used before, and ii) SB: in this group NMB were stopped and sweep gas flow decreased until regaining respiratory efforts. Thereafter, ventilation was switched to Pressure support mode (PS 10 cmH_2O, PEEP 10 cmH_2O) and sweep gas flow adjusted to keep $PaCO_2$ 30-50 mmHg while preserving SB at a respiratory rate of 30 to 70 bpm. Respiratory and hemodynamic data, as well as regional lung impedance, assessed by EIT (EIT-Pioneer Set, Swisstom, Switzerland), were collected at baseline and times 0, 3, 6, 12 and 24h. After 24 hours, animals were euthanized and lungs extracted for tissue analysis. Lung edema was estimated by the wet-dry weight ratio and lung injury by histological analysis (alveolar disruption, neutrophil infiltration or hemorrhage). Preliminary results of this study are presented here.

RESULTS. SB group exhibited a rapid shallow breathing pattern (Table 1). Median sweep gas flow was 7 (5.5-10) L/min in the Near-apneic ventilation group vs 10 (7-12) L/min in the SB group, with no differences in $PaCO_2$. No hemodynamic differences were observed. Regional impedance was similar between groups (Fig.1), as well as global end-expiratory lung impedance. No differences were observed in lung wet/dry weight ratio or in the histological lung injury score (Fig.2).

CONCLUSIONS. In this preliminary analysis, we found no differences between SB and Near-apneic ventilation in lung injury, lung function, or in regional lung impedance.

Fig. 1 (abstract 0435). Histological Lung Injury Score. Scored from 0= no alteration to 3= maximal injury

INTRODUCTION. Veno-venous extracorporeal CO2 removal (ECCO2R) is a promising new therapeutic option in the critical care setting. We conducted a prospective observational study of the use of ECCO2R in selected voluntary centers during two years aiming to assess the prevalence of the ECCOR2 use mainly among COPD and ARDS patients.
METHODS AND PATIENTS. Two medical devices: Hemolung (Alung Technologies, Pittsburgh, USA) and iLA Activve (Xenios Novalung, Heilbronn, Germany) were selected after literature and medico-economic evaluations. A specific medical and nurses training was provided in each center. Data were collected on a dedicated form and were centralized by the coordinating center. Primary outcome was the number of patients treated per month and per center during the 2-years study period. Secondary outcomes were ICU and hospital-mortality and adverse events/complications related to device use.
RESULTS. We present results from 70 patients recruited in 10 centers (41 men, 29 women, median age 65 years (IC 25-75: 61-74)). The utilization rate was of 0.19 (min: 0.04, max: 1.20) patient/month/center. Fifty-nine patients were under invasive and 11 under noninvasive mechanical ventilation. Hemolung was used in 53 patients (60% in jugular site, cannula size: 15.5 F) and iLA Activve in 19 (56% in jugular site, cannula size: 18 F, 24F for femoral site). Main indications were COPD AE (n=30) and ARDS (n=24). Twenty-one were treated as a part of a clinical trial and 49 were treated as decided by the physician in charge according to current practice. Mean duration of ECCO2R was 5days (IC25-75: 3-8). Thirty-two ECCO2R treatments were discontinued because of clinical condition improvement, 12 because of complications, 9 because of death and 16 for futility. Twenty-one hemolysis (either biological: free Hb > 100μmol/L or clinical), 17 hemorrhagic complications, 11 thrombosis, 1 cannula disinsertion, and 1 local hematoma occurred. Thirty-five deaths occurred during ICU stay, 36 during the hospitalization, 3 of which in relation with ECCO2R.
CONCLUSION. Our data indicate a preferential use of veno-venous ECCO2R devices in very severe (as illustrated by the overall high mortality) COPD and ARDS patients; with a lower than expected rate of utilization. Safety remains a major concern, indicating the need for further technological improvements as well of for optimization of anticoagulation regimen. Ultimately, RCTs will help to delineate clinical indications in these 2 main settings (COPD and ARDS).

INTRODUCTION. High flow nasal cannula (HFNC) has been shown to decrease the reintubation rate in critically ill patients after planned extubation. As compared to conventional oxygen therapy, HFNC decreases work of breathing and respiratory rate and improves oxygenation. Recently, a novel interface made it possible to deliver high flow oxygen therapy through the tracheostomy cannula.

OBJECTIVES. To evaluate if high flow oxygen therapy delivered through tracheotomy cannula has the same physiological effects of HFNC in tracheostomized patients at risk of reconnection after disconnection from the ventilator.

METHODS. After a planned disconnection from mechanical ventilation, 11 tracheostomized patients underwent a cross-over study alternating high flow and standard oxygen therapy (HF TRACH and LF TRACH), respectively, according to an ON-OFF design:

1) HF TRACH;
2) LF TRACH;
3) HF TRACH.

Heated and humidified HF TRACH oxygen therapy was delivered at flow rates between 50 and 70 L/min (F&P, Auckland, New Zealand). The diaphragmatic electrical activity (Eadi) signal was continuously recorded (Maquet, Solna Sweden) to obtain the mean Eadi peak (Eadi$_{PEAK}$). Work of breathing, respiratory rate and gas exchange parameters were assessed at the end of each study step.

RESULTS.

CONCLUSIONS. Our data show that, differently than HFNC oxygen therapy, the application of high flows to the tracheostomy cannula does not improve oxygenation and work of breathing. Our finding that, as compared to LF TRACH, HF TRACH does not decrease the Eadi$_{PEAK}$ suggests that it has no impact on the neural ventilatory drive.

OBJECTIVE. There are few studies on the effects hypertension has on survival outcomes in out-of-hospital-cardiac arrest (OHCA) patients, although hypertension is a major risk factor for the incidence of cardiac arrest. This study aims to investigate whether hypertension is associated with survival outcomes in cardiac arrest patients across age groups.

METHODS. This study was conducted using the national cardiac arrest registry of OHCA patients who survived to hospital admission from 2012 to 2016. The clinical histories of hypertension were obtained from patients´ medical records. The endpoint was cerebral performance category (CPC) 1 and 2 (good CPC) and survival to discharge. Multivariable logistic regression analysis was performed on the data collected. The final model with an interaction term was evaluated to compare the effects of hypertension across age groups.

RESULTS. A total 11,610 patients (61.0% hypertensive patients and 39.0% non-hypertensive patients) were included. The group over 80 years old with hypertension were more likely to have good neurologic recovery (AOR 2.53 [1.43-4.50]) and those under 65 years old with hypertension were more likely to survive to hospital discharge with statistical significance (AOR 1.19 [1.04-1.35]).

CONCLUSIONS. Hypertension does not adversely affect the survival outcomes of OHCA patients across all age groups of this study. In the group over 80 years old, HTN is significantly associated with survival with favorable neurologic recovery.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0439

INTRODUCTION. Perioperative cardiac arrest (CA) is one of the worse unfavorable outcome associated with noncardiac surgery. Knowing about predictors & outcome may help improve quality care of these patients.

OBJECTIVES. To study incidence, characteristics, predictors & outcome of perioperative CA in patients undergoing major noncardiac surgery & admitting to the general SICU.

METHODS. This prospective observational study was done in perioperative (pre, intra & 24 hours postoperative) CA patients undergoing major noncardiac surgery & admitting to the general SICU of the 3rd referral university hospital (2,400 beds, 50 ORs, > 34,000 noncardiac surgery/yr) from Jan 2013-Dec 2017. Patients < 18 yrs, undergoing cardiac, neurosurgical, traumatic & transplant surgery were excluded from this study. Study data including: patient demographic data, co-morbidities, ASA physical status, detail of the event associated with CA, type of CA, epinephrine dose, time to ROSC, TTM, 90 days neurological outcome & mortality.

RESULTS. There were 132 CA (77.37: 100,000 operation. 4.5% of ICU admission), as 10, 98 & 24 patients with ROSC time of 8+ 18, 4 + 26 & 14 ± 37 mins & 90 days mortality of 68%, 40% & 78% for pre, intra & postoperative CA respectively. Late & inadequate hemodynamic resuscitation were the main causes of preoperative CA especially in septic shock, most of the EKG were PEA which ¼ also had intraoperative CA & 38% had unfavorable neurological outcome at 90 days. Severe hypovolemic shock (41%) either from severe bleeding or septic shock, airway complications (19%), perioperative MI (12%), massive PE (10%), serious cardiac arrhythmia (8%) & the rest were from anaphylaxis, invasive procedure (eg, line placement), air embolism, LAST & MH were the main causes of intraoperative CA which most of the EKG were PEA, VF & asystole. Two patients had immediate ECPR with good outcome & 6 patients had ECMO supports which 4 patients had good outcome. Most of the causes of postoperative CA were hypoxia either from airway obstruction or pulmonary aspiration, almost half occurred in the recovery room which most EKG were asystole. Postoperative CA that occurred on the floor had worst neurological outcome & highest mortality. Three fourth of the patient did not have hypothermic (33C) TTM because of unfavorable surgical conditions but there wasn't significant different of the neurological outcome between TTM of 33 C & 36 C (p< 0.05). Data from multivariate analysis of poor neurological outcome at 90 days were hypoxic arrest, older, higher ASA physical status, more initiate time of CPR & ROSC time, higher vasopressor, lower Hb & lower MAP in the first 48 Hr & not have TTM.

CONCLUSIONS. Perioperative CA was significant associate with poor perioperative outcome. Efforts should be made to prevent this catastrophic event especially in sick surgical patient undergoing major noncardiac surgery. Early identifying, immediate and effective CPR & TTM may help improve neurological outcome.

Oxygen and carbon dioxide in patients after cardiac arrest

L. Peluso, I. Belloni, L. Calabro, J. Creteur, J.-L. Vincent, F.S. Taccone
Hopital Erasme, Intensive Care, Brussels, Belgium
Correspondence: L. Peluso
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0440

INTRODUCTION. The relationship between oxygen or carbon dioxide levels with outcome after cardiac arrest (CA) has yielded conflicting results. Few studies have combined the analysis of PaO_2 and $PaCO_2$ in this setting.

HYPOTHESIS. High PaO_2 and low $PaCO_2$ values are associated with better outcomes after CA.

METHODS. We reviewed all comatose patients admitted after successful resuscitation from CA to our Department between January 2009 and December 2017. Inclusion criteria were age ≥18 years, non-traumatic CA and survival ≥24 hours after admission. We analyzed all arterial blood gas data for the first 24 hours after admission, and we calculated the maximum and minimum values of PaO_2 and $PaCO_2$. Combination of $PaCO_2$ and PaO_2 values were analysed per quartiles.

We assessed ICU mortality as well as neurological outcome. Poor neurological outcome was defined as a Cerebral Performance Category (CPC) score of 3-5 at 3-months.

RESULTS. A total of 412 patients met the inclusion criteria; of those, 355 had complete PaO_2 and $PaCO_2$ values (10 [8-12] blood gas analyses per patient over the first 24 hours) and were included in the final analysis (median age: 65 [52-73] years). Overall, 208 (59%) patients died during the ICU stay and 241 (68%) had poor neurological outcome. Survivors and non-survivors had similar maximum and minimum PaO_2 values, as well as maximum and minimum $PaCO_2$ values. Results were similar in patients with good and poor neurological outcome. There were no differences in outcomes in relation to quartiles of maximum PaO_2 while the lowest (i.e. ≤41mmHg) and the highest (i.e. ≥55mmHg) quartiles of maximum $PaCO_2$ had the highest rates of ICU mortality (P=0.001) and poor outcome (p=0.02). The worst outcomes (87%) were found in the lowest combination of PaO_2 and $PaCO_2$ quartiles (i.e. ≤140mmHg + ≤41mmHg), and the best outcomes in patients with PaO_2 of 200-299 mmHg and $PaCO_2$ of 49-55 mmHg (29% mortality and 41% of poor CPC).

CONCLUSIONS. In this study, extreme $PaCO_2$ values were associated with poor outcome after CA. Outcomes were the worst in patients with concurrently low PaO_2 and $PaCO_2$ values.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0441

INTRODUCTION. Acute kidney injury (AKI) is a common complication after out-of-hospital cardiac arrest (OHCA) associated with increased morbidity and mortality.

OBJECTIVES. The aim of the study was to evaluate if biomarkers measured in urine early after OHCA could predict AKI and patient outcome.

METHODS. \This was a prospective observational a priori planned substudy of the Norwegian Cardiorespiratory Arrest Study (NORCAST) in resuscitated, comatose OHCA patients admitted to Oslo University Hospital. Urine samples were collected at admission and day three post arrest, and analysed for β-2-microglobulin (β2M), osteopontin and trefoil factor 3 (TFF3). Outcomes were AKI according to the KDIGO criteria within three days, in addition to six-month mortality and poor neurological outcome defined as a cerebral performance category 3-5. Patients with known chronic kidney disease, or who died within 24 hours of ICU stay, or for some reason did not receive active treatment, were excluded.

RESULTS. Among 195 included patients (85 % males, mean age 60 years), 88 (45 %) developed AKI, 88 (45 %) died and 96 (49 %) had poor neurological outcome. In univariate analysis, increased urine β2M, osteopontin and TFF3 levels sampled at admission and day three were independent risk factors for AKI, mortality and poor neurological outcome. Exceptions were that β2M measured at day three did not predict any of the outcomes, and TFF3 at admission did not predict AKI. In multivariate analysis, combining clinical parameters and biomarker concentrations, the area under the receiver operating characteristic curve (95 % confidence interval) were 0.729 (0.658-0.800), 0.797 (0.733-0.861) and 0.812 (CI 0.750-0.874) for AKI, mortality and poor neurological outcome, respectively.

CONCLUSIONS. In comatose OHCA patients, urine levels of β2M, osteopontin and TFF3 at admission and day three were independent risk factors for AKI, mortality and poor neurological outcome.

INTRODUCTION. Monitoring of cerebral function and prognostication of clinical outcome in comatose, sedated patients after out of hospital cardiac arrest (OHCA) is challenging. Currently, a multimodal approach is recommended, including clinical neurological examination, imaging, biomarkers and neurophysiological tests.
OBJECTIVES. The aim of the present study was to examine whether consecutive bedside transcranial doppler (TCD) examinations during the first week after OHCA could reflect pathophysiological mechanisms of brain damage, and whether flow patterns were associated with clinical outcome six months later.
METHODS. This was a sub-study of the Norwegian Cardiorespiratory Arrest Study (NORCAST). Altogether 259 primary successfully resuscitated comatose adult OHCA patients admitted to ICU between 2010 and 2014 were included. Patients underwent standardised post-resuscitation care including target temperature management (TTM) to 33° C for 24 hours. We aimed to perform bedside TCD, blinded to the treating physician, both during TTM within the first 24 hours, at day three after rewarming and at day seven in those still alive. Primary endpoint was Cerebral Performance Category (CPC) at six months, dichotomized into good (CPC 1-2) and poor outcome (CPC 3-5). Predictive values of TCD at day seven were analysed by logistic regression, and time series analysis using linear mixed methods (LMM) was used for the whole time-series data.
RESULTS. TCD was performed in 53, 44 and 109 patients during TTM, after rewarming and at day seven, respectively. Peak systolic velocity (PSV) in the middle cerebral artery (MCA) at day seven was significantly associated with late outcome as was LMM time-series data. PSV was lowest during TTM, increased after rewarming at day three and thereafter normalised at day seven for patients with good outcome. For patients with poor outcome peak flow remained high (figure). Resistance index and pulsatility index were not associated with clinical outcome.
CONCLUSIONS. TCD is a simple method for bedside monitoring of intracranial blood flow in OHCA patients. Specific dynamic changes of TCD-parameters were observed both during and after TTM. However, only late TCD seven days after cardiac arrest was associated with clinical outcome at six months.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0443

INTRODUCTION. Extracorporeal cardiopulmonary resuscitation (ECPR) has been introduced as a potentially life-saving procedure in refractory cardiac arrest.
METHODS. Eligible patients for this analysis had to undergo ECPR after unsuccessful cardiopulmonary resuscitation with a minimum of three defibrillation attempts. For extracorporeal life support (ECLS) we used Cardiohelp system (Maquet-Cardiopulmonary-AG, Hirrlingen, Germany) or Levitronix CentriMag blood pump (Levitronix LLC, Waltham, MA, USA). LUCAS II (Physio-Control, Lund, Sweden) system was used for chest compressions during ECPR insertion. The relations of blood lactate and pH levels, measured before ECPR insertion and after 24 hours as well as comorbities (diabetes, hypertension, BMI) to the clinical outcomes at 3, 6 and 12 months were evalueated.
RESULTS. We analyzed data from 36 patients treated with ECPR for refractory cardiac arrest. The mean age of our patients was 53 years. Out-of-hospital cardiac arrest (OHCA) occurred in 22 patients, 14 patients suffered from in-hospital arrest (IHCA). Baseline value of lactate was 12.52 ± 4.63 mmol/l, initial pH 6.97 ± 0.33. In comparison with survivors, patients who died had significantly higher initial lactate levels (16.05 ± 1.56 vs. 10.01 ± 1.03; $P < 0.05$) and lower baseline pH (6.77 ± 0.06 vs 7.06 ± 0.04; $P < 0.05$). Moreover, survivors had significantly lower lactate levels after 24 hours and lower BMI (26.4 vs 33.4; $P < 0.05$). Diabetes or hypertension in our group have no influence on the mortality. The difference of mortality in the group of OHCA or IHCA was also not significant. With good neurological outcome (CPC 1-2) survive 34% three months, 28% six months and one year 24% of the patients.
CONCLUSIONS. ECPR give the last chance to survive refractory cardiac arrest. The initial levels of blood lactate and pH are significantly associated with clinical outcomes of ECPR.

0444

ICU characteristics and outcome after cardiac arrest in patients ≥ 90 years old

K. Roedl, D. Jarczak, S. Becker, V. Fuhrmann, S. Kluge, J. Müller
University Medical Center Hamburg-Eppendorf, Department of Intensive Care Medicine, Hamburg, Germany
Correspondence: K. Roedl
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0444

INTRODUCTION. The world's population is ageing rapidly, thus the proportion of elderly patients suffering from cardiac arrest (CA) is expected to increase markedly. However, only little is known about long term neurological outcome and characteristics during intensive care unit (ICU) stay of patients ≥ 90 years suffering from CA.
OBJECTIVES. The aim was to evaluate ICU-characteristics and outcome after CA in patients ≥ 90 years.
METHODS. We conducted a single-center retrospective study and included all adult patients ≥ 90 years after CA and return of spontaneous circulation (ROSC) treated at the Department of Intensive Care Medicine of the University Medical Center Hamburg-Eppendorf. Patient characteristics, admission diagnosis, severity of disease, course of the disease and ICU mortality were assessed.
RESULTS. Overall we could identify 48 patients ≥ 90 years suffering from CA and which had ROSC, and were treated at our centre. Of these 27 (56%) were female and had a median age of 91.7 (90.7 - 92.6) years. 41 (85%) patients suffered from in-hospital CA. Cardiac events leading to CA were observed in 19 (40%) patients. Initial rhythm was shockable (VT/VF) in 12 (25%), non-shockable (PEA/Asystole) in 30 (63%) and unknown in 6 (13%) patients. Time to ROSC was median 4 (1.6 - 9.5) minutes. 39 (81%) patients needed mechanical ventilation, 44 (92%) received catecholamine support, 4 (8%) received renal replacement therapy and 17 (35%) received transfusion

of red blood cells during ICU-stay. ICU non-survivors had significantly higher SAPS II score and lower pH on admission (both p < 0.05). Highest lactate levels were observed in ICU non-survivors (6.2 (4 - 9) mmol/l vs. 2.8 (1.9 - 4.3) mmol/l, p < 0.001). Need for mechanical ventilation and red blood cell transfusion was significantly more common in ICU non-survivors. 26 (54%) of patients died during ICU stay, of patients surviving ICU-stay 3 (14%) had bad neurological outcome (CPC III/IV) at ICU-discharge.

CONCLUSIONS. ICU survival of patient's ≥ 90 years after CA is low. However, resuscitation and post-CA care in this age group seems to be not futile.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0445

INTRODUCTION. Disseminated intravascular coagulation (DIC) with the fibrinolytic phenotype during the early phase of post cardiopulmonary resuscitation (CPR) affects the outcome of out-of-hospital cardiac arrest (OHCA) patients.

OBJECTIVES. We evaluated changes in coagulation and fibrinolysis during percutaneous cardiopulmonary support (PCPS) in OHCA patients.

METHODS. A review of the computer-based medical records of OHCA patients was retrospectively conducted and included 431 patients who were divided into to two groups; patients who underwent PCPS and those did not undergo PCPS during the early phase of post CPR. Pre-hospital factors, platelet count, coagulation and fibrinolysis markers and lactate levels within 24 hours after CPR and resuscitation were evaluated. DIC was diagnosed by Japanese Association of Acute Medicine scoring system. Organ dysfunction was assessed by sequential organ failure assessment (SOFA) score. Hyperfibrinolysis was defined as an FDP level of ≥ 100 μg/mL, and the FDP/D-dimer ratio was used as a surrogate marker of fibrin (ogen) olysis. The outcome measure was all-cause hospital mortality.

RESULTS. Patients who underwent PCPS exhibited significantly lower platelet counts, prolonged prothrombin time ratio, decreased levels of fibrinogen and antithrombin, extreme increases in the levels of FDP, D-dimer and FDP/D-dimer ratios associated with higher prevalence of DIC than those who did not undergo PCPS (95.3% vs. 53.6%). Incidence of hyperfibrinolysis was significantly higher in patients with PCPS than those without PCPS (55.8% vs. 17.8%). Patients who underwent PCPS more frequently developed multiple organ dysfunction syndrome (48.9% vs. 14.4%) with increased levels of lactate. There were no differences in survival probability (Log Rank, p=0.130) and outcome (Death 55.8% vs. 40.5%) between the two groups.

CONCLUSION. Patients who underwent PCPS showed dynamic changes in platelet counts, coagulation and fibrinolysis during early phase of post CPR and were associated with high prevalence of DIC, hyperfibrinolysis and organ dysfunctions.

Neuron specific enolase as a prognostic biomarker after cardiac arrest

J. Worthy, F. Baldwin, R. Gray
Royal Sussex County Hospital, Brighton, United Kingdom
Correspondence: J. Worthy
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0446

INTRODUCTION. Neuron Specific Enolase (NSE) with a cut off value greater than 33μg/L at 1-3 days post cardiac arrest (CA) is a highly predictive biomarker of poor neurological outcome [1]. This cut off value was based on studies with patients who were not treated with therapeutic hypothermia (TH). Since this recommendation in 2006 there have been many studies to assess the cut off value for patients treated with TH. Some have found unacceptable false positive rates (FPR) and have suggested cut off levels of 78.9μg/L (0% FPR) at 48 hours[2].

OBJECTIVES. To assess the usefulness of NSE along with clinical assessment in our ICU to prognosticate on post CA patients.

METHODS. An observational retrospective study was carried out on all patients who had an NSE requested post CA over the time period 1st April 2017-1st April 2018. The NSE result, TH, survival to ICU discharge and GCS on ICU discharge were recorded.

RESULTS. A total of 43 patients with an NSE result were identified. The results of the patients who died on ICU are shown in table 1 and the survivors to ICU discharge are shown in table 2.

The average time of NSE testing was 75 hours post admission. Our results found 5 patients with NSE levels between 33μg/L and 78.9μg/L who survived to ICU discharge and went to a rehabilitation ward. 100% of patients with an NSE of > 78.9μg/L had a poor outcome resulting in eventual death.

CONCLUSIONS. Our data supports that using a NSE cut off level of 33μg/L has an unacceptable FPR to predict a poor neurological outcome and that a cut off level of > 78 μg/L at 72 hours post admission is highly predictive of a poor outcome with a 0% FPR in all patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0447

INTRODUCTION. Prognosis of patients with out-of-hospital cardiac arrest (OHCA) has improved due to better post-resuscitation care, but irreversible brain damage is still frequent. As prognostication is challenging, a multimodal approach is recommended, including clinical neurological examination. A major concern is self-fulfilling prophecy due to withdrawal of life sustaining therapy (WLST) in patients assumed to have poor prognosis but with an unrecognised potential for good recovery.
OBJECTIVE. To clarify the predictive accuracy of clinical neurological examinations performed by neurologists or intensive care unit (ICU) staff (blinded to the treating physician), and elucidate the optimal time point for making predictions.
METHODS. Prospective inclusion of all successfully resuscitated adult comatose OHCA patients admitted to the ICU in 2010 - 2014. Patients underwent standardised post-resuscitation care including targeted temperature management (TTM) at 33°C for 24 hours. A structured examination by a neurologist including brain stem reflexes, Glasgow Coma Score (GCS), cortical responses and other focal neurological tests was done 72 hours after rewarming and sedation stop. Patients were also examined daily by ICU staff using a simplified protocol. The main outcome was survival with good vs poor Cerebral Performance Category scores (CPC 1 - 2 vs CPC 3 - 5) at 6 months. Descriptive statistics with predictive power and logistic regression analyses were performed. Significance limits were set at p< 0.05. Chance corrected k and Bland- Altman analyses were used for comparison of evaluations by ICU staff vs. neurologists.
RESULTS. We included 259 patients, median age 61 years, and 49.5% of all had CPC 1-2 at 6 months. 72 h after sedation stop 185 patients were alive. Among 49% that were still in coma (GCS < 9) at this time point, 32% had CPC 1-2 at 6 months. Of the 76 patients examined by a neurologist, 66% achieved CPC 1-2. The strongest neurological predictors for poor outcome were GCS, absent pupillary/corneal reflex, voluntary/reflex eye movements and early myoclonic state. All predictors had low sensitivities. Gag reflex, startle response, autonomic pain response, tendon reflexes and Babinski's sign were also associated with prognosis. WLST (20%) was absolutely predictive of poor outcome. Agreement between evaluations by ICU staff and neurologists were moderate-weak (k=0.69 to 0.21) with only absence of pupillary response and ventilator requirement as significant ICU predictors. GCS scores showed good agreement without significant bias between neurologists and ICU staff.
CONCLUSIONS. Neurological examination alone (72 h after sedation stop), is not accurate enough in predicting outcome in comatose OHCA patients, and should be interpreted with caution. As late awakening to good outcome occurs in 32% comatose patients 72 hours after sedation stop, early WLST should be avoided. Prognostication may be blunted by TTM and sedation.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0448

INTRODUCTION. Previous studies indicated that the optic nerve sheath diameter (ONSD) measured using brain computed tomography (CT) is a prognostic factor for poor neurological outcome after cardiac arrest. However, these studieswere conducted involving PCAS patients, and in these studies limitations existed owing to the single-centred and retrospective nature of the studies, and the small sample sizes. Additionally, TTM and the time at which the CT scan was performed were not controlled.
OBJECTIVES. We performed a prospective multi-centre observational study to investigate the correlation between the ONSD on early brain CT and neurological outcomes in patients undergoing targeted temperature management (TTM).
METHODS. This study used data from the Korean Hypothermia Network prospective registry between November 2015 and October 2016. Out-of-cardiac arrest patients who underwent brain CT within 2 h after return of spontaneous circulation (ROSC) were included. The primary endpoint was neurological outcomes at 6 months (cerebral performance category; CPC); the secondary outcome was hospital mortality. The ONSD was measured using unenhanced brain CT images.
RESULTS. In total, 374 patients were included from 18 hospitals, and 329 underwent CT within 2 h after ROSC. Six months after cardiac arrest, good (CPC 1-2) and poor (CPC 3-5) neurological outcomes were observed in 99 (30.09%) and 230 (69.91%) patients, respectively. There was no significant difference in the ONSD between groups (good outcome group: 5.61 ± 0.59 mm, poor outcome group: 5.69 ± 0.79 mm; p = 0.275), nor between discharged patients who survived and those with hospital mortality (5.63 ± 0.64 mm and 5.70 ± 0.67 mm, respectively, p = 0.399).
CONCLUSIONS. The ONSD on initial brain CT after ROSC was not correlated with neurological outcome at 6 months in patients who underwent TTM.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0449

INTRODUCTION. Systematic care of patients after OHCA and CAC developement is recommended by the guidelines, but important „contra" argument is prolonged transport of often hemodynamicly unstable patients in limited prehospital emergency care.
AIM. To determine if prolonged primarily transport of patients after OHCA to regional CAC influence initial hemodynamic parameters after admission, mortality a neurological outcome.
METHODS. Analysis from prospective OHCA Registry of regional CAC 2013 - 2017. Data were divided into 2 datasets: 1) INSIDE - when CAC is the nearest hospital and 2) OUTSIDE - patients transfered to CAC, but in past would be transferred to one of the 7 another closer hospitals in the region. We observed duration of transport, baseline characteristics,hemodynamic parameters on arrival to hospital and final outcomes (30-day/in-hospital mortality, length of ICU stay, artificial ventilation days, 1 year CPC).
RESULTS. 232 patients were enrolled after OHCA in years 2013 to 2017, 27 were excluded for insuficient data and 19 for secondary transfer to CAC. We analyzed 186 patients, 93 in both groups. We observed no differences in baseline characteristics in both groups: men (66,7% vs. 80,6%, p= 0.29), age (64,51±1.324 years vs. 61.25± 1.443 years , p= 0.1), shockable rhythm (65,6% vs. 74,2%, p= 0.26), bystander CPR (68,8% vs. 72%, p= 0.75), ROSC (median, IQR) :17 (11-26) min vs. 20 (15-30) minutes, p= 0.29, ACS (44,1% vs. 48,4%, p= 0.66) and catecholamine administration during transfer (80% vs. 70%, p= 0.18). We observed no differences in initial hemodynamic parameters in time of admission in both groups. Systolic blood pressure: *(median,IQR): 103 (82-120) vs. 105(82-124)mm Hg, p= 0.6,* serum lactate level (m*edian,IQR): 4.6 (2-8.1) vs. 3.5 (2-6.75) mmo/l, p= 0.372, pH (median,IQR): 7.242 (7.122-7.322) vs. 7.286 (7.177-7.318), p=0.159,* body temperature: *(median,IQR): 35.95 (35.08-36.5) vs. 36 (35.5-36.5), p=0.218* and oxygen saturation (SpO2):*(median,IQR): 95 (91-100) vs. 98 (94-100), p= 0.14.*
We observed no differences in catecholamins dosages. Norepinephrine (7.54±+1.75 vs. 5.98±1.17 mcg/min), p= 0.46 and dobutamine (66.31±45.81 vs. 38.6±15.62 mcg/min),p=0.56. There was no significant difference in in-hospital/30-day mortality (44.1% vs. 42.3%, p= 0.88). 1-year good neurological outcome (CPC 1,2) was identical (54,2% vs 54.2%, p= 0.999). Median of artificial ventilation duration without significant difference: (median/IQR) 3 (1-8) vs.5 (1-7.75) days, p= 0.36 and median of lenght of ICU stay without significant difference: (median/IQR) 6 (2-14.75) vs. 7 (3-12) days, p= 0.74.
CONCLUSION. Strategy of primary transport of patients after OHCA to CAC significantly prolonged time of transport, but didn´t affect hemodynamic parameters and outcome of patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0450

INTRODUCTION. We have identified a lack of Knowledge in CPR skills in our population. We want to improve this with an educational workshop in basic CPR directed to the relatives of our patients
OBJECTIVES. To describe the demographic characteristics and knowledge before a workshop in Basic Cardiopulmonary Resuscitation (BCPR) for relatives (potential bystanders) of patients admitted to the Intensive Care Unit (ICU). Assess the relationship between educational level, age and previous CPR training.
METHODS. We make an initial anonymous survey in each workshop for relatives (laymen) of patients admitted to a 22 beds ICU between November 2016 and November 2017. The workshop was carried out by the medical staff of the ICU (Instructors in advanced life support). We ask for 9 items that included: demographic characteristics (age, sex and educational level) and previous knowledge in CPR (facing an emergency situation, recognition of cardiac arrest, knowledge in CPR skills, previous training, belief in the importance of education in CPR and fear to use them) of attendants. The results are expressed as average for the continuous variables and percentages for the categorical variables. For hypothesis contrast we compare proportions using chi-square test.
RESULTS. A total of 90 people with an average age of 48.77 ± 17.83 years (oldest 83). A 65.2% were women. Attendants educational levels were a 26.1% Primary Education, a 36.4% had a General Certificate of Secondary Education and a 37.5% had an University degree. Only a 26.1% had witnessed an emergency situation and the 31.4% believed that they knew how to recognize a cardiac arrest. The 78.4% did not know CPR skills and the 76.1% had never received CPR training. There is not significant relationship between educational level (p = 0.177) nor age ≤ 65 years (p = 0.209) and have received BCPR training. The 62.9% of the attendants would not be afraid to deliver BCPR if they had the opportunity. Finally, 100% of our attendants believed that the training was useful.
CONCLUSIONS.

- We identified a loss formation in the CPR skills in our population. Almost the 80% of our population did not know them.
- In our population we did not find a relationship between age or educational level and having received training in CPR.
- We can complete our daily assistance work, performing relatives of our patients in BCPR and helping them to feel more secure.
- We can also minimize the hard experience of having a family member in the ICU, turning the ICU more human.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0451

INTRODUCTION. Training in CPR is a gap in our population. We start a project to diffuse basic CPR skills to relatives of our ICU patients. Is important for us to evaluate the ability to remember of our

attendants 6 months after the workshop and detect improvement points.
OBJECTIVES. To describe the demographic characteristics and assimilated knowledge of the attendants (laymen) 6 months after receiving a workshop in BCPR. Assess the association between age and educational level with the retention of knowledge.
METHODS. Phone survey at 6 months of workshop for relatives of patients admitted to a 22-beds ICU from November 2016 to November 2017. The workshop was carried out by the medical staff of the ICU (Instructors in advanced life support). Attendants were asked for: chain of survival correct sequence, frequency of compressions, use of CPR skills, fear to use CPR skills and workshop valuation. The results are expressed as averages for the continuous variables and percentages for the categorical variables. For hypothesis contrast we compare proportions using chi-square test.
RESULTS. Of a total of 45 surveyed, answered 33 (73.33%). The average age was 50.97 ± 17.20 years. 66.7% were women. The workshop average evaluation was 9.47 ± 0.73 out of 10 points.
Could you recognize a PCR? Yes: 97%/No: 3%
Chain of survival correct sequence: Airway-Help-CPR: 36.4%/Help-Airway-CPR: 45.5%/Help-CPR-Airway: 3%/Airway-CPR-Help: 15.2%
Chest compressions rate:60: 29%/80: 25.8%/100: 45.2%
Have you used CPR in this 6 months? No: 100%
Would you be afraid to use CPR? Yes: 12.1%/No: 87.9%
Would you go back to the workshop? Yes: 100%
Of the answered, 28.9% had Primary education, 33.3% had General Certificate of Secondary Education and 37.8% had an University degree. There is no significant relationship between age ≤ 65 years (p = 0.071) or educational level (p = 0.509) and the chain of survival correct sequence retention. We also didn´t find significant relationship between the age ≤ 65 years (p = 0.703) or educational level (p = 0.616) and the correct compressions frequency.
CONCLUSIONS

- The workshop evaluation of our attendants is satisfactory.
- After the workshop almost all respondents, know how to recognize a CPR.
- The retention of the correct sequence and compressions frequency at 6 months is improvable and we did not find significant relationship between age ≤ 65 years or the educational level of studies and better knowledge of CPR skills.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0452

INTRODUCTION. Since 2013, extracorporeal cardiopulmonary resuscitation (ECPR) has been used as a treatment option for refractory cardiac arrest at our university hospital. ECPR requires rapid activation of a multidisciplinary team and a well-organized ECPR infrastructure [1, 2]. In 2017, we started optimising our ECPR infrastructure for out-of-hospital cardiac arrest by introducing regular training sessions with simulation cases, evaluating all procedures and introducing a dedicated ECPR-cart. This infrastructure is also used for in-hospital cardiac arrest (IHCA).
OBJECTIVES. The objective of this retrospective analysis was to determine the effect of the regular training and the introduction of a dedicated ECPR-cart on the ECPR procedures. We hypothesize that this led to a reduction in time needed to initiate extracorporeal life support (ECLS) in IHCA.
METHODS. A single-centre, retrospective review was conducted a year after the start of training and introduction of the ECPR-cart. All adult patients (≥18 years) with a witnessed, refractory IHCA who received ECPR from 2013 to 2018 were included. The primary outcome was time-to-ECLS, defined as time from start of arrest to adequate flow on ECLS. Data are presented as median [IQR]. Statistical analysis was performed using a Mann-Whitney U test.
RESULTS. 13 patients received ECPR for a witnessed, refractory IHCA from 2013 to April 2017. The median age was 62 [60-67], most were male (69,2%) and the Charlson Comorbidity Index (CCI) was 2,5 [2,0-3,0]. The most common causes of arrest were cardiogenic shock (30,8%) and myocardial infarction (23,1%) (Table 1).
After start of training and introduction of the ECPR-cart in May 2017, 4 patients received ECPR, with median age of 53 [33-60] and CCI of 1,5 [0,5-1,5]. The time-to-ECLS was significantly reduced from 40 minutes [25-45] to 27 minutes [22-33] (p = 0,019) (Figure 1). Successful weaning of mechanical circulatory support remained similar for both time periods (pre 46,2 % vs. post 50%).
**CONCLUSIONS.** Optimisation of the ECPR infrastructure significantly reduced time-to-ECLS. It can be imagined that this ultimately will improve survival with good neurological outcome of ECPR for IHCA.

University Hospital of A Coruña, Intensive Care, A Coruña, Spain
Correspondence: E.A. Ines
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0453

INTRODUCTION. The prognosis for postcardiac arrest patients remains very bleak, not only because of anoxic-ischemic neurological damage, but also because of the postcardiac arrest syndrome,a phenomenon often severe enough to cause death before any neurological evaluation.

OBJECTIVES. To describe patients recovered from cardiorespiratory arrest (CRA) and analyze variables that are related to neurological prognosis.

METHODS. Retrospective observational study of 2015-2017 CRA who were admitted to the ICU. 32 patients who died without neurological evaluation are excluded. We collect demographic variables, comorbidity, related to CRA (location, attention times, first rhythm), complementary tests, stays and prognosis at discharge and at one year (Cerebral Performance Categories Scale (CPC) and exitus). Statistical analysis by contrast of hypothesis and comparison of means with SPSS.19.0

RESULTS. 70 patients, median age of 62 years and 70% men. Charlson index mean4.0 ± 2.5.52.9% extrahospitalar CRA. FV / TV without pulse in66.7%. Mean time to advanced CRA2.6 ± 3.4min; Total CRA time10 min. Most frequent cause was AMI54.3%, primary arrhythmia10% and IC5.7%. MEDA of SOFA6. Hypothermia was performed in 34.3%. Initial neurological examination in 41.4%, TAC at admission with edema42.9%. In neurological evaluation in ICU average GCS 10.9 ± 4.7 and 11.5 ± 5.8 on the FOUR scale. Hyperthermia in first 72 hours 2 patients (31.4%). In the evaluation of anoxic encephalopathy, EEG was performed in 24 patients (3.4% status), NMR in 4 (1diagnostic), evoked potentials in 2patients, and mioclonias5.7%. The median stay in the ICU was 4 days and hospital16.5. At discharge and at one year the mean CPC was 2.9 ± 1.7 and 1.7 ± 1.2, with mortality of 40%. Differences of worse neurological prognosis at discharge (CPC> 2) were identified in: cause of CRA (41% vs70%) p = 0.05), myoclonus (14.3% vs.0%, p = 0.03), tracheostomy at discharge (100% vs. 10.3%, p = 0.003), SOFA (8.3%). 2.6 vs.5.0 ± 3.3, p < 0.01), total CRA time (21.8 ± 17.5 vs 11.9 ± 10.7, p < 0.001), GCS (6.9 ± 4.5vs13.7 ± 1.6, p < 0.001) and FOUR scale (1.7 ± 1.7 vs.3.6 ± 0.8, p < 0.001). Multivariate analysis showed that lower GCS at admission (HR: 0.08, 95% CI: 0.06-0.1, p = 0.008) and a worse FOUR value (HR: 0.02, 95% CI: 0.00-0.05, p = 0.049) are associated to worse forecast at discharge.

CONCLUSIONS. Comparison of patients according to the neurological prognosis at discharge, a predictive capacity was found in the GCS and FOUR scale. No association with other variables was probably influenced by the sample size.

Follow-up evaluation of patients with heart failure: prognostic role of ambulatory blood pressure monitoring

A.M. González González[1], A.M. Garcia Bellon[2], A.A. Rojas Sanchez[2], M. De Mora Martin[2]
[1]Regional Hospital of Malaga, Malaga, Spain; [2]Regional Hospital of Malaga, Cardiology, Malaga, Spain
Correspondence: A.M. González González
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0454

INTRODUCTION. Ambulatory blood pressure monitoring (ABPM) is routinely used in patients with high blood pressure. However, its use in patients with heart failure (HF) has been poorly reported.

OBJECTIVES. Our aim was to evaluate circadian variation in blood pressure in this group of patients and their prognostic role.

METHODS. We included 184 patients followed-up in a Heart Failure Unit. They underwent an echocardiogram, laboratory tests and a 24 hours ambulatory blood pressure monitoring. All patients were followed-up for 1 year. Primary event was defined as hospitalization or death due to HF.

RESULTS. Mean age 63 ± 10; 75% males. BMI 30.1 ± 6 Kg /m2. Cardiovascular risk factors: Hypertension 56.5%; diabetes 34.7%; dyslipidemia 40%; obesity 29.3%. Smokers 22.9%. Etiology of HF: Hypertensive 19.5%; ischemic 12%; ischemic-hypertensive 27.1%; enolic 9,8%; myocarditis 4.3%; valvulopathy 5.2%; idiopathic 21%. Therapeutic regimen: SRA blockers 93.4%; beta blockers 85.7%; diuretics 81%; spironolactone 42.3%; statins 68,4%; antiplatelets/anticoagulants 89%. Patients presented optimal blood pressure values (systolic BP: 112.63 ± 15.4, diastolic BP: 65.1 ± 7.9), however, the vast majority (80.4%) had an altered circadian pattern. Table 1.

Table 1 (abstract 0454). See text for description

Circadian patterns	Global
Dipper n(%)	36 (19,6)
No-dipper n(%)	94 (51,1)
Riser n(%)	54 (29,3)
Dipper extremo n(%)	0(0)

In 20 patients (10.9%) a major event occurred at 1 year follow-up, with higher proportion of events among patients with altered circadian pattern (non-dipper or riser: 12.2% vs dipper: 5.6%; 0.2).

CONCLUSIONS. In our area, patients with HF despite an optimal BP control, most of them presented an altered circadian pattern. In addition, this group of patients presents a tendency to a greater proportion of hospitalization and/or death due to HF. Longer-term studies are needed to confirm that finding.

0455

Study of left ventricular diastolic dysfunction in critically chronic obstructive pulmonary disease patients with and without corpulmonale

O. Momtaz

Fayoum University, Faculty of Medicine, Critical Care, Fayoum City, Egypt

BACKGROUND. There is growing data reporting increased risk of developing left ventricular diastolic dysfunction (LVDD) in patients with COPD though classically linked to presence and severity of corpulmonale.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0455

OBJECTIVE. To evaluate the possible burden of left ventricular diastolic dysfunction and other left sided cardiac changes associated with COPD with and without corpulmonale and their relation to COPD severity and right sided cardiac affection.

PATIENTS AND METHODS. This study included 35 patients with severe and very severe COPD admitted to the medical ICU and 25 selected healthy volunteers. Pulmonary function tests (PFTs), echocardiography and tissue Doppler imaging (TDI) studies were performed for patients and control to obtain comparative data.

RESULTS. LVDD was detected in 31(88.6%) COPD patients compared to 6(24%) control patients with risk ratio 24.5.There was significant increase in left atrial diameter and LVDD parameters among COPD patients. Increased PASP was encountered in 23(65.7%) of the COPD patients; 20(86.9%) patients had LVDD whereas 64.5% of LVDD patients had increased PASP. There were negative correlations between PASP and LVEDD, LVESD and E/e´ ratio. PASP at 31 mmHg and different PFTs´ parameters were predictive of LVDD.

CONCLUSION. COPD patients have higher risk of LVDD, proportional to the disease severity and usually occurs earlier than evident RV dysfunction. TDI is a better tool than the conventional echocardiography in LVDD assessment. We recommend the routine use of echocardiography and TDI in ICU-COPD admitted patients for focusing LVDD and selecting patients for optimizing heart failure therapy.

Thyrotoxic burden in the ICU and the value of bedside thyroid ultrasound in the diagnosis of thyrotoxicosis and thyrotoxic cardiac emergencies in critically-ill patients

O. Momtaz

Faculty of Medicine, Fayoum University, Egypt, critical care, fayoum city, Egypt

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0456

BACKGROUND. Hyperthyroidism, second to diabetes, is the second common endocrinal disorder in the general population. The most common causes of hyperthyoidism are diffuse toxic goiter (Graves' disease) (GD) (1%), solitary toxic nodules (STN) (0.1%) and toxic multinodular goiter (TMG) (0.53%) [1]. Thyroid ultrasound (US) has been used as an adjunctive tool to assess different thyroid diseases in specialized centers and outpatient clinics. This test is rapid, safe, feasible, easily available and informative in many cases if performed by expert personnel [2-4]. However, its use in the ICU to diagnose thyrotoxicosis has not been studied.

AIM OF THE STUDY. This study aimed to:

(1) Assess the thyrotoxic burden in critically ill patients
1) admitted in ICU.
(2) Evaluate the value of thyroid ultrasound as a rapid and feasible bedside diagnostic tool in early evaluation of suspected thyroid disease in critically ill patients especially those with life threatening cardiac emergencies.

PATIENTS AND METHODS. 854 patients admitted in 2 general intensive care units from Jan to November 2011 were evaluated. All patients suspected to have thyrotoxicosis were assessed by thyroid ultrasound and by measurement of serum levels of Ft3,Ft4,TSH, echocardiography and continuous ECG monitoring. Radioisotope scanning was done in selected cases.

RESULTS. Out of 854 admitted patients, 113 (13.2%) were suspected to have thyrotoxicosis. Thyrotoxicosiswas proved in 28 patients (24.7% of suspected cases and 3.3% of all admitted cases):

15% of all suspected cases had Graves' disease and 9.7% had toxic nodules. Most diagnosed patients (No: 16, 59.3%) had masked thyrotoxicosis. Seventy-six patients (67.3% of suspected patients) were admitted as critically ill cardiac patients and presented mainly by cardiac arrhythmias, heart failure, acute chest pain and malignant hypertension and 21 of these patients(27.6%) were proved to be thyrotoxic.

CONCLUSION. Thyrotoxicosis and thyrotoxic cardiac emergencies should be thoroughly and rapidly investigated as most cases are easily overlooked. Thyroid ultrasound is a feasible, rapid, accurate, noninvasive bedside tool useful in diagnosis of thyrotoxic emergencies in ICU.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0457

INTRODUCTION. Fluid challenge (FC) evaluates hemodynamic effects on stroke volume index (SVI) or cardiac index (CI) following the administration of a small aliquot of fluid in a defined time period (1). Patients can be considered FC responder based on predefined SVI and CI thresholds and time-points.The FC, which is actually not standardized in the literature (2), is deemed the gold standard to assess the reliability of the hemodynamic test passive leg raising (PLR).

OBJECTIVES. The primary study aim was to assess whether changing FC definition would affect the assessment of fluid responsiveness. Secondary aim was to evaluate the impact of different FC definitions on PLR reliability.

METHODS. Hemodynamically unstable critically ill patients requiring fluid administration were randomly recruited. PLR was used according to the decision of the attending intensivist. FC consisted in 500 ml of crystalloids infused over 10 minutes. The fluid responsiveness was evaluated considering a) SVI or CI as hemodynamic targets; b) a SVI or CI increase of ≥10% or ≥15%; 10, 15, and 30 minutes as time-points. Receiving operator characteristics (ROC) curves of PLR were compared with the following gold standards: 10-minute response in CI or SVI ≥10%.

RESULTS. 85 FCs and 30 PLRs were analyzed. The rate of fluid responsiveness ranged from 27.1% (CI evaluated at 15' threshold 15%) to 48.2% (SVI evaluated at 10' threshold 10%). A mean (SD) of 19.7% (3.2%), 10.9% (5.1%), and 20.3% (6.0%) of patients changed responder/non-responder classification at 10, 15, and 30 minutes, respectively. A mean (SD) of 8.8% (2.6%) patients changed responder/non-responder classification after increasing the threshold from 10% to 15% (Tables 1-2). The effect on PLR reliability of different FC definitions is summarized in Figure 1. PLR sensitivity and specificity ranged from 54.1% to 81.1% and from 79.5% to 100.0%, respectively, whereas the area under the curve (95% CI) from 0.7 (0.6-0.8) to 0.9 (0.8-1.0) (see. Figure 1) FC subgroups evaluated after 30 minutes for both CI and SVI showed a significantly smaller area under the curve.

CONCLUSIONS. Rates of responsiveness and classification as responder or non-responder are affected by FC definitions. The reliability of PLR could be questioned when the assessment of the effect of FC administration is performed after 15 minutes.

INTRODUCTION. Passive leg raising (PLR) is considered as a reliable test to predict fluid responsiveness in critically ill patients. However, it requires either a continuous monitoring of cardiac output (CO) or repeated transthoracic echocardiography measurement of CO derived from the velocity-time integral (VTI) of the flow in the left ventricular outflow tract (1). As critically ill patients are routinely equipped by a central venous catheter, central venous pressure (CVP) can be measured. By analogy with the CVP rules to stop a fluid challenge (2), we suggested that an increase in CVP by more than 5 mmHg during PLR could predict preload unresponsiveness and avoid any CO measurement during the PLR test.

OBJECTIVES. We aimed to assess whether a high increase in CVP during PLR can predict preload unresponsiveness diagnosed by the absence of increase of VTI by more than 10% (3).

METHODS. We prospectively included critically ill patients equipped with a central venous catheter and for whom the physician in charge decided to test preload responsiveness by a PLR test. For each patient hemodynamic parameters were recorded before and during PLR such as mean arterial pressure (MAP), CVP and VTI.

RESULTS. Twenty-four measurements were obtained in 18 patients. Their age was 73 ± 10, their SAPSII was 52 ± 21. At baseline, norepinephrine was already administered in 22 measurements, its mean dose was 0.40 ± 0.45 μg/kg/min, the lactate concentration was of 1.6 ± 0.5 mmol/L, the MAP was 77 ± 9 mmHg and their mean CVP was 8 ± 4 mmHg. After the PLR test, 11 cases were defined as preload responders with an increase in CVP of 5 mmHg in one of them, and 13 cases were defined as preload non-responders with only two cases with an increase in CVP of 5 and 6 mmHg. There was no significant difference of the mean changes in CVP between responders and non-responders: 2.7 ± 1.9 mmHg and 2.3 ± 1.7 mmHg (p=0.7) respectively. There was no correlation between the changes in CVP and the changes in VTI (r=-0.08; p=0.7) (fig 1). Neither the change in CVP, nor its baseline value predicted preload unresponsiveness with areas under the receiver operating characteristic curves (with 95% CIs) being 0.56 (0.34-0.76) and 0.52 (0.31-0.73) respectively (fig 2).
CONCLUSIONS. Assessing the changes in CVP during PLR is not accurate to predict preload unresponsiveness in critically ill patients.

INTRODUCTION. In the last decades the use of dual-chamber pacemakers has become relevant as it allows the physician to ensure the best dyastolic function and filling time by calculating the optimal atrioventricular interval to achieve a right systolic function for improving the clinical status of the patients with AV disorders.

OBJECTIVE. To select the optimal AV interval between two technics measured by a routine echocardiography in patients with acute AV block after the implantation of a dual-chamber pacemaker in our cardiac estimulation unit in intensive care.

METHODS. Prospectively study in a two-month period (1 november - 31 december 2017) in which we registered all patients with acute AV block admitted in our ICU of 18 beds and with an indication of dual-chamber pacemaker implantation. A routinary echocardiography was performed by our cardiac estimulation unit physicians (intensivists) in the next 6 hours after the implantation (maximum). Two technics were applied (image 1): First, calculating the AV by the Ritter's Method, using a short-AV interval of 50 ms and a long-AV interval of 200 ms. In all patient we assured using the mitral doppler that there was neither E-A fusion nor truncated A wave. Second, measuring the Time Velocity Integral (TVI) of the Left Ventriclular Outflow Tract (LVOT) at different AV intervals selected (100, 150, 180 and 200 ms), making the average of 3 cardiac cycles of each interval. The average time in applying both methods were noted.

RESULTS. In the two month-period, 28 patients with cardiac arrhythmia were admitted in our unit. 18 (64.3%) with AV disorders. 13 (46.4%) with dual-chamber pacemaker implantation. Only 7 (25%) patients fullfill the inclusión criteria (AV block and US in next 6 hours maximmum) and were admitted in our study. 5 male (71.4%), mean age 72±8.5 years. Average times applied: with Ritter's method, 7.5 min (IC 95:5.2-9.8) and with TVI method, 9.7 min (IC95:7.5-11.9). Complete results on image 2.

CONCLUSIONS. In our study we demonstrate the high variability of AV interval amongst patients. The use of bedside echocardiography in ICU in these patients is an assumable procedure, technicaly and temporarily, and it may facilitate the selection of the optimal AV interval after a dual chamber pacing implantation, although our sample is small and we need the long-term follow up to evaluate the clinical improvement.

INTRODUCTION. The intracavitaryECGmethod (ICECG) is recommended as accurate, safe and cost-effective for assessing the proper location of the tip of central VenousAccessDevices (VADs)[1]. This method is considered applicable when there is a identifiable P wave.
OBJECTIVES. We hypothesised that *f* waves resulting from chaotic depolarisation in atrial fibrillation (AF) may be utilised as a surrogated of P waves.
METHODS. Eighteen patients with atrial fibrillation undergoing cardiac surgery were enrolled in the study. They all underwent central VAD positioning and intraoperative transesophageal echocardiography (TEE). After general anaesthesia induction, a TEE probe was placed so to obtain a mid-esophageal bicaval view, with visualization of the superior vena cava (SVC), of the cavo-atrial junction (CAJ) and of the right atrium (RA). Then a VAD was insered into the internal jugular vein, the guidewire was removed and the catheter filled with normal saline. The proximal end of the catheter was connected to the ECGmonitor in order to have an ICECGtracing. Under TEE visualization, the trace was recorded with the catheter tip in three different positions: in the SVC (approximately 2 cm above the CAJ), at the crista terminalis (i.e. at the CAJ), and in the upper part of the RA (2 cm below the CAJ). The tip of the catheter was finally left in corrispondence of the CAJ. The *f* wave pattern was evaluated in all traces by three different criteria of measurement: 1) the mean height of *f* waves visible in the TQtract, considering only the waves higher than one mm (method A); 2) the height of the highest f wave visible in the TQtract (method B); 3) the difference between the highest point (most positive peak) and the lowest point (most negative peak) of the *f* waves visible in the TQtract (method C).
RESULTS. When the tip was placed at the CAJ, the mean value of the *f* waves was significantly higher than in the other two positions (SVC and RA), regardless of the measurement method. All three methods were effective in discriminating the tip position at the CAJ. According to the ROCanalysis, method B proved to be the most effective in predicting the tip position at the CAJ if compared to the position in SVC and in RA (AUC±SE 0.84±0.02 and 0.86±0.02, respectively).
CONCLUSIONS. Our study demonstrates that ICECG technique can be used for detecting the location of the tip of central VADs in AF

patients: the highest activity of the f waves is an accurate indicator of the tip location at the CAJ. Though each method was significantly accurate in detecting the correct tip location at the CAJ, the ROCanalysis suggests that method B was the most accurate.

INTRODUCTION. Focused echocardiography is a recognised clinical tool in intensive care practice (1). its use in a general ICU population has been associated with clinically relevant changes in practice (2). In our unit, focused echocardiography is used in a triggered fashion to answer specific clinical questions; the impact of daily "non-triggered" scans is unknown to us.
OBJECTIVES. To assess the impact of routine focused echocardiography, as opposed to triggered echocardiography, on the care of patients in the ICU
METHODS. A prospective audit of "routine" focused echocardiography of patients in a tertiary cardiac ICU. Each patient on the unit was scanned at least once a week in a standard focused echocardiographic sequence (3).
RESULTS. Over a one month period from 1st of March 2018 to 31st of March 2018, 22 routine scans were performed. 18 (82%) of these scans revealed clinical abnormalities. 1 scan (4.5%) led to a rapid change in management (institution of cardiac output monitoring and subsequent VA ECMO) which led to a subsequent improvement of the patient.
CONCLUSIONS. In a one month audit of our practice, the use of routine focused echocardiography demonstrated a large amount of pathology. Only one patient had changes in their management plan due to unexpected findings on echocardiography.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0462

INTRODUCTION. Cardiac Index CI is a key target of haemodynamic monitoring. Clinical assessment based on body surface temperature BST provides a rough estimate of CI ("cold shock" vs. "warm shock").

Non-contact infrared thermometers provide a more accurate estimate of BST than clinical examination. In a recent study, a complete non-invasive estimate of CI (CI_CNI) based on BSTs and biometric data provided at least comparable estimation of the gold-standard CI derived from thermodilution (CI_TD) compared to two uncalibrated devices based on pulse contour analysis (ClearSight (CI_CS) and Flo-Trac (CI_FT); both Edwards Lifesciences).

OBJECTIVES. We hypothesized that bias and percentage error of CI_CS and CI_FT could be improved by a combination of the data from both devices or by a combination with CI (CI_CIN). We investigated the agreement of these combinations with CI_TD and compared their predictive capacities with those of CI_CS, CI_FT and CI_CNI alone.

METHODS. In 22 patients (15m; 7f; APACHE-II 28±6) with TD-Monitoring (PiCCO; Pulsion; Germany) a total of 176 datasets were recorded (8 datasets per patient within 24h). Immediately before TD we measured BST on the forehead, forearm (middle and distal), finger and great toe with a non-contact infrared thermometer (Thermofocus; Tecnimed) to derive CI_CNI. Calculation of CI_CNI is also based on age, gender, weight and height.
Simultaneously, we recorded CI_CS and CI_FT.
These estimates of CI were compared to CI_TD.
Statistics: Multiple regression analysis; Bland-Altman Analysis (Primary endpoint); ROC-AUCs regarding CI_TD≤2.5 and CI_T≥5L/min*m^2.
Derivation and validation of CI_CIN from this dataset have been presented at the ISICEM 2018.

RESULTS. Among the un-combined devices, CI_CIN provided better bias (-0.039 L/min/^{2}) and percentage error (PE; 49%) values compared to CI_CS (-0.85 L/Min/m^2; 60%) and CI-FT (-0.097 L/Min/m^2; 65%). Combination of CI_CS with CI_FT (CI_CS_FT) markedly improved the bias (0.0L/min/m^2), whereas the PE (49%) for this combination was not lower than for CI_CNI alone. CI_CS_CNI combining CI_CS and CI_CNI had a markedly improved bias (-0.001 L/min/m^2) and PE (47.5%) compared to CI_CS alone, but not compared to CI_CNI. The best values for bias (0.0003 L/min/m^2) and PE (43.7%) were found for CI_FT_CNI derived from CI_FT and CI_CNI. The largest ROC_AUC regarding CI_TD ≤2.5 was found for CI_CNI alone (0.793; p< 0.001 except as indicated). The AUCs were 0.627 for CI_FT (p=0.060), 0.679 (p=0.005) for CI_CS, 0.772 for CI_FT_CNI and 0.775 for CI_CS_CNI.
ROC_AUCs regarding CI_TD≥5 were 0.794 (CI_FT), 0.888 (CI_CS), 0.906 (CI_CS_FT), 0.920 (CI_CNI), 0.924 (CI_CS_CNI) and 0.944 (CI_FT_CNI).

CONCLUSIONS. Combination with CI_CNI markedly improved the estimate of CI_TD by CI_CS and CI_FT.
Un-combined CI_CNI provides at least comparable estimates of CI_TD as CI_CS and CI_FT.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0463

INTRODUCTION. The clinical usefulness of inspiratory flow pattern manipulation remains unclear.

OBJECTIVES. The purpose of this study was to compare the effects of flow patterns (sinusoidal, constant and decelerating) on dynamic measurements of cardiac preload dependence such as arterial pulse pressure variation (ΔPP) and distensibility index of the inferior vena cava (dIVC).

METHODS. Over four months (May 1st, 2013 to August 31th, 2013.) a prospective, crossover, observational study was performed in an 18-bed medical surgical intensive care unit at Tunis military hospital. Inclusion criteria were predefined as follows: mechanical ventilation with volume assist-control mode, full adaptation to ventilator and sinus rhythm. The study design was a 30 minutes crossover with 60 minutes washout during which time the patients received usual ventilator with decelerating inspiratory flow pattern. Each inspiratory flow waveform was maintained for 30 min. During the last 5 min of this period the physiological signals were collected and measures (ΔPP and dIVC) were performed. This trial is registered with Clinicaltrials.gov, number NCT01892696

RESULTS. Among 82 patients admitted in the ICU during the study period, 60 patients were included. The decelerating waveform was significantly associated with a lower mean of Peak pressure (Ppeak) and Plateau pressure (Pplat) compared to both constant and sinusoidal flow patterns (p< 0.001).Although the decelerating waveform was associated with a slightly higher mean airway pressure (Pmean) than the other two flow patterns, this difference did not achieve statistical significance. There was no difference between sinusoidal and constant waveforms. In contrast the decelerating waveform produced significantly lower values of ΔPP and dIVC than did both constant and sinusoidal waveforms.

CONCLUSIONS. Our findings suggest that decelerating waveform was significantly associated with a lower mean of Ppeak and Pplat and produced significantly lower values of ΔPP and dIVC compared to both constant and sinusoidal flow patterns

Correspondence: A.M. González González
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0464

INTRODUCTION. Ambulatory blood pressure monitoring (ABPM) permites the evaluation of 24 hours blood pressure pattern. It is well defined the prognosis value of the abnormalities in the circadian variation in hypertensive patients. In the phisiopathology of heart failure, neurohumoral mechanism plays an important role. Nevertheless, the circadian variation in nonhypertensive heart failure patients has not been well evaluated.

OBJECTIVES. To evaluate 24 hours monitoring blood pressure in nonhypertensive heart faire patients.

METHODS. We studied 80 patients with a clinical diagnosis of nonhypertensive CHF. They were followed-up by the Heart Failure Unit. We permormed a 24-h ambulatory blood pressure monitoring as well as an echocardiogram and anaytical test.

RESULTS. 80 patients. Mean age: 62,7 ± 12. Males: 72,5%. Mean BMI: 29,6 ± 5 Kg/m^2. Mean time of follow-up of CHF: 69 ± 66 months. Associated risk factors: dyslipidemia 25% Diabetes 20% obesity 45% active smoking 30%, ex-smoking 27,5%.
Therapeutic regimen applied: RAS blockers 85%; betablockers 92,5%; loop diuretic 75%; spironolactone 35%; statins 55%; antiplatelet/anticoagulant drugs 75%, nitrates 20%, digoxin 30%
The 24 h ABPM measurements are in Table 1.
The majority of CHF patients (77,5%) have an abnormal pattern of ABPM, as it is shown on on Table 2.

CONCLUSIONS. Nonhypertensive heart failure patients had, in majority, an abnormal circadian rhythm of blood pressure. It is well

known the prognosis values of this alterations. This highlights the high cardiovascular risk and the neurhumoral alterations of this patients with chronic heart failure, whether they are hypertensive or not.

Table 1 (abstract 0464). See text for description

Mean ABPM (mmHg)	24 hours	Daytime	Nightime
Sysolic BP	107,7 ± 13,8	109,6 ± 14,2	104,5 ± 14,5
Diastolic BP	64,4 ± 7,8	66,4 ± 8,8	60,4 ± 7,6

INTRODUCTION. Patient's requiring hemodialysis have high mortality rates. Overly rapid UF rates can lead to intradialytic hypotension leading to poor outcomes. Conversely, fluid overload may also be a predictor of mortality[1,2]. There is a lack of literature on methods to individualize UF rates for optimal fluid removal. The left ventricular outflow tract velocity time integral (LVOT VTI) is a validated non-invasive echocardiographic surrogate for stroke volume. We hypothesize that lack of VTI proven volume responsiveness is suggestive preload independence, therefore, may have a lower propensity for intradialytic hypotension.

PURPOSE. We propose the use of bedside echocardiography proven preload dependence as a predictor of intradialytic hypotension.

METHODS. We conducted a prospective observational study within a tertiary medical center from September 2016 to June 2017. We included patients with the need for intermittent hemodialysis with a minimum UF rate of 5cc/kg/hr, adequate echocardiography windows, patient consent and catheter dialysis access. Patients with age < 18 years of age, pregnancy, AV fistula/graft access, more than one vasopressor/inotrope, hemorrhagic/hypovolemic shock and inability to consent were excluded. Baseline vitals obtained before dialysis. We obtained an apical five-chamber view; three VTI measurements were recorded on end expiration pre and post a 50 cc normal saline bolus. Fig 1,2 Percentage increase in VTI was deemed to be delta VTI (dVTI). The primary outcome was intradialytic hypotension, which was defined as a systolic or MAP drop of > 30 or > 10 mmHg respectively.

RESULTS. 37 patients were recruited for the study. For analysis , we used logistic regression and ROC curves for the statistical analysis. We also found predictive values. Using a dVTI cutoff of 9% or higher, the odds ratio (OR) for developing intradialytic hypotension was 17 (CI 2.19-99). The PPV and NPV were 66.7 and 89.5% respectively. The sensitivity and specificity were 85.7 and 73.9 respectively. The AUROC was 0.776 (CI 0.600-0.952). Fig 3 The regression yielded an OR of 1.2 (CI 1.08-1.4) for every percent increase in dVTI.

CONCLUSIONS. Evidence of preload dependence through the use of bedside echocardiography may predict intradialytic hypotension. Conversely, a lack of response had an excellent negative predictive value. Preload dependence is a predictor of intradialytic hypotension and should be studied in more extensive clinical trials.

INTRODUCTION. In the intensive care. unit, Acute Hypotensive Episodes (AHE) represent a phenomenon of high clinical relevance. If not promptly treated, AHEs may lead to critical conditions, and they are associated with a more than double mortality rate compared to normopressive subjects and side effects of late treatment (e.g irreversible organs damage) [1].

AHE prediction has been the subject of several previous studies, showing it is possible to predict such events. We present a method that, by means of machine learning and a statistical model framework, predicts AHE onset by several minutes using information from ECG and Arterial Blood Pressure (ABP) recordings.

Additionally, we proved that by introducing variables related to baroreflex sensitivity (BRFX) in the previous model we were able to improve the quality of the prediction (AUC) by 9.8%.

OBJECTIVES. The aim of this study is to predict the onset of AHE using a mathematical framework applied on ECG and ABP waveforms from bedside Monitor recordings of ICU patients.

METHODS. We define an AHE by the 2009 Physionet Challenge definition:

30 minutes interval in which 90% of MAP is below 60mmHg [1].

Data were pulled from the MIMIC-II Waveforms Database.

The final cohort counted 83 records, of which 32 (38.55%) hypotensive.

The first model (Model A) we deployed was based solely on blood pressure variables, whereas in the second (Model B) we introduced BRFX Features.

BRFX was estimated using a bivariate point process framework based on a closed-loop Heart Rate (HR) - Systolic Blood Pressure (SBP) model [2].

Following several processing stages, we extracted indicators describing BRFX activity.

The prediction was performed 10 minutes ahead of the AHE onset, using 10 minutes worth of data (time windows starting 20 minutes before the AHE onset and ending

10 minutes prior) using Linear Discriminant Analysis.

RESULTS. Model A obtained an AUC of .74, while Model B further improved results (AUC) by as much as 9.8%.

CONCLUSIONS. Results from this study show that it is possible to extract relevant information from a beat-to-beat analysis, able to generate a prediction by using only 10 minutes of data previous to the event. Additionally, the inclusion of BRFX further improves the outcome. Indeed, machine Learning is proving to be an extremely useful tool for supporting clinicians in critical care, although further improvements are still advocated, towards even more accurate outcomes.

INTRODUCTION. The hemodynamic monitoring is fundamental for the diagnostic approach and therapeutic guide in the Intensive Care Unit (ICU). A continuous non-invasive monitoring of cardiovascular function is required. The magnetic cardiac pulsepresiometer (PPC) is a device of regional invention, inexpensive, non-invasive, easy application to patient's bedside which in healthy volunteers is able to record the amplitude of the arterial pulse continuously, obtaining the measurement of cardiac output by means of electromagnetism

OBJECTIVE. The goal of this study was to determine the correlation between the measurement of cardiac output by PPC and Fick method in the ICU.

METHODS. This prospective, observational, longitudinal study was conducted at the ICU, Centro Médico Nacional del Bajío UMAE 1, in León Guanajuato between December 2017 and February 2018. Patients were admitted over 18 years with a functional central venous with any diagnosis, regardless of the hemodynamic status. The cardiac output following the Fick method and with the PPC was measured at the first 4 hrs from admission to the unit. Patients who had a tracheostomy or a disfunctional central venous catheter dysfunction were excluded. The statistical analysis was performed with the statistical package MedCal V 19.1

RESULTS. We included 13 patients, with a mean age of 36.3 years, 7 women (53.84%), 6 men (46.15%), the mean APACHE II and SOFA were 25.3 and 7.6 points respectively; more frequent admission diagnosis was subarachnoid hemorrhage.

Finding a positive correlation between the non-invasive measurement of cardiac output measured by the PPC and that calculated by the Fick method using the samples obtained from the central venous catheter, r = 0.91 (fig. 1). With a concordance by kappa coefficient of 0.67, which is considerable.

CONCLUSION. The magnetic cardiac pulsopresiometer is a low-cost device that can be used at the patient´s bedside to perform a non-invasive monitoring of cardiac output in critical patients.

INTRODUCTION. For patients with sepsis and septic shock, we recommend the infusion of intravenous fluids (30mL/kg) within the first three hours of presentation, rather than vasopressors, inotropes, or red blood cell transfusions.

Static or dynamic predictors of fluid responsiveness should be employed in order to determine further fluid management. Guidelines state a preference for dynamic measures (eg, SVV, PPV etc) since they are more accurate than static measures (eg, CVP) at predicting fluid responsiveness.

OBJECTIVES. The objective of this study is to determine the agreement between stroke volume variation (SVV) measured simultaneously by the FloTrac®/Vigileo® system and BioZ® system to assess fluid status in patients with sepsis or septic shock.

METHODS. In this retrospective observational study, we evaluated the medical records of patients who monitored by stroke volume variance parameters measured simultaneously by the FloTrac®/Vigileo® system and BioZ® system in patients with sepsis or septic shock in the medical intensive care unit at a tertiary university-affiliated hospital, from June 2017 to January 2018. Patients with arrhythmia or extracorporeal therapy or without mechanical ventilation were excluded.

RESULTS. Total 14 patients with sepsis or septic shock were analyzed. The mean age of subjects was 72.4 ± 10.4 and 4 patients (28.6%) were female. Each parameters were measured average 9 times in one patient (total 125 times). The mean RASS score was -3.14 ± 0.86 and the mortality rate was 28.6% (4 patients). All patients was treated with vasoactive drugs and 4 patients had the heart failure.

There were no significant correlations between central venous pressure and SVVs measured by the FloTrac®/Vigileo® system and BioZ® system (CVP vs. SVV (the FloTrac®/Vigileo®); r = -0.063, P=0.488,

CVP vs SVV (BioZ®); r = -0.199, P=0.027, SVV (the FloTrac®/Vigileo®) vs SVV (BioZ®); r = 0.048, P=0.597). And there was no agreement between central venous pressure and SVVs measured by the FloTrac®/Vigileo® system and BioZ® system (CVP vs. SVV (the FloTrac®/Vigileo®); kappa = 0.057 (95% CI -0.010 ~ 0.214), CVP vs SVV (BioZ®); kappa = 0.039 (95% CI -0.009 ~ 0.087), SVV (the FloTrac®/Vigileo®) vs SVV (BioZ®) ; kappa = 0.005 (95% CI -0.103 ~ 0.112).

CONCLUSIONS. Our preliminary study showed disagreement the hemodynamic parameters measured by one of the two devices and it should be interpreted with caution before therapeutic interventions.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0469

INTRODUCTION. Deciding fluid status of ICU patients is very important and difficult issue. Recently critical care USG has been investigating for this aim as an easy, quick and noninvasive tool. Most frequently investigating parameters are cardiac output(CO), stroke volume(SV), LVOT Vmax variability, inferior vena cava variability index (IVCVI), and carotis blood flow(CBF) and carotis Vmax. However all of them have their own limitations in image acqusition and measurements.

OBJECTIVES. Aim of this study is to investigate applicability of CO and other parameters in the evaluation of fluid status in the medical ICU patients.

METHODS. All adult ICU patients regardless of fluid status included in the study and tried to measure CO, SV, LVOT Vmax, IVC variability, CBF and carotis Vmax. If heart visualized which windows were visualized(apical 4 chamber(A4C), apical 5 chamber(A5C), parasternal long axis(PLAX), parasternal short axis (PSAX)) were also recorded. If any obstacles for measurement of them were exist they recorded. Why they could not visualize or why measurements could not be performed, if patient has severe aortic or mitral regurgitation(AR, MR), atrial fibrillation, COPD(chronic obstructive pulmonary disease) or receiving mechanical ventilation. If they are obese or have abdominal distention were also recorded. Experienced intensivist were performed all measurements, color, pulse wave continue way doppler and M and 2D modes were used for the measurements.

RESULTS. 61 patients were included in the study their mean age was 72±13 years, APACHE II: 24±11, 41% of them were on mechanical ventilation, 53% of them had COPD, and 17 had atriall fibrillation. In 2, 18, and 20% of the patients carotis artery, IVC and heart could not be visualized respectively. Among 49 patients whose heart could be seen in 47% of them PSAX, 35% PLAX, 31% A4C, 45% A5C windows could not be visualized enough to measurements. 16 and 10 of the patients had severe MR and AR respectively. At the end of the study valuable cardiac measurements(CO(mean± SD: 5.4±2.3 l/min, SV(268 ±91 ml, LVOT Vmax:1.1±0.3 m/sec) could be performed in only 56% of the patients. Mean CBF of the patients: 547±238 ml/min, carotis Vmax:0.75±0.87 m/s and IVC VI : 40±22%)

CONCLUSIONS. These results suggest that availability of measurements of CO and SV may be low in some ICU populations and if there is no TEE chance trying to standardize measurement protocol for IVC and carotis parameters would be wise for the noninvasive evaluation of fluid status. Further studies are necessary to explore applicability of these methods and compare their performances.

Platelets count and serum calcium could be two important parameter for aritificial intelligent decisions in fluid resuscitation

Z. Qin

Ruijin Hospital School of Medicine, Shanghai Jiaotong University, Burn Center, Shanghai, China

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0470

INTRODUCTION. Fluid resuscitation in initial phase for post-burn patients is considered as a model for researching the hypo-volemic shock in critical care. Artificial intelligence decision system in critical care would be an up-and-coming and revolutionary work in near future.

OBJECTIVES. The present study try to explore on which indicators are needed to be parameters for AI decision-making

METHODS. A study involving adult patients with extremely severe burn admitted to our hospital from January 2010 to July 2015. The relationship between initial serum calcium and influence factors was assessed. The dynamic changes in platelet counts and serum calcium of first 10 days post-burn injury were analyzed.

RESULTS. The incidence rates of hypocalcemia of patients were 97.2% (138/142), and severe hypocalcemia accounted for 36.62% (52/142). It was found that the initial serum calcium was correlation with total burn area, admission time after injury and initial albumin (r respectively -0.195, -0.273, 0.564, p respectively 0.020,0.001,0.000). Initial pH and albumin were the independent risk factors for severe hypocalcemia of patients with extremely severe burn (with OR respectively 0.000,1.199,95% CI respectively 0.000-1.081,1.092-1.315, p respectively 0.011,0.000). The platelet count was decreased from 1st to 4th day post-burn and gradually increased between 4th and 10th day post-burn in both the survival and no survive (no survival) groups. However, in the survival group the platelet count returned to normal within 1 week after injury but not in the no survive group. The mortality was significantly higher in patients with platelet counts that did not return to normal within 1 week compared to those when the platelet count returned to normal (27.2% vs 6.1%, P < 0.01). Multi-variable Cox regression analysis showed that a platelet count that did not return to normal within 1 week after burn was an independent risk factor for mortality in severely burned patients (hazard ratio (HR): 2.249; 95% CI: 0.993 to 5.096), P = 0.041). The sensitivity and specificity were measured as 0.714 and 0.710, respectively using a ROC curve. Multi-factor logistic regression analysis suggested that the reason for the burn, the area of full-thickness burn, and the time from the injury to being admitted to hospital were independent factors correlated with early recovery of the platelet count.

CONCLUSIONS. Platelet count and serum calcium in the early stage post burn of patients with extremely severe burn was significantly associated with causes of injury, total burn area, admission time after injury, with inhalation injury and receiving mechanical ventilation, pH and albumin were the independent risk factors for severe hypocalcemia. They could be two important parameters for aritificial intelligent decisions in near future.

Correspondence: J. Vermassen

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0471

INTRODUCTION. Retrospective identification of patients with septic shock where the digital documentation is done in natural language may be time-consuming since all patient records have to be manually reviewed. This approach is potentially further complicated since there may be underreporting if the terminological description "septic shock" is not explicitly mentioned in healthcare records.

OBJECTIVES. This study aims to investigate whether patients who have had septic shock, can be reliably identified from clinical notes in electronic health records using NLP.

METHODS. Electronic health records were collected from all adult patients admitted to the intensive care unit of the Ghent University Hospital from 2010 until 2014. Four search strategies were used to detect patients who had septic shock. The first one was to use hospital clinical coding data for "septic shock" (ICD-9 785.52). Using Intersystems iKnow text analytic technology (1), we developed an explicit strategy ("septic shock" literally stated in the records), an implicit strategy (mention of the combination of "infection", "need for vasopressors" and "rise in lactate") and a combined explicit-implicit strategy. The Ghent University Hospital COSARA-database, which is prospectively capturing every septic shock in near real-time, is considered our gold standard. Pairwise comparison between search strategies were calculated and statistical significance was attained at p < 0.05.

RESULTS. Of the 9202 patients admitted during the defined period, 653 (7.1%) suffered from septic shock according to the COSARA-database. Hospital clinical coding data identified 602 (6.5%) patients. The explicit, implicit and combined strategy identified 572 (6.1), 818 (8.9%) and 1117 (12.1%) patients respectively. The implicit strategy and the combined explicit-implicit strategy proved significantly inferior and superior, respectively, to all other strategies (all p < 0.0001). When compared to the COSARA gold standard, the explicit strategy had the highest specificity (97.5% [95% CI: 97.2% - 97.9%]) compared to the implicit (94.1 % [95% CI: 93.6% - 94.6%]) and the combined explicit/implicit strategy (92.5% [95% CI: 91.9% - 93.1%]). The highest sensitivity was found for the combined strategy (72.9% [95% CI: 69.3% - 76.3%]) vs. the explicit (55.3% [95% CI: 51.4% - 59.1%]) and the implicit strategy (47.6% [95% CI: 43.7% - 51.5%]). The combined strategy also had the highest negative predictive value (97.8 [95% CI: 97.5% - 98.1%]) vs. the explicit (96.6% [95% CI: 96.3% - 96.9%]) and the implicit strategy (95.9% [95% CI: 95.6% - 96.2%]). Positive predictive value was low for all search strategies.

CONCLUSIONS. NLP is able to filter clinical notes in electronic health records and identify patients with septic shock, which may save substantial research time.

Association between postoperative 30-day mortality and night and weekend postoperative admissions to the surgical intensive care unit in a setting with day-time intensivist coverage

T.K. Oh[1], I.-A. Song[2], J. Hong[1]

[1]Seoul National University Bundang Hospital, Anesthesiology and Pain Medicine, Seongnam, Korea, Republic of; [2]Seoul National University Bundang Hospital, Seongnam, Korea, Republic of

Correspondence: J. Hong

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0472

INTRODUCTION. The time of admission is important to consider in the care of postoperative patients in the surgical Intensive Care Unit (ICU).

OBJECTIVES. This study aimed to investigate the correlation between postoperative surgical ICU admission time and 30-day mortality after ICU admission.

METHODS. This was a retrospective observational study in a tertiary care hospital ICU, with daytime intensivist coverage. We collected the electronic medical records for all patients who were admitted to the postoperative ICU after undergoing a surgery between January 1,

2007 and December 31, 2016. The primary outcome was to examine the differences in 30-day mortality after ICU admission stratified by the ICU admission time interval: office hours (08:00-15:59), evening (16:00-23:59), and nighttime (00:00-07:59).

RESULTS. Over the 10-year study period, there were 16,615 postoperative ICU admissions; 6846 (41.2%), 8,186 (49.3%), and 1,583 (9.5%) were during office hours, evening, and nighttime, respectively. The 30-day mortality after ICU admission during the nighttime was higher than that after ICU admission during office hours (odds ratio: 1.77, 95% confidence interval: 1.59-1.97, P< 0.001). Compared to Sunday, 30-day mortality was significantly lower for ICU admission from Monday to Friday [Sunday versus Monday (OR: 0.72), Tuesday (OR: 0.56), Wednesday (OR: 0.58), Thursday (OR: 0.52), Friday (OR: 0.54), P< 0.001].

CONCLUSIONS. We found an increase in postoperative 30-day mortality when the postoperative ICU admission occurred during the nighttime as opposed to during office hours. Additionally, postoperative 30-day mortality was significantly higher when postoperative ICU admission occurred during the weekend rather than weekdays.

Visit of minors in an intensive care unit: what do the health personnel believe?

E. Calvet Gonzalez, J. Valls Matarín, R.M. Peradejordi Torres, A. Jorge Castillo, S. Calvo Alonso, I. Sandalinas Mulero
Hospital Universitari Mútua Terrassa, ICU, Terrassa, Spain
Correspondence: E. Calvet Gonzalez
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0473

INTRODUCTION. The visit of minors aren´t get used planning in the organization of the Intensive Care Unit (ICU), although they belong to the family group[1,2].

AIMS. Determine the beliefs and compare the attitude of health staff in the presence of minors in an intensive care unit of adults.

METHODS. A transversal descriptive research in a polyvalent ICU with 62 professionals, between September and December 2017. Each professional was given a translated Knutsson[3] questionnaire with 10 closed questions and 2 open ones.

Descriptive statistics with absolute frequencies and percentages. Chi-squared test or Fisher´s exact test to determine the relation between profession and the different variables. Significance p < 0.05.

RESULTS. 61 questionnaires were collected (98.4% of the population): 18 physicians (29.5%) and 43 nurses (70.5%).

50% of physicians would restrict the entrance of 0 to 6-year old minors versus 76.2% of nurses (p=0.04).

Likewise, if the minor was between 7 to 12 years old, 16.7% of medical staff would restrict such visits versus 46.5% of nurses (p=0.02). Only 8.2% of professionals would prohibit it if the child was between 13 to 17 years old (p=0.06).

75% of health staff thought that minors´ access could entail in risk of infection for the children and 55% for the patient. 60% of survey respondents (69.1% nurses and 38.9% physicians, p=0.03) believed that the environment could intimidate the minor, and 66.7% (74.4% nurses and 47.1% physicians, p=0.04) thought that the patient´s condition could affect the child. Nevertheless, they would permit 0 to 6-year-old minors to access the ICU if the patient was dying (70.6% physicians/ 41% nurses, p= 0.04), awake and alert (57,5% nurses/ 77,8% physicians) and close relatives (parents) (60% nurses/ 66,7% physicians).

CONCLUSIONS. The health personnel isupports minors' visiting in a ICU of adults if they are >6 years old. Staff show a more positive attitude towards visits in special circumstances such as close relatives, awake patient and death regardless of their age. The main reasons for the restriction them are: environment, patient´s condition and risk of infection.

Nurse staff show a less positive attitude in relation to minors´ visits.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0474

INTRODUCTION. Besides ASA as the gold standard for the assessment of patients' physical status prior to anaesthesia, morphometric scores such as the Charlson Comorbidity Score, have been proposed to evaluate postoperative risk stratification. Though techniques of machine learning have been successfully applied in similar contexts, little is known whether they perform generally better than classic statistical methods in predicting mortality in low-frequency populations.

OBJECTIVES. Aim of this study was to compare different classes of statistical and machine learning models for predictive accuracy regarding postoperative mortality.

METHODS. Secondary analysis of a retrospective study at a university hospital in Germany (clinicaltrials.gov identifier NCT01810133). The study was approved by the federal data protection officer and the hospital ethics commission (EA1/007/13). All patients with a digitalized electronic anaesthesia record between January 2006 and December 2011 who were not treated in the intensive care unit were eligible for inclusion. Emergency and ambulatory cases were excluded, and only cases with complete data were analysed. The dataset included the following information categories: ASA PS, surgical discipline, priority of surgery (elective or urgent/emergency), localization of surgery, age, gender, ICD-coded diagnoses, and in-hospital death. If the patient underwent >1 surgical procedure during his hospital stay, only the data of the first surgical intervention was included in the analysis. RStudio version 1.0.153 was used for data analysis. Model classes included in the comparative analyses were logistic regressions (LR), simple decision trees (FFT), Charlson Comorbidity Score (CSS), classification and regression trees (CART), ASA PS (ASA), and random forests (RF).

RESULTS. Figures 1a and 1b show the predictive accuracy of the best performing models in the holdout set compared to ASA and the CCS. The median predictive accuracy (AUC) over all models was 0.93 (range = 0.89 to 0.98, mean = 0.93). Logistic regression (AUC = 0.98) and random forests (AUC=0.96) performed best, followed by a simple FFT (AUC=0.91), the CCS (AUC=0.91) and the more complex CART (0.89) decision trees. All models outperformed anaesthesiologists' intuitive judgment of how ill a patient was (AUC = 0.80).

CONCLUSIONS. Gains in predictive accuracy beyond those of anaestheiologists' assessment by means of ASA can be achieved using statistical and machine learning approaches. Which model is best suited to a particular decision problem, however, is an empirical question that cannot be answered a priori. Both simpler and more complex models may outperform each other in different situations.

Can quadriceps femoris muscle thickness measured by ultrasonography predict fluid and malnutrition status in critically ill patient?

U. Özdemir[1], M. Özdemir[2], B. Kaya[1], M. Türkoğlu[1], G. Aygencel[1]
[1]Gazi University Medical Faculty Hospital, Medical Intensive Care Unit, Ankara, Turkey; [2]Baskent University, Nutrition and Dietetics, Ankara, Turkey
Correspondence: U. Özdemir
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0475

INTRODUCTION. Skeletal muscle loss due to immobilization, systemic inflammation, sepsis and malnutrition in critically ill patients is the major cause of morbidity and mortality(1). Quadriceps femoris muscle thickness(QFMT) measured by ultrasonography(USG) can successfully predict lean body mass(2). However, it is not known how the maximal compressed QFMT(MCQFMT) and uncompressed QFMT (UCQFMT) are affected in different fluid and malnutrition conditions in medical intensive care unit(MICU) patients.
OBJECTIVES: The purpose of this study is to measure QFMT in MICU patients by USG and to determine the malnutrition status independently from the volume status of the patients.

METHODS. All patients older than 18 years admitted to Gazi University Hospital MICU between August 1, 2017 and March 1, 2018 were included in this study. Within first 24 hours left and right MCQFMT, UCQFMT were measured in all patients by USG(GE, S7 model USG device and 4C-RS 2-5 MHz convex probe). Concurrently, NUTRIC2 and NRS2002 scores were recorded.
RESULTS: 56 patients were included in the study. The median age of the patients was 71.5[56.2-82.7] and 55.4% were male. 23(41%) patients died. There was a significant difference between survivors and non-survivors for thickest MCQFMT(1.03 [0.62-1.28] vs 0.70[0.5-0.96] cm, p=0.035). There was also a significant difference between thickest UCQFMT in normovolemic and hypervolemic patients (2.02[1.26-2.65] vs 2.70[1.8-3.2] cm, p=0.028) but there is no difference in MCQFMT(p=0.192). In 20 patients without malnutrition according to NUTRIC2 score, right, left, thickest MCQFMT were 1.00[0.57-1.27], 0.95[0.61-1.28], 1.09[0.63-1.38] cm respectively. In 36 malnourished patients, right, left, thickest MCQFMT were 0.62[0.46-0.97], 0.65[0.46-1.01] and 0.73[0.50-1.11] cm respectively. There were significant differences between right, left, thickest MCQFMT according to NUTRIC2 score (p values: 0.048, 0.040, 0.044 respectively) but no difference found in UCQFMT(p values: 0.225, 0.090, 0.151 respectively). We didn't compare QFMT according to NRS2002, because all patients were malnourished according to this score.
CONCLUSIONS. Volume status of MICU patients effects UCQFMT measurement and should not be used as a marker of malnutrition in this patient group. MCQFMT measurements, independent from volume status of MICU patients, are significantly related with nutritional status according to NUTRIC2 score. Further studies are needed to determine the use of MCQFMT measured by USG in the detection of malnutrition.

INTRODUCTION. Optic nerve sheath diameter (ONSD) determined by ocular ultrasonography (OU) has been associated with elevated intracranial pressure (EICP). However, most studies have analyzed ONSD and its optimal cut-off point for EICP in Caucasian populations. Considering that ONSD may differ according to race and ethnicity, it is important to determine ONSD cut-off reflecting EICP in Indians.
OBJECTIVES. To investigate normal range of ONSD and its optimal threshold for detecting EICP in adult Indian ICU patients.
METHODS. Prospective, single-center study was performed in adult (age>18 years)patients with suspected EICP admitted to ICU, after institutional ethical committee approval and consent from patients/caregivers. ONSD was measured 3mm behind the globe using a 13-MHz US probe over a closed eyelid. EICP was defined as significant brain edema &/or midline shift, with/without compression of ventricle or basal cistern, effacement of sulci, and transfalcine herniation by Computed Tomography (CT) of Brain. The person performing the ONSD was unaware of the history and examination findings of the patients and the radiologist reporting the CT brain were aware of the history of the patients. The results of the ONSD are described as the

median (25th-75th percentile). A receiver operator characteristic (ROC) curve was generated to determine the optimal cut-off point for identifying EICP.

RESULTS. A total of 188 patients were enrolled. The patients were divided into 2 groups as follows: patients with EICP, n=129 (68.5%); patients without EICP, n=59 (31.5%). ONSD in patients with EICP (5.8mm [5.5-6.2]) is significantly higher than those without EICP (5.1mm [4.8-5.4]) (P< 0.05). ONSD >5.5mm yielded a sensitivity of 98.01% (95% CI: 93.3%-100%) and a specificity of 86.16% (95% CI: 66.3%-95.8%).

CONCLUSIONS. The optimal cut-off point of ONSD for identifying EICP was 5.8mm. ONSD seen on OU is a feasible method for detection and serial monitoring of ICP in Indian adult patients.

INTRODUCTION. Bedside ultrasound is now extensively used by intensivists worldwide to optimize patient management at the bedside [1]. However, monitoring is discontinuous and relies on intensivist availability. Therefore, teaching bedside ultrasound to ICU nurses holds great promise, as they typically spend far more time at the bedside.

OBJECTIVES. To assess the feasibility of teaching bedside ultrasound to ICU nurses.

METHODS. We enrolled 8 ICU nurses into our UltraNurse training program that relied on a focused 3-phase approach [2] within our 24-bed university hospital ICU. First, these UltraNurses attended two 4-hour theory and practice sessions led by an ultrasound-certified intensivist. Our UltraNurse scanning protocol consisted of anterior and posterolateral lung ultrasound (LUS) imaging as well as measuring the left ventricular outflow tract flow velocity time integral (LVOT-VTI) using pulsed wave Doppler as a proxy for stroke volume. UltraNurses then performed 5 bedside ultrasound examinations under direct supervision. Finally, they continued performing bedside ultrasound examinations until full proficiency was reached. Every examination was supervised by ultrasound-certified intensivists and graded on dexterity, image quality and accuracy of interpretation, using Likert scales. A priori, full proficiency was defined as 5 consecutive examinations performed without assistance and interpreted correctly. Using structured questionnaires, UltraNurses were interviewed frequently to identify barriers and facilitators for our program. Data are given as medians and interquartile range.

RESULTS. All UltraNurses reached full proficiency status. This required 13 [12-18] examinations for LUS and 13 [11-16] for LVOT-VTI. Total time required to become fully proficient was 21 [14-26] weeks for LUS and 26 [19-29] weeks for LVOT-VTI. Figures 1 and 2 depict UltraNurse progress. Table 1 shows UltraNurse characteristics. Total duration of the program was 7 months in which 123 patients underwent 230 examinations. Varying support from intensivists and perceived high workload were barriers for our program while facilitators included intensivist enthusiasm, increased work satisfaction and improved perceived valuable contribution to the treatment team.

CONCLUSION. This is the first report to show that teaching bedside ultrasound to ICU nurses is feasible. The number of examinations to reach full proficiency for our UltraNurse protocol was small, although this took many weeks. Teaching bedside ultrasound to ICU nurses deserves widespread consideration. It holds great promise for increasing ICU nurse work satisfaction but most importantly for further improving management of our critically ill patients. We are currently evaluating the clinical impact of our UltraNurse program.

The additional value of strain imaging to detect right ventricular dysfunction in critically ill patients: a sub-study of the Simple Intensive Care Studies-I

M.E. Vos[1], Y.M. Hummel[2], F. Keus[1], G. Koster[1], I.C.C. van der Horst[1], SICS Study Group

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0478

INTRODUCTION. Right ventricular (RV) dysfunction is common in the critically ill and associated with adverse clinical outcomes. Critical care ultrasonography (CCUS) evaluates RV function with conventional measurements such as Tricuspid Annular Plane Systolic Excursion (TAPSE) and peak systolic tissue velocity at the tricuspid annulus (RV s'). Myocardial deformation imaging is a relative new technique to assess regional systolic function and is expressed in strain. Several studies suggest that strain imaging has an additional diagnostic and prognostic value compared to CCUS. In patients with heart failure and pulmonary hypertension, RV strain detected RV dysfunction when conventional CCUS measurements were preserved. However, the diagnostic value of RV strain has never been evaluated in a large unselected population of critically ill patients.
OBJECTIVES. The objective of this study was to investigate the association between TDI-derived RV strain and conventional CCUS measurements to evaluate RV function in an unselected population of critically ill patients.
METHODS. This sub-study was part of the Simple Intensive Care Studies-I (SICS-I: NCT02912624; Hiemstra et al. BMJ open 2017). This prospective cohort study included all consecutive adults who were acutely admitted with an intensive care unit (ICU) stay expected to last beyond 24 hours. Patients with atrial arrhythmias were excluded. Within 24 hours after admission transthoracic ultrasonography was preformed, recording TAPSE, RV 's and color tissue Doppler images of the RV free wall and septum in the AP4CH view. Offline strain analysis was preformed to calculate global longitudinal RV peak strain (GLPS) and RV free wall longitudinal peak strain (RVLPS). TAPSE < 17 mm, RV s' < 9,5 cm/s, GLPS > -17% and RVLPS > -20% were considered as reduced RV function.
RESULTS. From March 2017 until July 2017, 238 patients were included in the SICS-I of which 51 patients were included in this sub-study. Baseline characteristics are displayed in table 1 in the appendix. Moderate correlations were found between TAPSE & GLPS (r= -0,65, p=0.00) and TAPSE & RVLPS (r= -0.58, p=0.00). The same applies for RV s' & GLPS (r= -0.57, p=0.00) and RV s' & RVLPS (r= -0.56, p=0.00). GLPS and RVLPS detected RV dysfunction in 8 out of 32 patients with normal TAPSE and/or RV s'. When examining the profile of these patients, a common feature was myocardial ischemia.
CONCLUSIONS. This pilot study provides additional arguments for the application of strain imaging in the critically ill. RV strain seems to have an added value for detecting RV dysfunction when conventional measurements of RV function are preserved, especially in patients with underlying cardiac pathologies.

Diagnostic performance of the BLUE-lung ultrasound protocol in critically ill patients undergoing thoracic CT: a prospective observational study

M.E. Haaksma, B. Hilderink, L. Arts, M. Winkler, J. Smit, A.R.J. Girbes, L. Heunks, P.W.G. Elbers, P.R. Tuinman
VU Medical Center, Amsterdam, Netherlands
Correspondence: M.E. Haaksma
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0479

BACKGROUND. The BLUE protocol was developed to match artifacts of lung ultrasound (LUS) with the final diagnosis in patients in respiratory distress presenting to the emergency department. Since then, it has found its way into routine use on the intensive care unit (ICU) to assess respiratory failure [1]. However, the diagnostic accuracy of this protocol has never been verified in an ICU setting.
OBJECTIVE. We set out to determine diagnostic performance of the BLUE protocol in ICU patients undergoing thoracic CT-scan.
METHODS. This prospective single center observational study included patients admitted to our 24-bed university hospital ICU who underwent thoracic CT scan. LUS was performed within 3 hours of the CT scan according to the BLUE protocol without venous analysis [1]. The ultrasound operator was blinded for the result of the CT scan. Additionally, an intensivist, blinded for the result of the CT scan, provided a BLUE-protocol diagnosis (pulmonary edema, pneumothorax, obstructive lung disease and pneumonia) based on the LUS

findings in combination with clinical information. The reference test was the diagnosis made by one radiologist based on the CT scan.

RESULTS. 61 patients, of which 41 were male, were included with a median age of 61 (IQR 25). Of all diagnoses, signs for pneumothorax yielded the highest effective accuracy with 89%. Overall diagnostic accuracy of the BLUE protocol was 48%. Intensivists diagnosis based on LUS and clinical findings yielded an accuracy of 62%. Sensitivity, specificity, PPV and NPV for the four final diagnoses are shown in Table 1.

CONCLUSION. In ICU patients undergoing thoracic CT, the highest accuracy of the BLUE protocol without venous analysis is 89% for pneumothorax, while overall accuracy is 48%. When LUS findings are combined with clinical findings its accuracy increases to 62%.

Development of an intensive care advanced echo course
A. Blackstock, S. Morton, J. Powell-Tuck, J. Aron
St George's Hospital, Intensive Care Unit, London, United Kingdom
Correspondence: J. Aron

INTRODUCTION. The use of echocardiography in intensive care (ICU) is increasing and has been shown to have a positive impact on patient care.[1] The Focussed Intensive Care Echo (FICE) has been developed as an entry level course in ICU echo with a curriculum developed around 2D scanning.[2,3] However, the use of echocardiography as a haemodynamic monitor requires further competency development to use effectively and reliably.

OBJECTIVES. The aim was to develop an advanced ICU echo course that builds on the FICE curriculum to include more advanced techniques such as continuous/pulse wave Doppler, colour flow Doppler and M-mode.

METHODS. A one-day advanced echo course was developed and taught at St George's Hospital, London in March 2018. The course was tutorial-based with small groups rotating through stations scanning live models, simulators and reporting videos. These consisted of a step-wise increase in techniques used, starting from advanced 2D views, and progressing through 2D and M Mode measurement, the use of colour flow to assess haemodynamically significant valvular pathology and the use of spectral analysis to assess haemodynamic response to interventions. This culminated in case-based discussions compromising clinical decision making based on echocardiography findings (Figure 1).

An online questionnaire was administered to all participants before and after the course to gain an understanding of previous experience and confidence in advanced echo techniques

RESULTS. All participants (n=20) completed the questionnaire pre and post; 5 senior house officers, 12 registrars and 3 consultants. 75% had previously completed a FICE course; only 25% of people had performed 50 cases or more to become accredited.

Figure 2 shows the change in confidence following the course. On average, there was an improvement in confidence in every technique taught on the advanced echo course. Prior to the course participants felt it was highly likely (50%) or likely (50%) that the course would change their practice; following the course 63% felt it was highly likely, 32% likely and 5% felt it would perhaps change their practice (one participant did not answer).

CONCLUSIONS. A one-day advanced echo course in a tutorial based structure allows participants to develop confidence and knowledge in echo skills that are beyond the FICE curriculum. It is hoped that this can then be incorporated in participants' clinical practice. We anticipate this course can be expanded nationally to allow more clinicians to include echo assessment in their clinical practice on ICU.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0482

INTRODUCTION. Complications arising from central venous catheter (CVC) placement are mostly due to pneumothorax or malposition . Correct position is currently confirmed by chest X-ray (CXR), while ultrasound (US) might be a more suitable option.
OBJECTIVES. We investigated whether CVC malposition and iatrogenic pneumothorax could be accurately detected by US compared to CXR.
METHODS. Design - Single-center prospective, observational study conducted at the VU University Medical Center in the Netherlands. The study population consisted of critically ill adult patients who underwent central venous cannulation of the internal jugular vein (IJV) or subclavian vein (SV). The US evaluation of pneumothorax and CVC malposition consisted of three parts; vascular US of the IJV and SV bilaterally, lung-US to detect pneumothorax and a cardiac US examination combined with contrast enhanced ultrasound. Primary outcome was the feasibility and accuracy of bedside ultrasound in detecting CVC misplacement. Regarding pneumothorax, the overall agreement percentage and Cohen's kappa coefficient between US and CXR were secondary outcomes.
RESULTS. Between April 2016 and June 2017, 450 CVCs in 427 patients were included, with a median age of 68.5 (±IQR: 13.0). 70.2% of the population was male. Malposition occurred in 2.3% of all central line placements and pneumothorax in 0.9% - 2.2%. Vascular ultrasound of the IJV and SV bilaterally and lung-US were feasible in 100% of the cases, whereas cardiac US examination was feasible in 88.9% of the cases. Sensitivity of US to detect CVC malposition was 0.727 (95% CI: 0.435 - 0.924) and specificity was 0.995 (95% CI: 0.984 - 0.999). In 442 out of 450 cases (98.2%) US and CXR showed agreement for pneumothorax with a Cohen's κ-coefficient of 0.421 (95% CI: 0.255 - 0.587).
CONCLUSIONS. To our knowledge this is the largest study so far investigating the feasibility and accuracy of US to detect CVC malposition and associated pneumothorax. In conclusion, US is a suitable diagnostic modality to detect CVC malposition and iatrogenic pneumothorax with an excellent specificity and moderate sensitivity. Furthermore, US has multiple advantages over CXR in the critical care setting; it is performed faster and does not subject patients to radiation.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0483

INTRODUCTION. The techniques of image-guided percutaneous abscess drainage (IGPAD) are relatively simple and minimally invasive option of treatment for AP (acute pancreatitis). IGPAD has a significant impact on patient care, and can affect hospital length of stay, the development of sepsis, organ failure and reducing the cost of treatment.
OBJECTIVES. To compare approach by percutaneuous drainage or open surgery in a sample of patients with acute pancreatitis admitted to Intensive are Units (ICU).
METHODS. Observational and prospective study. Period study: January 1, 2016 to December 31, 2016. Inclusion criteria: diagnosis of AP and admission in ICU. Variables: age, gender, APACHEII and SOFA in the first 24 h, organ failure, need for percutaneuous drainage or surgery, ICU length of stay (LOS), hospital LOS and hospital mortality. A p-value of 0.05 was considered Statistically significant.
RESULTS. 126 patients were admitted. 67,7% of the patient were male and mean of age was 59,9+15,6 years. The most common aetiologies were gallstones (48%) and alcohol (12,6%). SOFA in admision was 9,3+4,0. Mortality 34,9%. In the case that drainage percutaneous of the collections were made, the patients were: younger (51,7±14,4 vs 61,7±15,4; p=0,02) and female (80,5% vs 18,3; p=0,8). Severity scores in the first 24 hours were not significant (APACHE II 12,2 vs 14,1; p=0,3 and SOFA 9,3 vs 9,2; p=0,8). Patients who had IGPAD showed a statistically lower rate of hemodinac failure 25% vs 75% (p=0,03), renal failure 7,1% vs 92,9% (p=0,05), sepsis 31% vs 69% (p< 0,05), mechanical ventilation 22,5% vs 77,5% (p=0,08), abdominal compartment syndrome was significantly less frequent (41,7% vs 58,3%; p=0,01), unlike the rest of complications collected, and higher rate of lengh of stay in ICU (30,1±28,2 vs 12,8 ±23,2 (p< 0,05). No significant differences were found in terms of mortality depending on whether percutaneous drainage was performed or not (11,9% vs 88,1%; p=0,2)
CONCLUSIONS. In our population patients undergoing this treatment had better results in terms of organ failure (hemodynamic, renal), less lengh of mechanical ventilataion, less rate of abdominal compartment syndrome and intracavity lavage. IGPAD is a safe and effective procedure for the treatment of abdominal abscess and fluid collections in patients admitted to ICU.

INTRODUCTION. Pleural effusion is a common finding in patients admitted in ICU. It could be due to a pulmonary problem (primary) or accompanying other medico-surgical conditions (secondary).
OBJECTIVES. Assessing accurately the amount of pleural effusion may be helpful in weaning from mechanical ventilation by draining problematic pleural effusions.
METHODS. During one year period (September 1st 2016 to August 30 2017) patients admitted to a Referral-University hospital general ICU, were considered for inclusion. Enrolling criteria were mechanical ventilation ,chest X ray indicating possible pleural effusion , no primary pulmonary involvement , no progressive organ involvement and planned respiratory weaning.
Chest sonography was performed by a radiology senior(last year) resident and an ICU fellowship and the results compared with CT scan findings.
RESULTS. 67 patients were eligible. Pleural effusion rated as nil-minimal-moderate; severe without a strict milliliter definition.Accuracy of the results with the same day CT scan were 54% in radiologist as compared with 74% in intensivists assessment, differing significantly.
CONCLUSIONS. Chest sonography for evaluation of pleural effusion is more accurate when performed by intensive care fellow as compared with a senior radiology senior.

INTRODUCTION. Clinical studies of VAP (e.g. Acinetobacter strain) use to be carried out despite of mono- or polibacterial origin [1]. It is not suppose to be constructed methodologically correctly if the aim of clinical issues is addressed to just one strain of polibacterial VAP.
OBJECTIVES. To compare mortality prognostic factors of VAP due to multidrug-resistant A.baumannii (MDRAB) in case of mono- versus (vs) polibacterial origin.
METHODS. Ongoing retrospective cohort study of patients (pts) treated in ICUs with MDRAB strains as pathogens of VAP during 2014-2016.
RESULTS. Data of 164 pts were evaluated. Mono- vs polibacterial MDRAB VAP cases were found to be 77 (47 %) vs 87 (53%). In-hospital mortality of VAP due to MDRAB was 63,6% in mono- and 50,6% in polibacterial origin (p=0.115). Univariate analysis of survivors vs nonsurvivors in monobacterial MDRAB VAP: differences were found in medians of length of stay (LOS) after onset of VAP 26 days (d) (interquartile range (IQR) 19-61.5) vs 7 d (IQR 3-17), p< 0.001, SOFA score at the onset of VAP 5 (IQR 4-7) vs 8 (IQR 6-11), p=0.015, length of definitive antibacterial treatment 14 d (IQR 10-18) vs 7 d (IQR 4-13), p< 0.001, in means of oxygenation index 171.67 (SD 47.33) vs 145.56 (SD 60.65), p=0.042, SAPS II 41.27 (SD 12.24) vs 50.84 (SD 16.66), p=0.021 at ICU admission, and between proportions of previous hospitalization (≥2 d) in the preceding 90 d 11/46 (23.9%) vs 35/46 (76.1%), p=0.008, shock 17/58 (29.3%) vs 41/58 (70.7%), p=0.031, multiple organ dysfunction syndrome (MODS) 18/61 (29.5%) vs 43/61 (70.5%), p=0.019. Polibacterial MDRAB VAP: differences were found in medians of LOS after VAP diagnosis 29 d (IQR 14-39) vs 10.5 d (IQR 3.25-25.5), p< 0.001, SOFA score 5 (IQR 2-8) vs 8 (IQR 4-10), p=0.005 at the onset of VAP, length of definitive antibacterial treatment 14 d (IQR 9-17) vs 11.5 d (IQR 5-16), p=0.009, and between proportions of sepsis 36/79 (45.6%) vs 43/79 (54.4%), p=0.03, shock 20/57 (35.1%) vs 35/47 (74.5%), p< 0.001, MODS 20/57 (35.1%) vs 37/57 (64.9%), p=0.019, renal replacement therapy 6/23 (26.1%) vs 17/23 (73.9%), p=0.014.
In multivariate analysis odds ratio (OR) for in-hospital mortality: 9.43 for previous hospitalization (≥2 d) in the preceding 90 d (95% CI 1,68-57.94) for MDRAB VAP of monobacterial origin, but 7.45 for shock (95% CI 2.5-22.14) for polibacterial one.
CONCLUSIONS. Differences found in this study for prognostic factors of mortality due to monobacterial vs polibacterial MDR A.baumannii VAP discourage to use polibacterial VAP studies of MDR A.baumannii strains in case of correlation of this only pathogen with clinical issues as methodologically correct ones. Further studies are required to confirm our results.

Using of dexmedetomidine in term neonates with hypoxic-ischemic encephalopathy

D. Surkov
Regional Children's Hospital, NICU, Dnipro, Ukraine
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0486

INTRODUCTION. Hypoxic - ischemic encephalopathy (HIE) remains the one of most frequent causes of cerebral palsy and other severe neurological disorders in infants. There is compelling clinical evidence that therapeutic hypothermia in term babies with moderate to severe HIE improves neurodevelopmental outcome. Despite this, the challenge for the future is to find ways of improving the effectiveness of treatment [1, 4, 5].

OBJECTIVES. To evaluate possible neuroprotective effect of dexmedetomidine (DEX) in term neonates with moderate to severe HIE.

METHODS. Prospective single-center randomized clinical study in 52 term neonates with HIE Sarnat stage II-III was performed in NICU Level III in 2014-2016. All intensive care included therapeutic hypothermia, respiratory and hemodynamics support, antibiotics, TPN etc. as usual. Babies in control group received morphine sedation 10-20 mcg/kg/hour vs. dexmedetomidine 0.1-0.5 mcg/kg/hour in study group [3, 4]. End-points included Glasgow Coma Scale (GCS), aEEG, transfontanel Doppler, NIRS and serum neuronal biomarkers (neuron-specific enolase, protein S-100).

RESULTS. 52 term neonates were randomized in DEX (n=34, 65.4%) and standard care group (n=18, 34.6%). The average gestational age was 39.6 (37-42) weeks vs. 38.9 (37-41) weeks, the birth weight was 3533.8±859.2 vs. 3390.0± 510.4 grams respectively. There was no difference in initial Apgar score (4.3 [1-7] vs. 4.2 [1-7]). No significant differences between two groups in Doppler cerebral blood flow indexes, serum lactate level, NSE and S-100 protein as well as aEEG pattern were found. A significant difference between two groups was found in dobutamine dose (Estimating Variance, EV -1.87, 95% CI -3.25 to -0.48, p=0.009), mean blood pressure (EV 2.9, 95% CI -0.27 to 6.08, p=0.072). Also there was difference in GCS (EV 1.36, 95% CI -0.36 to 3.09) but not significant (p=0.118).

CONCLUSIONS. Dexmedetomidine is a safe sedative agent with stable hemodynamics profile, no adverse cerebral influence and possible neuroprotective effect in HIE, additional to standard therapeutic hypothermia.

The use of automated pupillometry to assess cerebral autoregulation

A.A. Quispe-Cornejo, I.A. Crippa, L. Peluso, L. Calabrò, J.-L. Vincent, J. Creteur, F.S. Taccone
Université Libre de Bruxelles, Department of Intensive Care, Erasme Hospital, Brussels, Belgium
Correspondence: A.A. Quispe-Cornejo
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0487

INTRODUCTION. Automated pupillometry (AP) can be used to quantify pupil light reflex (PLR) in critically ill patients. However, the complexity of sympathetic and parasympathetic pathways involved in the PLR may expand the use of AP to quantify other phenomena related to nervous system, such as the regulation of vascular tone and regional blood flow.

OBJECTIVES. To assess the association between AP and autoregulation of cerebral blood flow (CAR) in non-neurological critically ill patients.

METHODS. Observational ongoing study including critically ill patients admitted to the Intensive Care Unit. Exclusion criteria were: ocular diseases; intracranial disease; arrhythmias; extracorporeal membrane oxygenation; supra-aortic arteriopathy. Quantitative pupillometry was performed using the NPi®-200 pupillometer (Neuroptics®), which calculates the Neurological Pupil Index (NPI), pupillary contraction, latency, constriction velocity and dilation velocity. The mean value of these variables measured on each eye was calculated. Transcranial Doppler (DWL, Germany) was performed insonating the left middle cerebral artery (LMCA) with a 2MHz probe. LMCA blood flow velocity (FV) and arterial blood pressure (BP) signals were simultaneously recorded; Pearson´s correlation coefficient between BP and FV (Mxa) was calculated using MATLAB (MathWorks, USA). Impaired CAR was defined as Mxa>0.3.

RESULTS. We studied 35 patients (median age 61 [52-69] years and median APACHE II score on admission 16 [9-25]), including 20 (57%) with sepsis. Median NPI was 4.5 (4.1-4.8) and median Mxa 0.28 (0.13-0.50); 14 (40%) patients had altered CAR. We observed a significant correlation between Mxa and NPI (r=-0.51; p=0.001) but not with other variables measured by the AP. NPI was significantly lower in patients with altered CAR than others (4.0 (3.6-4.6) vs. 4.6 (4.4-4.8); p=0.03). NPI values had an AUC of 0.72 [0.53-0.90] to predict altered CAR. A NPI < 4.0 had a sensitivity of 44% and a specificity of 95% to predict altered CAR.

CONCLUSIONS. The Neurological Pupil Index measured with automated pupillometry allows to assess cerebral autoregulation in critically ill patients.

N-terminal pro-brain natriuretic peptide as a bio-marker of the acute brain injury

L. Tsentsiper, A. Kondratyev, N. Dryagina
Russian Polenov Neurosurgery Institute, Aneasthesiology and Intensive Care, St Petersburg, Russian Federation
Correspondence: L. Tsentsiper
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0488

INTRODUCTION. Recently along with neuro-visual and neurophysiological methods of study of brain injuries a lot of attention is drawn to the laboratory diagnostics methods. The detection of biomarkers levels facilitates an early diagnosis of brain tissues damage, allows to assess the prognosis of the disease and its outcome.

OBJECTIVES. Evaluate the significance of changes in the level of N-terminal Pro-Brain natriuretic peptide in patients with acute brain injury

METHODS. We studied 64 patients between 2008 and 2013, 36 male and 28 female patients. 1st group comprised 12 patients with severe brain trauma: 1a - survivors with good outcome (on Glasgow scale groups I-II) (n=8), 1b - dead or severely disabled (on Glasgow scale groups III-V) (n=4). 2nd group comprises 37 patients with intracranial and sub-arachnoid hemorrhages: Assignment to groups 2a (n=14), 2b (n=22) was done using the same criteria as group 1. 3rd group comprises 16 patients operated in conjunction with brain tumor. Assignment to groups 3a (n=6) and 3b (n=10) was done using the same criteria as groups 1 and 2. We tested the level of N-terminal Pro-Brain natriuretic peptide in blood we use immunochemiluminescent analyzer Immulite (normal range - 0-125 pg/ml). Testing was conducted between 1st and 3rd days after severe head injury, brain blood flow disruption of hemorrhagic type or brain tumor related surgery, and then every 2-12 days for the total duration of 21 days. For assessing the significance of differences we utilized Student's t-test.

RESULTS. Statistical analysis failed to demonstrate noticeable difference in the level of NTproBNP between groups 1,2,3. We detected the differences between subgroups (p< 0.01). Patients from groups 1a,2a,3a (n=28) NTproBNP level stayed below 700 pg/ml in 20 cases (71%), in the 8 cases (29%) the level was above 700 pg/ml, but by 14-21th day decreased to the normal values. For patients in subgroups 1b,2b,3b (n=36) in 28 cases (78%) NTproBNP level was above 700 pg/ml at least once, in 8 cases (12%) level stayed below 700 pg/ml but remain high for the entire duration of the study without significant decrease.

CONCLUSIONS.

1. All the patients with acute brain injury showed the increased level of NTproBNP above normal values, irrespective of ethiology of injury
2. In case when NTproBNP level increases above 700 pg/ml and/or does not decrease to the normal values it is possible to predict a negative outcome of the treatment.

Correspondence: S. Zeidan
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0489

INTRODUCTION. Patients with convulsive status epilepticus (CSE) often require mechanical ventilation (MV), either for general anesthesia (GA) in case of refractory CSE, or for airway protection. Guidelines for the management of refractory generalized CSE recommend to maintain GA during 24-48h, followed by a gradual withdrawal. Our objective was to evaluate the incidence of refractory generalized CSE among patients who required MV during pre-hospital management of SE, and to describe the management of GA in the ICU.

PATIENTS AND METHODS. This multicenter retrospective observational study was conducted in 4 French ICUs. All mechanically ventilated patients diagnosed with status epilepticus (SE) admitted in the ICU between 01/01/2014 and 12/31/2016 were included. Exclusion criteria were: age < 18 years, post anoxic SE, acute traumatic brain injury, initiation of MV in the ICU, transfer from another ICU, inclusion in a therapeutic trial on SE, non-convulsive SE. Collected data included type, duration and pre hospital treatment of SE, reason for MV, dosage and duration of GA drugs, EEG monitoring, relapse of SE, MV duration, in-ICU length of stay, complications (i.e. sepsis, acquired ventilation pneumonia, etc.) and mortality.

RESULT. Among the 251 medical files reviewed, 101 met the inclusion criteria and were analyzed. Most patients (n=74, 73,3%) had a non-refractory generalized CSE; only 14 (13,9%) had a refractory generalized CSE. The main reason for intubation was coma (n=59, 58,4%). Among patients intubated for persisting convulsions (n=28), two thirds (n=17) had received first and second line antiepileptic drugs at correct dose and 14 had actual refractory SE (2 had psychogenic seizures, 1 refractory partial CSE); the others (n=11) were intubated either directly after the first line, or before the end of the second line infusion. The median duration of GA before weaning was 12h (IQR [5-18]) and was similar in refractory CSE patients (p=0,79). Only 7 patients (6,9%) had a relapse of SE in ICU; they had similar refractory SE occurrence (n=2(12,8%), p=0,91) and GA duration (p=0,39), and none had history of epilepsy. GA duration >12h before weaning was associated with a higher rate of in-ICU complications (n=37 (74%) vs. n=27 (54%), p= 0,04), without decreasing the rate of SE relapse (n=4 vs n=3, p=0,72).

CONCLUSIONS. These data show that most patients admitted in ICU while receiving MV for CSE do not have a refractory status, but mainly coma without persisting convulsions. The mean duration of GA before weaning was < 24h, and thus in discrepancy with guidelines, but did not seem associated with a frequent relapse of SE. Patients with a duration of GA ≤12h had less complications in ICU, without increasing the rate of SE relapse. If this low rate of refractory SE and the safety of rapid GA withdrawal are confirmed, the recommended 24-48h duration of GA in ICU may be challenged.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0490

INTRODUCTION. Accurate diagnosis of consciousness level (CL) is a prerequisite to elaborate a prognosis and appropriate medical plan for patients suffering from a disorder of consciousness (DoC) after an acute brain injury (ABI). The clinical distinction between unresponsive wakefulness syndrome (UWS) and minimally conscious state (MCS) is a key step with a huge impact on decision making. However, this assessment is often challenging and may require specialized expertise. We hypothesized that pooling subjective reports of CL of a given patient across independent nursing staff members can help improving clinical diagnosis of MCS.

OBJECTIVES. To evaluate the diagnostic accuracy of a new clinical scale (DoC-Feeling) that capitalizes on the nursing staff subjective perception of patient's CL.

METHODS. All brain injured patients referred to our neurointensive care unit for consciousness assessment were prospectively screened between February 2016 and October 2017. Consents were obtained from patients' relative. UWS and MCS were defined according to the reference standard Coma Recovery Scale - Revised (CRS-R[1]). Nurses and nursing assistants were asked to rate their subjective perception of the best CL observed during their shift on a 100 mm visual analog scale. The index test DoC-feeling consisted in the median value of these multiple ratings obtained from the staff members in charge of the patient during the hospitalisation. Caregivers were blinded from other ratings as well as from expert evaluation. We evaluated the association between individual ratings and CS using a linear mixed model and the diagnostic accuracy of DoC-feeling using area under the receiver operating characteristic curve (AUC), sensitivity and specificity metrics.

RESULTS. 692 ratings performed by 83 nursing staff members were collected from 47 patients. 20 were in a UWS and 27 in a MCS. Main ABI etiologies were anoxic (53%) and traumatic brain injury (17%), with a median delay of 134 [IQR: 40-762] days. 20 patients (43%) were mechanically ventilated. Individual ratings were reliably associated with CL (t-value=6.47, df=45, p=10^{-7}). DoC-feeling scores were significantly greater in MCS than in UWS patients (59 mm [27-77] vs. 7 mm [2-11]; p=10^{-7}). Diagnostic accuracy of DoC-feeling evaluation revealed an AUC of 0.92 (95%CI: 0.84-0.99), yielding a sensitivity of 89% (71-98) and a specificity of 85% (62-97) for MCS diagnosis, using a 16.7mm cut-off value.

CONCLUSIONS. We propose a new clinical tool called DoC-feeling that capitalizes on the expertise of nursing staff to evaluate patients' consciousness. Together with the CRS-R as well as with brain imaging, DoC-feeling might improve diagnostic and prognostic accuracy of DoC patients.

PURPOSE. To document patterns of muscle changes in upper and lower limbs using ultrasound imaging and to determine if there is a difference between upper and lower limb musculature over the first 7 days of ICU admission in individuals with an acute traumatic brain injury.

METHODS. Adults with traumatic brain injury mechanically ventilated >48 hours were prospectively assessed. Patients underwent muscle ultrasound (US) of biceps Brachii (BB), tibialis anterior (TA) and rectus femoris (RF) to obtain measurements of muscle thickness and echointensity during the first 7 days of hospitalization. The change in muscle thickness (ΔTh) and echogenicity (ΔEcho) for all the three muscles (TA, RF and BB) between day 1 and day 7 was analyzed.

RESULTS. 25 patients were enrolled (age 35 ± 14 years; APACHE II median [IQR] 17 [14-22]). The following statistically significant changes were noted over time from baseline to day 7: the mean thickness reduced for all muscles: RF 22,35%; TA 19,70%; and BI 15,01%. The echointensity analysis increased for all muscles: RF 28.90%; TA 20.75% and BI 12.90% (suggesting deterioration in muscle quality). The changes to muscle thickness and echointensity were less affected in the upper limbs ($p < 0.001$).

CONCLUSION. Preferential reduction in muscle thickness and deterioration in muscle quality (echogenicity) was observed in the lower limb muscle groups over the first xxx days of ICU admission.

Correspondence: J. Anstey

INTRODUCTION. Hypertonic saline and mannitol are both widely used as osmotherapy in traumatic brain injury (TBI) patients in the management of intracranial hypertension. However, clinical outcome data comparing the two treatments are still lacking.

OBJECTIVES. We compared the association of mannitol and hypertonic saline with mortality in an international cohort of severe TBI patients.

METHODS. We performed a retrospective study involving 14 tertiary Intensive Care Units (ICUs) in Australia and Europe, that contributed data from the first 20 severe TBI patients in 2015 (GCS < = 8 post resuscitation) with an intracranial pressure (ICP) monitor in-situ for at least 72 hours. Baseline demographic details, illness severity (APACHE-II, Injury Severity Scores, and IMPACT-TBI Scores), ICP management strategies for up to 7 days of ICP monitoring, and outcome data were collected for each patient.

Those patients who received osmotherapy with mannitol only or hypertonic saline only during the first 96 hours of their ICU stay were compared with regards to mortality.

Hazard ratios (95% CI) comparing time to death between the two groups were derived using raw and multivariable Cox proportional hazards regression adjusting for treatment centre, Injury Severity Score (ISS), extended IMPACT-TBI score, and mean ICP over the first 96 hours.

RESULTS. Data on 262 patients was collected, with primary analysis performed on the 251 who survived the first 96 hours. Overall, 46 patients received mannitol only, and 46 patients received hypertonic saline only during this period.

HTS versus mannitol patients had a mean age of 40.5 (SD 16.8) versus 49.2 (19.2) years respectively (p=0.02), and 71.7% were male versus 76.1% (p=0.64). Injury Severity Score, APACHE-II and extended IMPACT-TBI for the HTS and mannitol groups respectively were 32.1 (11.3) versus 42 (15.9) (p=0.001), 20 [15-23] versus 22 [17-32] (p=0.1), and 25% [13-38] versus 34.5% [23-46] (p=0.023). There was no significant difference between groups with regards to ICPs and noradrenaline requirements in the first 96 hours.

Treatment with decompressive craniotomy (23.9% versus 21.7%, p=0.8), CSF drainage (45.7% versus 43.5%, p=0.83), barbiturate coma (13% versus 19.6%, p=0.4) and hypothermia (no patients) was similar between groups.

ICU and hospital mortality were significantly lower in the HTS than in the mannitol group (ICU mortality 15.2% versus 47.8%, p=0.001; hospital mortality 21.7% versus 52.2% p = 0.002). The raw hazard ratio for death with mannitol compared to HTS was 3.39 (95% CI 1.4-8.2, p=0.007).

After adjustment for centre, Injury Severity Score, extended IMPACT-TBI score, and mean ICP, the hazard ratio for death with mannitol rather than HTS use was 2.64 (95% CI 0.96-7.30, p=0.061).

CONCLUSIONS. These data raise concerns about mannitol when used as osmotherapy in TBI patients. Further studies are needed to understand whether choice of osmotherapy agents affects clinical outcomes.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0493

INTRODUCTION. Patients with neurological disorders require continuous and multiprofessional surveillance, and are sometimes admitted to the ICU (Intensive Care Unit), who spend a lot of time under in mechanical ventilation, which can lead to Ventilator-Induced Diaphragmatic Dysfunction (VIDD). To avoid such a change, assessments and treatments on the risk of developing muscle weakness are employed. There are no studies that show the efficacy of inspiratory muscle training (IMT) in non-collaborative neurocritical patients.

OBJECTIVES. Demonstrate that IMT is able to increase respiratory muscle strength in non-collaborative patients using mechanical ventilation in the ICU compared to patients who did not perform the training.

METHODS. This was a randomized clinical trial. The sample consisted of 27 non-collaborative patients of both sexes, older than 18 years old, using mechanical ventilation, who were divided into two groups: In trainig Group (TG) and Control Group (CG), who performed the MIP (Maximum Inspiratory Pressure) and the IMT (inspiratory muscular training for a period of 14 days. To analyze the data, the Shapiro Wilk test and the K-S distance test were used to see the distribution of the studied population. For the comparison of the pre and post ΔIPmax measurements (variation of the pre and post inspiratory pressure), the unpaired Student´s t-test was used, being considered significant values of p < 0.05.

RESULTS. There was a higher MIP variation in TG (59.2 ± 18.2 cm H2O) than in CG (44 ± 17 cm H2O).

CONCLUSIONS. IMT was able to increase MIP of non-collaborative neurocritical patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0494

INTRODUCTION. Status epilepticus (SE) is a emergency that requires prompt diagnosis and treatment. The identification of factors associated with a poor prognosis could be useful to guide and improve treatment.

OBJECTIVES. The aim of this study was to identify the risk factors for unfavourable prognosis and to obtain a prognostic prediction model for critically ill patients with SE.

METHODS. Retrospective study performed on patients admitted to ICU with SE between 2015 and 2016. We collected epidemiological and relevant clinical data related to SE. The prognosis was measured by the Rankin scale (severe disability or death).

Descriptive data were described as means (SD) for normally distributed continuous variables, medians (IQR) for non-normally distributed variables, and percentages for categorical data. The continuous variables were compared using a simple logistic regression analysis (OR), and the categorical data by the Chi-square test (RR). The factors associated with a poor prognosis were identified, and using a multiple logistic regression analysis a predictive model was obtained.

RESULTS. Fifty-eight patients were included, 53% were male, mean age was 60 yrs (40-70). Charlson Index 1 pts (1-3). The epileptic seizures occurred at the hospital in 43% of patients, and were more frequently generalized (83%). Persistence of seizures on first evaluation by the ICU team was found in 31% of cases (refractory SE 10%), 35% presented a structural lesion in CT and 38% alterations in the EEG. The antiepileptic drugs most frequently used were benzodiazepines (78%), Levetiracetam (36%) and 43% of patients required deep sedation (26% Propofol and 22% Midazolan associated with Propofol). Severity scores: APACHE II 17±10 pts, SOFA 5±3 pts, GCS 6±3 pts, and 76% of patients required mechanical ventilation (2 days, 1-9). ICU stay was 3 days (2-7) and hospital stay was 11 days (6-18). The prognosis was unfavourable for 29% of patients, with 14% mortality. In the univariate analysis, the variables related to a poor prognosis were: age (OR 1,05; 95% CI 1,01-1,09), **Charlson Index** (OR 1,45; 95% CI 1,04-1,20), **GCS** (OR 0,82; 95% CI 0,67-0,99), **APACHE II** (OR 1,12; 95% CI 1,03-1,23), **SOFA** (OR 1,27; 95% CI 1,03-1,57), **in-hospital seizures** (RR 3,54; 95% CI 1,08-11,57), **seizures on first ICU evaluation** (RR 4,01; 95% CI 1,19-13,36), **structural lesion** (RR 3,01; 95% CI 1,01-9,95) and **refractory SE** (RR 12,31; 95% CI 1,26-120,19). Using **multiple logistic regression,** we created a model including the following variables: **APACHE II** (OR 1,22; 95% CI 1,06-1,39), **structural lesion** (OR 11,79; 95% CI 1,86-74,84) and **refractory SE** (OR 44,61; 95% CI 2,26-881,51). The model obtained had a good prognosis

discriminatory ability: AUROC 0.85, CI 0.73-0.96; Hosmer-Lemeshow test X^2 3.94, p=0.86.

CONCLUSIONS. The risk factors for unfavourable prognosis were APACHE II, structural lesion and refractory SE. The predictive model obtained was able to discriminate the prognosis of patients with SE.

Effects of acute subdural hematoma on cerebral mitochondrial respiration in a porcine resuscitated model

T. Merz[1], S. Unmuth[1], M. Wepler[1,2], T. Datzmann[1], T. Kapapa[3], S. Röhrer[3], P. Radermacher[1], E. Calzia[1], O. McCook[1]

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0495

Introduction

Acute subdural hematoma (ASDH) assumes major importance in traumatic brain injury (TBI), in particular in the elderly and/or vascular co-morbid patient (1). Mitochondria assume importance during secondary TBI: they play a crucial role for neuronal survival (2), but may also be a source of detrimental reactive oxygen species (ROS, 3). Mitochondrial ROS formation is directly related to the degree of coupling of the respiratory chain (4), whereas limited uncoupling through expression of uncoupling protein 2 (UCP2) reduces tissue oxidative stress (5), however at the cost of ATP production (6).

Objectives

The aim of this experiment was to investigate cerebral mitochondrial respiration and uncoupling in a resuscitated porcine model of ASDH.

Methods

Anesthetized, mechanically ventilated and surgically instrumented pigs underwent ASDH (trepanation above the left parietal cortex and subdural injection of 20 ml of blood). Resuscitation, according to the guidelines of TBI management (7), comprised fluid and catecholamine administration to maintain mean arterial pressure at pre-ASDH levels and cerebral perfusion pressure >75 mmHg. 54 hours after ASDH, mitochondrial respiration on fresh homogenized ipsi- and contralateral frontal cortex was determined via high-resolution respirometry (Oroboros Oxygraph 2K; N=6): maximum capacity in the coupled (OxPhos) and uncoupled state (ETS) and leak compensation flux were determined. UCP2 was analyzed *in situ* in fixed brain sections.

Results

Two out of six animals died early (6 and 18h after TBI induction) due to cardiovascular failure unrelated to induction of ASDH. In these animals, maximum mitochondrial respiration in the coupled and uncoupled state were reduced (p=0.008 and p=0.004) and consequently OxPhos/ETS (p=0.004) and LEAK/ETS ratios were increased (p=0.002) in comparison to hemodynamically stable animals. The increased LEAK/ETS was associated with higher UCP2 expression in the hemodynamically unstable group, most pronounced in the ipsilateral hemisphere.

Conclusions

This study revealed dysregulated cerebral mitochondrial respiration in hemodynamically unstable animals after TBI in a long-term, resuscitated porcine model of ASDH-induced TBI. Increased UCP2 expression might be an adaptive response to reduce ROS formation as a consequence of stronger coupling of the mitochondrial respiratory chain (higher OxPhos/ETS ratio). Cerebral mitochondrial dysregulation seemed to be a crucial factor in TBI-related mortality.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0496

INTRODUCTION. The disorders of consciousness frequently follow after severe head injury. The non-communicating patients are categorized into three groups: comatose, vegetative state (VS) and minimally conscious state (MCS). Patients in VS have a loss of awareness and patients in MCS either have fluctuating awareness with non-reflex behavior (MCS minus) or response to command (MCS plus). The clinical fluctuations of awareness constitute an important part of MCS definition.

OBJECTIVES. The aim of this study is to quantified periods with high or poor treatment of information and to study the response evoked to better classify states of consciousness.

METHODS. We investigated whether the EEG counterpart of these rapid clinical fluctuations (fluctuations in alpha power band, complexity and information exchange (1,2)) modulated conscious access to external stimuli during an auditory task probing conscious access to global regularities (the 'local global paradigm' (3)). We identified time-windows characterized by high or low levels of postulated markers and studied the evoked responses of an auditory paradigm (Local-global) during the same corresponding periods. The local-global paradigm is designed to elicit early potentials post-stimulus, related to un-conscious processing, and late potentials, related to conscious processing. We used a method of generalization analysis, named decoding, consisting in training a classifier to quantify the level of early and late responses.

RESULTS. 96 patients underwent high density EEG recording with a 256-electrode geodesic sensor net (EGI, Oregon, USA) in intensive care unit.

The level of automatic and conscious responses, were higher in the rich periods than in poor periods (p-value=0.02 and 0.03 respectively, Wilcoxon paired test).There was no significant difference, in either low or high states, between VS patients and MCS- patients. In contrast, we found in MCS+ patients a specific increase, compared to the other clinical groups, of the decoding performance for the late responses (global effect).

CONCLUSIONS. These results support the idea that conscious process is not continuous and highlights the differences of global states of consciousness between different clinical diagnoses.

INTRODUCTION. Patients undergoing brain tumour surgery require proper level of analgesia and cardiovascular stability during operation and immediately thereafter. Contemporary anaesthetic techniques use for that purpose continuous *iv*infusion of opioid analgesic (1).

OBJECTIVES. Goal of this randomized clinical study was to compare the effects of two opioid analgesics, remifentanil and fentanyl, administered as continuous iv infusion during neurosurgery.

METHODS. A total of 32 patients, ASA II-III, with frontal region brain tumour were included in this single blind, controlled clinical study.- They were randomised in two similar groups.

Remifentanil (RF) group received RF 1-2 μg/kg of body weight *iv*bolus and continuously *iv*at the average infusion rate of 0.44 μg/kg/min, while the fentanyl (F) group received 100 μg *iv* bolus, followed by a continuous *iv* infusion at an average rate of 0.012 μg/kg/min. The infusion rates were adjusted according to the sympathetic response to operational stimuli. Postoperative infusion rates were 0.05μg/kg/min in RF group and 1-2 μg/kg/h in F group. At critical points of anaesthesia and operation (0 - baseline values;

1 - Intubation;

2 - brain manipulation,

3 - end of operation;

4 - 1 h postoperatively;

5 - 12 h postoperatively;

6 - 24 h postoperatively) haemodynamic parameters were recorded. Analgesic consumption and adverse effects of opioids were recorded during one day after the end of surgery.

Length of the operation in RF and F group were 227.5 (165-340) and 212 (175-298) min, respectively.

RESULTS. In almost all the critical points of operation and immediate postoperative course cardiovascular stability was similar. RF group showed tendency to lower, yet statistically not significant values. The only significant difference in heart rate was found during induction to anesthesia, when average values were lower in F than in RF group (72 vs 100/min). In RF group in 2 patients there was need for increase in the analgesic dose and in F group in only one patient. Adverse effects were found in 7 RF patients (43.75%) and in 2 F patients (12.5 %) Shivering was most frequent adverse effect found in the RF group, and it was registered in 4 patients.

CONCLUSIONS. There are no significant differences between the groups in cardiovascular stability. Postoperative pain control was similar in both groups. Adverse effects were more frequent in RF than in the F group (7 vs 2). Postoperative shivering was present in 4 RF patients, which is in accordance with literature data (2). Shivering can be explained by the development of acute opioid tolerance after long infusions of a very potent opioid, remifentanil.

INTRODUCTION. Guidelines "assist practitioner and patient decisions about appropriate health care for specific clinical circumstances."[1] Status Epilepticus (SE) requires appropriate emergent therapy to reduce mortality and morbidity. However, patients continue to receive inadequate initial doses of antiepileptic's (AED) which is exacerbated by a hesitancy to escalate care aggressively.[2] Thus institutional guidelines and order sets within the Electronic Health Record (EHR) are necessary and highly encouraged to help manage these complexities.[3]

OBJECTIVES. To assess quality measures in SE before and after the implementation of institutional guidelines and an order set in the EHR.

METHODS. We conducted a retrospective analysis of adults with SE discharged from 2012 - 2017 at a 1,382 bed academic medical center. The following quality measures were evaluated: continuous electroencephalogram (cEEG) use, mechanical ventilation (MV), benzodiazepine (BZD) administration, number of AED administered, length of stay (LOS), and mortality/hospice.

RESULTS. 353 patients were included. After guideline and order set implementation in October 2015 (n=86) more patients received cEEG (79.1% vs 36%; $p < 0.05$), MV (65.1% vs 21.3%; $p < 0.05$), and a second (37.2% vs 19.9%; $p < 0.05$) or third AED (47.7% vs 13.1%; $p < 0.05$) compared to the pre-implementation group (n=267). There was no difference in the amount of patients that received a BZD (88.4% vs 86.5%; $p = 0.657$). After implementation patients LOS was 8 (IQR 4, 15.5) vs 4 days (IQR 2, 6) ($p < 0.05$), and higher rates of death/hospice were observed (11.6% vs 3.4%; $p = 0.003$).

CONCLUSIONS. Our preliminary results reveal that after implementation, SE patients were more likely to receive cEEG monitoring, more AEDs, LOS doubled, and had a three-fold increase in mortality. These findings may have overlapping explanations: 1) the post-implementation group may have had higher rates of refractory SE and therefore more likely to receive additional treatment and monitoring, 2) the institutional guidelines increased awareness to the emergent nature of the disease which was followed by more aggressive pharmacologic interventions and cEEG monitoring. The rise in mortality observed aligns with previous literature reporting a mortality increase of nearly three times for refractory SE.[4]

INTRODUCTION. Although high piperacillin concentrations have been associated with clinical neurological deterioration in septic patients, no data have been reported on whether trough or peak drug concentrations are both associated with neurotoxicity.

OBJECTIVES. The aim of this study was to assess the association between piperacillin concentrations and EEG abnormalities in ICU patients with sepsis.

METHODS. We reviewed all ICU patients over a 5-year period (2012-2017) who were treated with piperacillin-tazobactam and in whom at least two β-lactam concentrations (trough, C_{min}; concentration 2 hours after the bolus injection, C_{2H}) and a concomitant EEG monitoring were available. Drug levels were measured using high-performance liquid chromatography. An "altered" EEG was defined when at least one between ictal EEG pattern, generalized periodic discharges (GPDs) or burst suppression was identified.

RESULTS. We collected 442 piperacillin concentrations (221 at C_{min} and 221 at C_{2H}) over the study period. Altered EEG was found in 62 (28%) of cases, with ictal EEG pattern in 38 of them. Piperacillin trough concentrations were higher in patients with an altered EEG than others (61 [33-98] vs. 33 [11-63] mg/L; $p < 0.001$). Also, C_{2H} were higher in patients with an altered EEG than others (96 [59-141] vs. 139 [98-174] mg/L; $p < 0.001$). The occurrence of altered EEG significantly increased over different ranges of C_{min} (from 3% for $C_{min} < 10$ mg/L to 50% for $C_{min} > 80$; $p=0.001$); similarly, the occurrence of altered EEG significantly increased over different ranges of C_{2H} (from 0% for $C_{min} < 60$ mg/L to 48% for $C_{min} > 160$; $p=0.001$).

CONCLUSIONS. There was a significant association between both minimal and maximal piperacillin concentrations and an increased occurrence of EEG abnormalities in ICU patients with sepsis. Monitoring of piperacillin levels should be considered when neurological and/or EEG alterations occur in patients with sepsis

Retention of knowledge on external ventricular drain care among nurses

R.C. Souza[1], E. Pires[2], L. Meira[3], G. Araujo[2], M. Bersaneti[2]
[1]Hospital Sírio Libanês, Nucleo de Pós Graduação, São Paulo, Brazil; [2]Hospital Sírio Libanês, Unidade de Terapia Intensiva, São Paulo, Brazil; [3]Hospital Sírio Libanês, Desenvolvimento de Enfermagem, São Paulo, Brazil

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0500

INTRODUCTION. Hydrocephalus is one of the most frequent complications in patients in neurosurgery units. In acute cases, hydrocephalus is treated by placing an external ventricular drain (EVD); however, an EVD increases the risk of infections and adverse events, resulting in increased morbidity and mortality[1,2].

OBJECTIVE AND METHODS. This quasi-experimental study was based on the training of nurses from an Intensive Care Unit (ICU) on EVD care guidelines. The study was conducted between November 2015 and March 2016 with the objective of evaluating the nurses' knowledge at three different times: before, one week after and three months after training.

The intervention was based on an expository class on the subject and a video that contained information on the techniques of dressing and handling of the system. It was performed during the participants´ work shift.

RESULTS. The sample comprised 38 nurses with a mean age of 33.7 ±4.8 years. Nurses from 20-29 and 30-39 years of age represented 21.1% and 65.8% of the sample, respectively. The nurses were predominantly female (33 women; 86.8%).

For the sampled nurses, an average of 9.5±5.0 years had passed since graduation. Time since graduation was more than 10 years for 50% of the sample. A total of 13 participants (34.2%) reported having prior experience in a neurological ICU. Overall, 94.7% of the nurses in the sample had a specialization; 73% of these nurses had ICU specialization, and 29.7% had two specializations.

The nurses with ICU specialization showed better retention for issues related to handling of the EVD system, with higher retention among 30- to 39-year-old nurses than among 20- to 29-year-old nurses. Although knowledge retention regarding treatment specificities did not differ significantly among the study phases, median retention was higher for this topic than for other topics.

CONCLUSIONS. In conclusion, in this study, although there was no significant knowledge retention among nurses three months after the intervention, the most experienced nurses with Intensive Care Unit (ICU) expertise performed better than the other nurses in the sample.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0501

INTRODUCTION. Neuromonitoring in patients with TBI is a fundamental pillar for the correct management of this pathology. There are different devices in neuromonitoring, however, not all are available in most intensive care units. The evaluation of the diameter of the optic nerve by CT is a useful tool and available in all units.

OBJETIVES. The main objetive is to correlate the diameter of the optic nerve measured in cranial CT with the values of Intracranial pressure (ICP) recorded by a pressure sensor, and its relationship with mortality.

METHODS. Our study includes patients admitted to the ICU due to Traumatic Brain Injury (TBI), who need neuromonitoring using an intracranial pressure sensor. Epidemiological data are collected, Glasgow Coma Scale, mortality, diameter of the optic nerve in cranial CT and previously registered intracranial pressure.

RESULTS. Our sample includes 20 patients, with average age: 45.65 years. 50% males. APACHE II average on admission: 19.68. 70%

needed urgent surgery upon admission. 65% had GCS < 8 at first assistance. 75% had GCS >12 at discharge. Mortality 25%.

We observed a statistically significant relationship between the diameter of the optic nerve and the recorded ICP, using Chi2 test (p 0.005), with good correlation using the Spearman test (p 0.003). Those patients with ICP < 15mmHg and optic nerve diameter < 4.8mm had better evolution (GCS >12 at discharge), and higher survival. If we perform a COR curve relating ICP and mortality, we obtain AUC 0.827 (95% CI 0.636 - 1) p 0.032. We plotted a cut-off at 15.5mmHg (Sensitivity 80% and Specificity 66%)

CONCLUSIONS. The management of patients with TBI is complex, neuromonitoring is essential for optimal management.

We observed good correlation between the diameter of the optic nerve and intracranial pressure, as well as mortality. It is a useful tool for the management of these patients.

INTRODUCTION. Positive final expiratory pressure (PEEP) is one of the main parameters determine gas exchange during mechanical ventilation. The use of high PEEP levels can lead to increase of intracranial pressure (ICP).

OBJECTIVES. To assess the systemic hemodynamics and lung mechanics during increased PEEP levels in neurosurgical patients with different baseline ICP levels.

METHODS. 22 critically ill patients with intracranial hemorrhages with ICP-monitoring, systemic hemodynamics and lung mechanics monitoring enrolled in the study. Mean age was 49 ± 13 years, male/female - 9/13. In 12 patients (group 2) increase PEEP to 15 and 20 cmH_2O was accompanied by an increase ICP, in 10 patients (group 1) ICP were stable during the study.

RESULTS. The increase of PEEP was accompanied by tendency to a decrease cardiac index and preload, an increase stroke volume variation and systemic vascular resistance index in both groups (Table 1, 2). In patients with unstable ICP (group 2, Table 2) was noted a more pronounced decrease in the global end diastolic index with an increase PEEP to 15 and 20 cmH20. Negative cerebral and hemodynamic effects were due to different states of lung mechanics (static compliance of respiratory system) in patients of both groups (Table 1, 2).

CONCLUSIONS. Patients with good lung compliance have a greater negative impact of increased PEEP levels on cardiac output and preload, which causes an increase in ICP, compared with patients with reduced lung compliance (Table 1).

INTRODUCTION. A daily spontaneous breathing trial (SBT) is the best approach to wean patients from the ventilator, but mode and duration of SBT are still controversial.

DESIGN. Multicentre randomised controlled trial, comparing two SBTs with very different work of breathing: T-piece for 2 hours vs. PSV 8 cmH2O for 30 minutes.

OBJECTIVE. To determine whether a low demanding SBT could improve extubation rate.

METHODS. During January 2016 and April 2017, in 18 Spanish ICUs, we recruited patients >18 yr. old after >24 hours of mechanical ventilation and ready for weaning. We excluded patients with tracheostomy or orders of non-reintubation. Patients were randomised to perform a SBT with T-piece for 2 hours or PSV 8 cmH2O for 30 minutes. The primary outcome was successful extubation rate, defined as remaining extubated 72 hours after the first SBT. Secondary objectives were reintubation rate, ICU and hospital length of stay, and ICU and hospital mortality. Variables associated with successful extubation were examined by multivariable logistic analysis.

RESULTS. We studied 578 patients in the 2-h T-piece SBT and 575 patients in the PSV 8 SBT group. Both groups were comparable at randomization. Successful SBT was higher in the PSV group than in the T-piece group (92.7% vs 84.1%; p < 0.001), whereas reintubation in patients who tolerated the SBT was similar in both groups (12.9% PSV group vs. 12.6% T-piece group; p = 0.9). Then, successful extubation was higher in the PSV group than in the T-piece group (80.7% vs. 73.5%; p = 0.004). The ICU mortality was not different (5% in PSV vs. 6.6% in T-piece; p= 0.3), but the hospital mortality was higher in the T-piece group (14.9% vs 10.4%, p= 0.022). The mortality at 90 days of randomisation was also higher in the T piece group (log Rank 0.033). The variables associated with successful extubation by logistic multivariable analysis were the length of MV before weaning (OR 0.96 in days of MV, p =0.02) and the SBT with PSV for 30 minutes (OR 1.5, p = 0.002).

CONCLUSIONS. The SBT using PSV 8 cmH2O for 30 minutes results in a better successful extubation rate compared with T-piece for 2 hours. The benefit was mostly related to a better tolerance of the PSV trial, without increasing reintubation. Unexpectedly, T-piece group experienced higher hospital and 90 days mortality.

INTRODUCTION. Arterial carbon dioxide tension ($PaCO_2$) affects cerebral blood flow (CBF) and cerebral oxygen delivery and may influence the course of developing brain injury after cardiac arrest. [1] The level of $PaCO_2$ can be modified by different ventilator settings in unconscious patients during post-resuscitation care but optimal targets remain unknown. [2]

OBJECTIVES. We conducted a randomized pilot trial to assess the feasibility of targeting low-normal or high-normal $PaCO_2$ in comatose, mechanically ventilated patients after out-of-hospital cardiac arrest (OHCA) and to evaluate the effect of low- or high-normal $PaCO_2$ on neuron-specific enolase (NSE) and cerebral oxygenation as measured by near-infrared spectroscopy (NIRS).

METHODS. In the Carbon dioxide, Oxygen and Mean arterial pressure After Cardiac Arrest and REsuscitation (COMACARE) trial, we used a 2^3 factorial design to randomly assign patients after OHCA and resuscitation to low-normal or high-normal levels of $PaCO_2$, arterial oxygen tension and mean arterial pressure. The results of low-normal (4.5-4.7 kPa) vs. high-normal (5.8-6.0 kPa) $PaCO_2$ comparison are reported here.

The primary outcome was serum concentration of NSE at 48 h after cardiac arrest. The main feasibility outcome was the difference in $PaCO_2$ between the groups during the first 36 h after ICU admission. Secondary outcomes included cerebral oxygenation measured with continuous NIRS.

RESULTS. A total of 123 patients were enrolled in the trial and 120 patients included in the final analysis. Despite a clear separation in $PaCO_2$ between the low-normal and high-normal groups (Figure 1), there was no significant difference in the median NSE concentration at 48 h after cardiac arrest (for low-normal $PaCO_2$, 18.8 μg/l [IQR, 13.9-28.3 μg/l] and for high-normal $PaCO_2$, 22.6 μg/l [IQR, 14.8-34.9 μg/l], p = 0.290). Median regional cerebral oxygen saturation (rSO_2) was significantly higher in the high-normal $PaCO_2$ group as compared with the low-normal group (Figure 2).

CONCLUSIONS. Targeting a specific narrow range of $PaCO_2$ is feasible in comatose, mechanically ventilated patients during post-resuscitation care. The level of $PaCO_2$, when within the normal range, did not affect the level of NSE at 48 h after OHCA. High-normal $PaCO_2$ resulted in better regional cerebral oxygen saturation indicating higher CBF and oxygen delivery.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0505

INTRODUCTION. Continuous infusion has proven to optimize beta-lactam antibiotic pharmacokinetic/pharmacodynamic (PK/PD) properties by increasing the time above the minimal inhibitory concentration ($\%fT_{>MIC}$)[1]. There is no consensus on the optimal PK/PD target but experts have recommended beta-lactam levels as high as 4 times the MIC [2]. It is largely unknown whether standard, empirical dosing of piperacillin/tazobactam (TZP) and meropenem (MER) reach adequate plasma levels when infused continuously in critically ill patients.

OBJECTIVES. To describe target attainment rates (%) of empirical, standard dosing of continuous infusion TZP and MER in critically ill patients.

METHODS. Daily sampling of patients admitted to the ICU receiving continuous infusion TZP or MER was attempted. Standard dosing for TZP was 16/2 g per day, while MER was dosed at 3g per day. Dosing was adapted based on renal function. Total plasma concentrations of TZP and MER were determined using ultra high-performance liquid chromatography coupled to mass spectrometry (UPLC-MS/MS). A level of protein binding of 30% and 2% was adopted for piperacillin and MER respectively. Target attainment was calculated for $100\%fT_{>4xMIC}$ for the micro-organism with the highest clinical breakpoint as published by EUCAST, i.e. 16 mg/L for TZP and 2 mg/L for MER.

RESULTS. 233 and 65 patients were included for TZP and MER analysis respectively. Over the entire antibiotic course, 137 (59%) and 16 (25%) of the patients receiving TZP, respectively MER in continuous infusion had one or more concentrations below the PK/

PD target of 4 times the MIC. When only the first 48 hours of therapy were considered, 79 out of 153 (52%) and 7 out of 35 (20%) patients did not achieve target concentrations for TZP and MER respectively. The observed piperacillin, respectively meropenem concentrations and the number of samples per day over the first 10 days of therapy are shown in figure 1.

CONCLUSIONS. ICU patients receiving empirical, standard doses of piperacillin/tazobactam (16/2g /24h) in continuous infusion tend to have plasma concentrations below the proposed PK/PD target level of 4 times the MIC while ICU patients receiving empirical, standard doses of meropenem (3g /24h) in continuous infusion are likely to achieve target concentrations.

INTRODUCTION. Sepsis-induced immunoparalysis, a phenomenon characterized by a severely suppressed state of the immune system, is increasingly recognized as the overriding immune dysfunction in sepsis. Norepinephrine represents the cornerstone vasopressor treatment for patients with septic shock, yet, *in vitro* evidence indicates it exerts anti-inflammatory effects. Therefore, norepinephrine could inadvertently compromise host immunity. Alternative vasopressors, such as phenylephrine or vasopressin, might hold an advantage in this respect. However, *in vivo* data on the immunomodulatory effects of vasopressors are lacking. We assessed the effects of norepinephrine and alternative vasopressors on the systemic immune response *in vivo* in mice. Furthermore, we performed a proof-of-principle study in healthy volunteers to translate these findings to the human setting.

METHODS. C57BL/6J mice received continuous intravenous infusion of norepinephrine (5 μg/kg/min), phenylephrine (50 μg/kg/min), vasopressin (0.0006 IU/kg/min) or placebo (PBS) for 3 or 24 hours via micro-osmotic pumps. Thereafter, they were challenged with 5 mg/kg bacterial lipopolysaccharide (LPS) i.v. to elicit a systemic immune response, or saline, and were sacrificed 90 minutes later. Additionally, 40 healthy male volunteers were randomized to a 5-hour i.v. infusion of either norepinephrine (0.05 μg/kg/min), phenylephrine (0.5 μg/kg/min), vasopressin (0.04 IU/kg/min), or saline (n=10 per group). One hour into the start of vasopressor/saline infusion, subjects were intravenously challenged with 2 ng/kg LPS.

RESULTS. In mice, both norepinephrine and phenylephrine profoundly enhanced LPS-induced plasma levels of the anti-inflammatory cytokine IL-10, while attenuating concentrations of virtually all pro-inflammatory mediators. Furthermore, norepinephrine reduced neutrophilic ROS production. Vasopressin exerted no effects on inflammatory parameters. In humans, norepinephrine and phenylephrine increased blood pressure before LPS administration, but did not prevent LPS-induced hypotension. Similar to the findings in mice, norepinephrine and phenylephrine profoundly enhanced LPS-induced plasma concentrations of the anti-inflammatory cytokine IL-10, while attenuating levels of pro-inflammatory cytokines IP-10, MCP-1, IL-8, and GM-CSF. Vasopressin neither affected blood pressure, nor cytokine response.

CONCLUSIONS. Norepinephrine and phenylephrine cause a distinct shift towards an anti-inflammatory cytokine profile during systemic inflammation in mice and men, which was not observed for vasopressin. Furthermore, norepinephrine attenuated ROS production, an important effector mechanism of neutrophils. These results may signify that norepinephrine contributes to the development of immunoparalysis in septic shock patients, and that vasopressin might represent an alternative agent with less untoward immunologic effects.

INTRODUCTION. Chest tube removal and turning in bed were reported as the most painful procedures performed in a multinational study of procedural pain in the ICU[1]. Little is known of the short-term consequences of such procedures, particularly patient´s perceptions at the end of the ICU stay.

OBJECTIVES. The objective of the study was to search an association between chest tube removal and other potential painful events that may occur in the ICU and self-reported pain at the end of the ICU stay when the patient is interviewed about the entire ICU stay

METHODS. We have conducted a multicenter, cluster-randomized, two-arm parallel, 3-period trial involving 34 adult ICUs to test the efficacy of a tailored multicomponent program (TMCP) for discomfort reduction in

critically ill patients[2]. To assess the primary endpoint, we used the French 16-item questionnaire on discomforts in ICU patients (IPREA) including the item pain, each item discomfort score ranging from 0, the lowest possible level, to 10 the highest. Since pain was the only item of IPREA whose score was not reduced by the TMCP, we included in the analysis all the patients regardless of the arm or the period. The associations of main patient characteristics at ICU admission, events or treatments that occurred in the ICU with the pain score (PS) were tested using Kruskal-Wallis tests or Spearman´s rank-correlation coefficients as appropriate.

RESULTS. During the 3 periods, 2130 patients with complete IPREA questionnaire were included. PS was correlated, negatively with age (ρ=-0.051; *p*=0.019) and positively with the duration of the pre-ICU hospitalization (ρ=0.068; *p*=0.002) and the length of stay (ρ=0.046; *p* =0.034) but not with SAPS 2 or gender. Surgical patients reported a higher PS than medical patients (3.11±2.87 vs 2.85±3.02, *p*=0.007). Among procedures or treatments occurring in the ICU, PS was correlated with chest tube removal, chest tube insertion, tracheostomy, complex dressing, intrahospital transport, central venous catheter insertion, gastric tube, and bladder catheter (table 1), but not with mechanical ventilation, non invasive ventilation, use of vasopressors, renal replacement therapy, extra corporeal membrane oxygenation, bronchial fibroscopy, upper gastrointestinal endoscopy, transesophageal echography, arterial catheter insertion, or lumbar puncture.

CONCLUSIONS. ICU survivors experiencing chest tube removal or intrahospital transport during the ICU stay reported at discharge a more painful ICU stay than patients not experiencing these events.

INTRODUCTION. The newly proposed septic shock definition has provoked a substantial controversy in the emergency and critical care communities.

OBJECTIVES. Our objective was to compare new (SEPSIS-III) versus old (SEPSIS-II) definitions for septic shock in a contemporary cohort of critically ill patients.

METHODS. Retrospective cohort of consecutive patients, age ≥18 years admitted to intensive care units at the Mayo Clinic between January 2009 and October 2015. We excluded patients without research authorization on file, and those admitted after elective surgery. We extracted demographics, clinical characteristics and outcomes from the validated electronic medical record database and compared patients who met the old, new, both, or neither definition of sepsis shock. Standardized mortality ratios were calculated using Acute Physiology and Chronic Health Evaluation (APACHE) IV predicted mortality.

RESULTS. The initial cohort consisted of 16720 patients who had suspicion of infection, of whom 7463 required vasopressor support. The median (interquartile range) age was 65(54-75) years and 4167(55.8%) were male. A total of 2690(36%) patients met both definitions, 3256(44%) patients met only the criteria for the old definition, 361(4.8%) met only the criteria for new definition, and 1156(15%) patient had infection and shock but met neither old nor new criteria. Compared to patients who met only old definition, the patients who met new definition had higher APACHE III score; (84[66-106] vs. 70[56-89], p< 0.01); Sequential Organ Failure Assessment day-1 score; (9[6-11]) vs. 6[4-9], p< 0.01), were older, (65[54-76] versus 64[54-75] years, p=0.03), and were more likely to have limited resuscitation preferences; (555[18%] versus 383[12%], p< 0.01). They also had higher hospital mortality (27% vs. 13%, p< 0.01) and a higher standardized mortality ratio (0.69 vs. 0.45, p< 0.01). Patients meeting both definitions faired worst, while the patients meeting neither of the definitions had better outcomes.

CONCLUSIONS. Compared to SEPSIS-II, SEPSIS-III definition of septic shock identifies patients further along disease trajectory with higher likelihood of poor outcome. This finding has implications for quality improvement and performance measures. A significant number of patients with infection and shock meet neither definition.

Hospital pre-alerting in a cohort of potentially septic patients brought into the emergency department by ambulance, is associated with more rapid delivery of antibiotics and improvement in physiological parameters at hospital admission

D. Hargreaves[1], J. de Carvalho[2], L. Hodgson[1], L. Smith[2], G. Picton[1], R. Venn[1]

INTRODUCTION. Although prompt administration of antibiotics are associated with improved outcomes in sepsis (1), it is unclear whether using a pre-hospital sepsis screening tool provides significant clinical benefit (2). In 2015 our regional ambulance service introduced a prehospital sepsis screening tool (coined 'Code Yellow'), which combines physiological parameters and symptoms and signs of compromised perfusion, to be used when paramedics suspected an acute infection. Positive cases were given initial resuscitation, pre-alerted and rapidly delivered to the local emergency department (ED).

OBJECTIVES. To evaluate whether outcomes and processes of care were improved with use of sepsis pre-alert tool in a cohort of potentially septic patients brought by ambulance to two UK EDs. Mortality risk was assessed by the UK National Early Warning Score (NEWS) in the pre- and hospital environments.

METHODS. A dual-centre, prospective cohort (2015-16) of ED patients brought in by ambulance (n=1232), identified as potentially septic at triage, was analysed for mortality (death at 30 days) and change and trend in mortality risk (NEWS score pre-hospital, in the ED, and at first recording on admission to the medical ward). Cases where the ED had been pre-alerted (Code Yellow positive) were compared with those identified on ED arrival.

RESULTS. 58% (714/1232) of the cohort were Code Yellow. There was no difference in 30-day mortality (19% vs 18%, p=0.515), age, gender, previous medical history, admission time and day, AKI or lactate between the groups. [Fig 1]

Mortality risk, indicated by first pre-hospital NEWS, was greater in the Code Yellow group (9 [IQR] vs 7 [IQR], p< 0.001). This difference was maintained in first ED NEWS score also (7 vs 6, p=0.04) but by admission to a medical ward there was no significant difference in NEWS between the groups (3 [IQR] vs 3 [IQR], p=0.125). [Fig 2]

Repeat measure factorial analysis of variance of the differences in scores and the trend in change of score were very significantly different (p < 0.0001). [Fig 3]

The Code Yellow group was significantly more likely to receive antibiotics within 1 hour (72% vs 49%) p< 0.0001, and a completed sepsis resuscitation bundle (34% vs 21%) p< 0.0001.

CONCLUSIONS. A prehospital sepsis tool with hospital pre-alert identified a cohort with a higher risk of death. The group identified had improved delivery of antibiotics and significant improvement in trend for mortality risk (assessed by NEWS score) by the time of admission to a hospital ward. They had similar in-patient outcomes to those not pre-alerted. This equivalent outcome and mortality risk on admission to the ward could be interpreted as an overall mortality benefit.

INTRODUCTION. Rapid pathogen identification is essential for optimizing antimicrobial treatment (AMT) during sepsis. Culture based methods are slow and their sensitivity is impaired by concurrent AMT. A novel multiplex real-time PCR has recently been developed (BSI-PCR, Microbiome), enabling detection of microbial DNA of common pathogens directly in blood.
OBJECTIVES. To determine the diagnostic accuracy of BSI-PCR results in sepsis patients acutely admitted to the Intensive Care Unit (ICU).
METHODS. Patients were enrolled as part of the Molecular Diagnosis and Risk Stratification of Sepsis (MARS) cohort in two tertiary ICUs in the Netherlands from 2012 to 2014. We selected subjects presenting with presumed sepsis and related organ failure or septic shock, in whom a blood culture was ordered within 24h from start of AMT. Whole blood specimens (5 mL) were simultaneously collected, in which enrichment and isolation of microbial DNA (Polaris method) and BSI-PCR runs were performed. Likelihood of infection and potential causative microorganism(s) were prospectively recorded by trained observers based on a post-hoc assessment of available clinical and microbiological evidence. Accuracy of BSI-PCR was then determined using these causal pathogens as reference test (RT).
RESULTS. Out of 791 sepsis patients, 325 (41%) patients had a PCR sample available at ICU-admission. Pneumonia was the most common source of infection (53%), followed by abdominal infections (19%). BSI-PCR identified one or more pathogens in 169 (52%) patients (Table 1), with a median of 2 (IQR 1-2) positive results per patient. In 99 (30%) patients, at least one identified pathogen was in accordance with the RT. In comparison, performed clinical blood cultures revealed a presumed causative pathogen in 63 (19%) patients. Discordant positive PCR results were observed in 101 (31%) patients, but for 29 patients these were related to a RT classifying the pathogen as unknown. In 156 (48%) patients BSI-PCR did not identify any pathogen. However, for 79 (51%) of these subjects this could likely be a true negative finding, since their RT post-hoc infection likelihood was classified as only possible or none. The multiplex set up of BSI-PCR consists of both species-specific and generic PCRs (Table 2). The positive predictive value (PPV) per individual PCR varied from 16-82% and the overall PPV of BSI-PCR results was 54% (Table 2). False positive rate per individual PCR varied from 0-8%. Ct-values for true positive results were significantly lower than for false positive results (median 32.0 (IQR 27.7-35.8) versus median 37.7 (IQR 35.3-40.0); $p < 0.001$).
CONCLUSIONS. BSI-PCR identified a causative pathogen in 30% of patients with presumed sepsis and the overall positive predictive value was 54%.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0511

INTRODUCTION. Interleukin-6 (IL-6) is a pro-inflammatory cytokine known to increase during acute conditions such as those observed in intensive care units (ICUs). Elevated levels of IL-6 at ICU discharge were shown to be associated with increased mortality after sepsis or pneumonia (1).

OBJECTIVES. We aimed to study the impact of IL-6 levels on outcomes of ICU patients from a large multicenter cohort.

METHODS. We conducted a post-hoc study of the FROG-ICU cohort (NCT01367093) (2), a prospective, observational, multicenter cohort study conducted in 21 ICUs in France and Belgium. All consecutive adult patients admitted to ICU and requiring mechanical ventilation and / or inotropes were included. Clinical and demographic data were collected prospectively. Plasma and urine samples were collected at admission and at ICU discharge. The prognosis of the patients was followed up to 1 year. We included all patients for whom IL-6 measurements were performed. Correlations with the occurrence of organ failure or prognosis were performed using univariate and multivariate analyzes. A value of $p < 0.05$ was considered significant.

RESULTS. 2076 patients were included in the study, 65% were males. Patients had a median age of 63 (51-74) years, an SAPS II score of 49 (36-63), and IL-6 level at admission was 100.9 [43.5 - 261.7] pg / mL and 31.5 [15.3 - 61.5] pg / mL at ICU discharge. The level of IL-6 at admission is not correlated with the number of circulating leukocytes The admission level of IL-6 varies with (a) the admission diagnosis ($p < 0.001$), the highest rates being observed in patients with sepsis and pancreatitis, (b) the SOFA score (rho = 0.32, $p < 0.001$), (c) mortality in ICU (survivors: 89.34 [38.67 - 226.50] vs non-survivors: 164.35 [77.50 - 528.93], $p < 0.01$) The IL-6 level at ICU discharge is correlated with mortality at day 90 and at one year (J90: 28.4 [13.6 - 54.0] vs 53.9 [30.5 - 89.4] pg / mL and J365: 28.2 [13.7 - 53.8] vs 50.7 [25.0 - 91.9] pg / mL for survivors vs deceased, $p < 0.001$ for all). The AUC of IL-6 for predicting mortality at day 90 is 0.726 (0.684-0.768). An IL-6 level> 31 pg / mL is associated with a hazard ratio of 4.2 (2.8-6.3) and 2.7 (2.0-3.5) for mortality at day 90 and at one year respectively. These associations persist after adjustment on SAPS II score.

CONCLUSIONS. The levels of IL-6 at admission and at ICU discharge are confirmed to be associated with morbidity and mortality in ICU and after discharge. The monitoring of inflammation at ICU discharge may allow to identify patients at risk of mortality.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0512

INTRODUCTION. Sepsis consistently ranks among the most fatal disease syndromes globally. Various efforts have been made to improve standards for diagnosis, management and outcome reporting. Understanding the burden of disease is essential for monitoring the effectiveness of international strategies to improve management of sepsis.

METHODS. We assessed 30-year temporal trends in sepsis mortality globally using the WHO Mortality Database. Sepsis was defined by International Classification of Disease (ICD) versions 9 and 10 as previously described (1). We obtained sepsis-related, sex-specific mortality data from countries with "high usability data" from the WHO Mortality database and computed Age-Standardised Death Rates (ASDR). We used Joinpoint regression analysis to describe trends in sepsis morality.

RESULTS. A total of 34 countries were included in Europe, Australasia, and North America. In men, the median ASDR for all countries decreased from 36.2 / 100 000 (IQR 29.2 - 48.9) in 1985 to 27.1 /100 000 (IQR 21.4 - 40.3) in 2015. For women, the median ASDR for all countries decreased from 23.2 / 100 000 (IQR 17.2 - 31.0) in 1985 to 19.6 / 100 000 (IQR 14.0 - 15.3) in 2015. For men, the countries with the greatest percentage change over the observation period include Finland (- 80.9%), Iceland (-76.0%), New Zealand (-70.2%) and Ireland (-68.9%) while increases in mortality were observed in Denmark (+5.8%), Israel (+15.9%), Greece (+16.3%), and

Lithuania (+39.2%). For women, the greatest percentage decreases were observed in Finland (-79.4%), Iceland (-76.6%), Bulgaria (-70.0%), and Ireland (-62.3%) and increases were observed in Denmark (+20.4%), Lithuania (+23.0%), Greece (+33.5%), and Malta (+43.0%). The results of Joinpoint trend analysis are shown in Figure 1.

CONCLUSION. Overall, we observed a decrease in reported sepsis-related mortality across the majority of analysed nations between 1985 and 2015. However, there remains significant variability between health systems with respect to trends in sepsis-related mortality and between sexes in some countries. System-level and population-level factors may contribute to these differences and additional investigations are necessary to further explain these trends.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0513

INTRODUCTION. Morbid obesity and ARDS both affect respiratory mechanics mainly through their respective impacts on chest wall and lung elastances. We present a unique series of patients combining very severe morbid obesity and moderate to severe Acute Respiratory Distress Syndrome (ARDS).

OBJECTIVES. We describe the use of trans-pulmonary pressures (TPP) measurements for optimization of external PEEP setting.

METHODS. The monocentric observational study was performed in 10 morbidly obese patients admitted for moderate to severe ARDS. We performed an incremental PEEP trial (5 cm H_2O steps) with TPP measurement (NutriVent probe, Sidam, Italy) in a semi-recumbent position as previously described (ref 1). A decremental PEEP trial after a recruitment maneuver was not performed since the safety of such a maneuver in this specific population is largely unknown. We defined two ways for determination of external PEEP setting: (1) PEEP necessary to obtain a positive expiratory TPP and (2) PEEP necessary to obtain a plateau pressure between 28 and 30 cmH_2O (ref 2, maximal alveolar recruitment Express strategy). Data are expressed as numbers (%) and medians (interquartile range). Statistical analysis was made using the XLSTAT software.

RESULTS. We enrolled during 5 years 10 morbidly obese patients (62 (46-66))) admitted for a moderate to severe ARDS. Clinical characteristics are displayed in Table 1. The Express strategy indicated a PEEP setting of 17,5 cmH_2O (IR 15-20) whereas TPP-guided PEEP was 30 cmH_2O (IR 20-30), p=0,003. Driving pressure was higher in the Express strategy PEEP setting (10 cm H_2O (IR 9-12)) than in the TPP-guided PEEP (8 cm H_2O (IR 6-10)), p=0,78 . TPP-guided PEEP setting was higher than indicated by the Express strategy in all but one patient. Two patient suffered from transient hypotension when external PEEP was set at 25 and 30 cmH_2O, while no patient displayed an inspiratory TPP higher than 25 cmH20. Additional data will be provided during the meeting: pressure-volume curve at ZEEP (8 patients), CRF measurements (6 patients) and ABG and capnometry values at each PEEP level (7 patients).

CONCLUSIONS. In our ARDS patients with extremely severe obesity, an incremental PEEP trial with TPP measurements appeared to be safe and indicated a PEEP setting significantly higher than for the commonly-used ARDS strategies. Such an approach deserves further comparisons with other modalities of monitoring, such as CRF measurements, EIT studies, etc.

INTRODUCTION. Currently, there is limited evidence of PEEP titration techniques and predictors of the alveolar de-recruitment in recovering ARDS patients.

OBJECTIVES. To evaluate predictors of lung collapse after PEEP decrement in recovering ARDS patients.

METHODS. We conducted a prospective observational study in ARDS patients undergoing PEEP reduction. Eligible criteria were adult patients with ARDS by Berlin definition 2010, in recovery phase defined as PF ratio > 100 and using stable ventilator setting for > 24 hours with FiO_2 < 65% and PEEP $\geq$ 8 cmH_2O, SpO_2 >90% and no hemodynamic instability. All eligible patients were ventilated with Engstorm ventilators. Respiratory parameters including end expiratory lung volume(EELV) measured by nitrogen washout/washin technique, lung strain, respiratory system compliance(C_{RS}) at the baseline and 5 minutes after PEEP reduction were recorded. PEEP was decreased by 2 cmH_2O when primary physicians decided to perform decremental PEEP titration. Lung collapse events, defined as >2% decrease in SpO_2 or >10% decrease in PaO_2 from the baseline, were continuously observed during a 2 hour period after PEEP reduction.

RESULTS. Totally, 25 decremental PEEP procedures were performed in 16 ARDS patients. The majority of the patients were male with the median age of 65.5, median APACHE II of 15, median PF ratio of 260 and median PEEP of 10. The median baseline C_{RS} was 35.63 ml/cmH_2O. There were 8 lung collapse events occurring after PEEP reduction. Most of the events(75%) appeared within 30 minutes after the procedures. The decreased EELV and increased lung strain at 5 minutes were associated with the lung collapse events with the thresholds of 10% (AUC 0.808, 95% CI 0.592 to 1.000, p = 0.017) and 24% (AUC 0.817, 95% CI 0.611 to 1.000, p = 0.014), respectively. However, the change of C_{RS} was not associated with the lung collapse.

CONCLUSIONS. The 10% reduction in EELV and 24% increase in lung strain at 5 minutes after PEEP reduction predicted alveolar de-recruitment in 2 hours after the procedure, while the change of respiratory system compliance did not predict the event. A protocol of PEEP titration guided by the changes of these 2 parameters should be further studied in recovering ARDS patients to confirm our results.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0515

INTRODUCTION. Tissue Doppler Imaging (TDI) is a useful echocardiographic technique extensively used to evaluate global and regional myocardial systolic and diastolic function. TDI uses Doppler to quantify the velocity of tissue rather than blood, and it can, therefore, be used to estimate the velocity of any moving tissue, including the diaphragm. However, TDI of the diaphragm has never being attempted before, meaning that no information so far exists regarding the values of diaphragmatic velocity during contraction and relaxation of the muscle even in healthy subjects. In this study, diaphragmatic motion was investigated using TDI in healthy individuals, in patients who succeeded a weaning trial and in weaning failure patients.

METHODS. Diaphragmatic TDI was easily recorded in 10 healthy individuals (5males and 5 females), in 9 weaning failure and in 23 weaning success patients. Weaning success or failure was identified using the generally accepted criteria at the end of a 20 min T-piece trial. In all subjects the following diaphragmatic TDI-derived parameters were measured: TDI peak contraction and peak relaxation velocity, velocity time integral (VTI) during inspiration, and the slope of the initial steepest part of the velocity waveform of diaphragmatic motion during relaxation, ie, the TDI-derived maximum relaxation rate (fig). We recorded 15 breaths for each individual, analyzing a total of 600 breaths. All the above mentioned diaphragmatic TDI-derived parameters in the three groups of participants were compared for differences between groups. Statistical analysis was performed with Kruskal-Wallis ANOVA after a Kolmogorov-Smirnov test for normal distribution.

RESULTS. TDI peak contraction velocities were no different between healthy volunteers and weaning success patients (1,3 $\pm$0,2 cm.sec^{-1} vs 1,5$\pm$0,6 cm.sec^{-1}); on the contrary, weaning failure patients exhibited significantly higher peak contraction velocities (4$\pm$3 cm.sec^{-1}, p< 0.01). Furthermore, similar differences between the three groups were found in peak relaxation velocities (1,32$\pm$0,3 cm.sec^{-1} vs 1,7$\pm$0,6 cm.sec^{-1} vs 2,4 $\pm$2 cm.sec^{-1} , p< 0.01) and in the TDI-derived relaxation rate (5,3$\pm$1,9 cm.sec^{-2} vs 12,4$\pm$4 cm.sec^{-2} vs 45$\pm$29 cm.sec^{-2}, p< 0.01). VTI was not found statistically different in the three groups.

CONCLUSIONS. Our results suggest that diaphragmatic TDI may be a valuable technique for the evaluation of the diaphragmatic contraction and relaxation. More studies are necessary to validate the normal values in males and females, the influence of aging on these values and to confirm the possible alterations of these values in diaphragmatic fatigue and in patients with difficult weaning.

Effects of timing of tracheostomy on mortality in a heterogeneous population of critically ill patients admitted to Italian ICUs

M. Greco, M. Cecconi
Humanitas Research Hospital, Anesthesia and Intensive Care Department, Rozzano, Italy
Correspondence: M. Greco
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0516

INTRODUCTION. Tracheostomy is commonly performed to reduce complications of prolonged mechanical ventilation (MV). Delayed tracheostomy has been associated with increased mortality. However, evidence on timing of tracheostomy is still conflicting, and may vary according to the reason for ICU admission. (1)

OBJECTIVES. To identify whether early tracheostomy (performed within 9 days of MV) reduces mortality compared to delayed tracheostomy according to ICU admission diagnosis. We identified four admission diagnosis groups: trauma (not limited to brain injury), admission after surgery without known infection, admission due to infection, and other reasons.

METHODS. This is a secondary analysis from the GiVITI Prosafe prospective cohort study,(2) including tracheostomized patients aged ≥16 admitted to 261 Italian ICU between 2011 and 2013.

We performed bivariate analyses to check for association between mortality, tracheostomy timing, and covariates. Logistic regression was used to estimate odds ratio for hospital mortality, controlling for patient comorbidities, patient clinical condition at ICU admission and ventilation characteristics, and ICU admission reason. We tested for interaction between tracheostomy timing and ICU admission diagnosis.

RESULTS. From a total of 14,949 included patients, 10,075 had early and 4,874 late tracheostomy.

There were 2,949 (29.3%) deaths in early tracheostomy and 1,968 (40.4%) deaths in late tracheostomy group. The effect of tracheostomy timing on mortality depended on ICU admission reason. Late tracheostomy increased odds for mortality in patients admitted after surgery (31% [13-53%]) or for infection (23% [8-39%]), while it had no effect on trauma patients (OR 0.99, 95% CI 0.80-1.23) or patients admitted for other reasons (OR 0.97 [0.81-1.16]). With interaction between timing and admission diagnosis, late tracheostomy resulted in an 81% (53%-213%) increase in odds for mortality in surgical patients, in a 64% (40-92%) increase after infection, and in a 73% (44-207%) increase in patients admitted for other reasons. There was no association with trauma.

CONCLUSION. Using a large sample of critically ill patients undergoing tracheostomy, this study determined that the effect of timing of tracheostomy on mortality depends on patients' reason for ICU admission. Early tracheostomy is beneficial in patients admitted to ICU for infection or after surgery, while no clear effect was found in patients with trauma (not limited to brain trauma). Results of this study should be confirmed by further trials.

INTRODUCTION. Reverse triggering (RT) is a diaphragmatic contraction triggered by an insufflation initiated by the ventilator [1]. This type of patient-ventilator dyssynchrony is often missed in clinical settings and can have important clinical impact such as increased tidal volume, breath stacking or eccentric diaphragm contraction. The Better Care system® (Sabadell, Spain) uses patient's flow and airway pressure signals to detect different types of dyssynchrony [2]. As part of the BEARDS study (NCT03447288) of the PLUG group, an algorithm to detect RT was recently developed based on tracings with either electrical activity of the diaphragm (EAdi) or esophageal pressure.

OBJECTIVES. We aimed at validating the accuracy of an automatic detection of reverse triggering with a software using flow and airway pressure only.

METHODS. Three researchers visually reviewed the airway pressure, flow and electrical activity of the diaphragm (EAdi) recordings of 9 patients included in a physiologic study (DIVIP study: NCT02434016). These patients were selected based on recent intubation (within 24h), use of a controlled mode and expected to stay on the ventilator at least another 24h; they had a one hour continuous recording of all signals.

Reverse triggering was defined as an EAdi starting after a machine triggered breath. To detect events with a potential clinical relevance we only kept events with peak>5µV. Discrepancies were solved by consensus. We then compared expert assessment with the results of the automatic detection of RT on the same breaths. Sensitivity, specificities, predictive values, accuracy and kappa for inter-rater agreement were calculated using standard formulas.

RESULTS. The 9 patients included had a mean±SD age of 62±19, 67% were male, 78% had a medical cause of admission, and APACHE II score of 24±10. Their median [IQR] length of mechanical ventilation was 5 [4-10] days and 89% were discharged alive from the ICU.

Among the 9 recordings, 7 were performed during pressure or volume control ventilation and 2 during pressure regulated volume control. A total of 1621 breaths were assessed of which 177 breaths (11%) were considered as RT>5 µV by experts. RT occurred mostly during the insufflation phase more rarely during the exhalation phase, and sometimes induced breath stacking (Figure). The automatic detection had an accuracy of 97%: a sensitivity of 89%, a specificity of 98%, a positive predictive value of 84%, a negative predictive value of 99% and a Kappa index of 85% [$_{95\%}$CI=81%; 89%].

CONCLUSIONS. Automatic detection of RT having potential clinical relevance seems reliable and could allow easy bedside continuous assessment and quantification. Future studies will determine the impact of this patient-ventilator dyssynchrony.

INTRODUCTION. Adaptive metabolic response to injury includes utilization of alternative energy substrates, such as ketones, to protect the brain against further damage. Here, we investigated cerebral ketone metabolism at the acute phase of traumatic brain injury (TBI) in humans, focusing on the impact of caloric intake, glycemic targets and endogenous ketosis.

METHODS. This was an observational cohort study conducted in TBI subjects (N=34; mean age 49 years, mean GCS 7) who underwent cerebral microdialysis for the measurement of total brain interstitial tissue ketone bodies (KBs). We first analyzed (Study 1; N=24) changes of brain KBs from fasting (0 Kcal; mean 37 h from hospital admission) to initial caloric intake (500 Kcal; mean 16 h from nutrition start) and the influence of glycemic targets (categorized as tight [4-6 mmol/L] vs. moderate [6.1-10 mmol/L]) in this setting. We further examined (Study 2; N=10) the relationship between brain and endogenous circulating plasma KBs.

RESULTS. Initial caloric intake was associated with a significant decrease in total fasted brain KBs (from 32.9 [IQR 19.8-45.1] to 13.3 [8.8-25.9] μmol/L, p=0.0002, paired t-test), which was paralleled by a concomitant increase in brain and blood glucose (both p< 0.01). Brain KBs were higher at tight vs. moderate glycemic targets (41.2 [32.3-83.7] vs. 17.3 [9.4-32.5] μmol/L, p=0.001). Endogenous circulating plasma KBs reached markedly elevated levels (mean 1.14 [range 0.17-3.82] mmol/L), and correlated strongly with brain KBs (r=0.83, p< 0.0001).

CONCLUSIONS. Our data at the acute phase of TBI demonstrate increased endogenous production and transfer of KBs to the injured human brain, where they may act as supplemental cerebral energy substrate in conditions of limited carbohydrate availability. These unprecedented clinical findings might have implications for glycemic and nutritional control in neurointensive patients.

INTRODUCTION. Until the development of the SITS-MOST study, treatment with recombinant plasminogen activator (rt-PA) was only given in large centers. Treatment with rt-PA within the first 4.5 hours from the onset of the symptoms is beneficial .In our center, with no previous experience, we propose the treatment of intravenous cerebral reperfusion in the scope of the ICU, through a protocol based on a clinical pathway.
OBJECTIVES.

1) To describe the population affected by an ischemic stroke and treated with intravenous fibrinolysis within the first 3-4.5 hours of the onset of the symptoms.
2) To analyze the factors that influence the latency times and the variables of efficacy and safety.
3) To describe and compare the populations treated with rtPA i.v. in the pre and post periods ECAS III
4) To compare the population treated in our center in the first 4.5 hours with those of the SITS-MOST registry.

METHODS. All patients between March 2006 and December 2015 who had received fibrinolytic treatment were included. Demographic data, baseline status, intensity of pre-treatment neurological deficit, times of transfer and activation of stroke code, latency times, efficacy and safety variables were collected.
RESULTS. Fibrinolysis was performed in 493 patients; 52.1% were male, mean age 75 years old; 95.5% were previously independent. NIHSS score of 10.86 (SD 6.55). Latency times were as follows: start-ED 81.56 min, ED-CT 25.11 min, ED-needle 48.28 min and start-needle time 129.22 min. The ED-needle time decreased from the year 2010 (p < 0.001). The onset of symptoms-ED was lower in the in-hospital patients group and in those who arrived through the EMs with higher neurological impairments (p < 0.05). Mortality at 3 and 12 months was of 13.2 and 16.5%. The hemorrhagic transformation was symptomathic in the 3.9%, and the clinical presentation associated was TACI form (p < 0.001). When the pre and post ECASS III periods were compared, in 2010-2015 period, the patients were older (72.78 vs 66.39 years old). Time of latency, start-activation and ED-needle times decreased (p < 0.01). No differences were detected in the efficacy and safety variables. Patients at our center were older than the SITS registry (67 vs 77 years old). ED-needle and onset of simptoms-needle times were much lower in our patients (36 vs. 65 min and 105 vs 140 min, respectively). Although the number of symptomatic intracraneal haemorrhages was slightly higher (1.7% vs 3.6%), they did not present higher mortality and their functional prognosis was better (mRS 0-1 40.8% vs 51.2%).
CONCLUSIONS

1) Our latency times were short; and clinical and functional outcome were good.
2) In-hospital activation and transfer through EMS were associated with short latency times.
3) Treatment in the first 4.5 hours was as safe and effective as in less than 3 hours.4) Compared to the SITS-MOST register, our latency times were shorter and the functional prognosis was better.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0520

INTRODUCTION. Mechanisms underlying recovery of consciousness implicates brainstem, subcortical and cortical regions as well as their connecting neuronal pathways.[1,2] Intracerebral hemorrhage (ICH) may cause both focal injury to specific brain regions and also diffuse injury (i.e., from edema) affecting connecting neuronal pathways.[3]

OBJECTIVE. To determine the significance of focal structural lesions and diffuse injury in impairment and recovery of consciousness following ICH.

METHODS. We studied a consecutive series of spontaneous ICH patients that underwent MRI within 7 days of the bleed. We assessed consciousness by testing for command following during daily interruption of sedation at the time of MRI acquisition and ICU discharge, and determined functional outcomes using the Glasgow Outcome Scale-Extended (GOS-E) at 3 months. ICH and edema volumes and location, and midline shift (MLS) were quantified. A machine learning approach using logistic regression with elastic net regularization was applied to identify MRI parameters that best predict consciousness.

RESULTS. From 158 ICH patients that underwent MRI, 66% (N=105) were conscious and 34% (N=53) were unconscious at the time of MRI. Almost half of the unconscious patients (49%, N= 26) recovered consciousness by ICU discharge. Consciousness at ICU discharge was best predicted when combining focal lesions within the anterior-forebrain-mesocircuit with measures of MLS, and ICH and edema volumes (AUC: 0.74, 95%-CI: 0.73 to 0.76). Patients predicted to recover consciousness at discharge had better 3-month functional outcomes (GOS-E $\geq$ 4: 35% vs 0%; p-value=0.02).

CONCLUSION. Focal lesions in key structures within previously described circuit models of consciousness together with measures related to mass effect of the hemorrhage (ICH and edema volume, MLS) best predict early recovery of consciousness. MRI within one week of injury might be helpful to identify patients that will recover consciousness early and predict 3-month functional outcomes.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0521

INTRODUCTION. Hepatic encephalopathy is a complication of liver disease and/or portosystemic shunts. Its pathophysiology is incompletely understood; mechanisms include hyperammonia in association with systemic inflammation. An impairment of blood-brain barrier (BBB) permeability is also hypothesized. Thus, most frequently neurological symptoms in cirrhotic patients are attributed to hepatic encephalopathy. Metabolomics enables to detect a wide range of metabolites without any a priori. In a recent metabolomic study including patients who underwent cerebrospinal fluid (CSF) collection, our group outlined that drugs that usually don't cross BBB were retrieved in the CSF, suggesting a potential neurological toxicity of drugs. CSF collection is invasive.

OBJECTIVES. Hence, we aimed to describe the drugs present in the plasma of cirrhotic patients, using the same metabolomic approach.

METHODS. We conducted a retrospective study of plasma samples in the Hepatological ICU. Plasma samples from cirrhotic patients displaying neurological symptoms were compared to plasma from cirrhotic patients without neurological symptoms, and to plasma from healthy controls. Liquid chromatography coupled to high-resolution mass spectrometry was performed and then after the metabolic fingerprints were compared to database and between the different groups.

RESULTS. Plasma samples were obtained from 12 cirrhotic patients with neurological symptoms (age 59 [40-68], MELD 20 [16-31], alcohol 58%), 13 cirrhotic patients without encephalopathy (age 56 [55-64], MELD 17 [14-29], alcohol 38%) and 9 healthy controls. Among 495 identified metabolites, 25 corresponded to xenobiotics or its derivatives. Fluoxetine was detected with a more than 200 fold increase, aminosalicylic acid with a more than 10 fold increase and benzyl alcohol (present in cough pills and antiseptics) with a 3 fold increase in cirrhotic patients with neurological symptoms as compared to cirrhotic patients. In cirrhotic patients with or without neurological symptoms, propranolol was detected with a more than 8500 fold increase, acetaminophen with a 40 fold increase, penicillamine and ampicillin both with a 2 fold increase as compared to healthy controls. Interestingly, several substances which were not expected to have systemic diffusion were detected in cirrhotic patients and in healthy controls: eugenol, isoeugenol (used in mouth bathing solution), triethanolamine (trolamin, used in cutaneous creams) and resorcinol monoacetate (used in mouth bathing solution and in cutaneous creams).

CONCLUSIONS. Cirrhotic patients, especially those with neurological symptoms, display dramatically increased levels of several xenobiotics in plasma. These results confirm that PK/PD parameters of commonly used drugs are highly modified in those patients. This suggests a potential role of xenobiotics in the pathophysiology of encephalopathy in cirrhotic patients.

Impact of tolvaptan on osmolar efficacy of hypertonic saline in severe traumatic brain injury: a single centric, prospective, double blind, investigator initiated, randomized controlled clinical trial

B.P. Das[1], S. Kamath[2], U. Rao[2], G. Yadav[1]
[1]IMS-BHU, Anaesthesia and Critical Care, Varanasi, India; [2]NIMHANS, Neuroanesthesia & Neurocritical Care, Bengaluru, India
Correspondence: B.P. Das
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0522

INTRODUCTION. The recent Brain Trauma Foundation guidelines did not carry forward its earlier recommendations on osmotherapy in severe traumatic brain injury (TBI) because of insufficient high quality evidence from comparative studies. HTS is no more advantageous than mannitol in maintaining hyperosmolar state and controlling ICP, which might be due to urinary sodium loss, which curtails its superior osmolar effect.

OBJECTIVES. The current study attempts to explore the impact of tolvaptan when added to HTS on osmolar efficacy in patients with severe TBI.

METHODS. After ethics committee approval and written informed consent from the guardians, a single-centric, prospective, double-

blind, investigator-initiated clinical comparative trial was conducted in between october 2016 to october 2017 at Trauma ICU, IMS-BHU, Varanasi, in which 76 adult patients with severe TBI belonging to age group 15-70years, receiving aliquots of 2.5ml/kg of 3% HTS for refractory-ICH, were randomised to receive tolvaptan (Group A) or placebo (Group B) to achieve target ICP < 22 mmHg and CPP >60mmHg. We evaluated ICP, along with serum and urine sodium and osmolarity over 6 days. Chi-square and student-t test were used for qualitative and quantitative data, respectively. Statistical significant difference was declared when p-value ≤0.05.

RESULTS. The demographic variables were comparable. A total of 372 and 502 boluses of HTS, respectively, were administered during the study period (p=0.01). Addition of tolvaptan increased serum sodium and osmolality significantly in a sustained manner throughout the study period (p=0.03 and 0.02, respectively) (Fig 1), which translated into better ICP control with lesser boluses of HTS (p=0.01). The outcome parameters (duration of hospital stay 22 ± 10 vs 42 ± 11 days; p = 0.04) and unfavorable GOS (GOS = 1 to 3) at 6 months (10/40 vs 18/36; p = 0.02) and mortality at 6 months (8/40 vs 14/36; p = 0.03) were better with tolvaptan use (Group A) (Fig 2).

CONCLUSIONS. Addition of tolvaptan to HTS not only curtails the effect of urinary sodium loss, thereby increasing osmolar efficacy but also leads to better ICP control in severe TBI, translating into better GOS with mortality benefit.

Reduction effect of ramelteon, a melatonin receptor agonist, for delirium in ICU patients: a subgroup analysis from MELIt trial

Y. Yasuda, M. Nishikimi, M. Higashi, T. Yamamoto, A. Numaguchi, N. Matsuda
Nagoya University Graduate School of Medicine, Department of Emergency & Critical Care Medicine, Nagoya city, Japan
Correspondence: Y. Yasuda
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0523

INTRODUCTION. We reported that ramelteon, a selective melatonin receptor agonist, decreased the occurrence rate and duration of delirium in ICU patients (1), but a subgroup who has more benefit from ramelteon for the prevention of delirium among ICU patients remains unknown.

OBJECTIVES. To evaluate the different effects of ramelteon for the delirium in ICU patients according to a degree of illness severity.

METHODS. This subgroup study was performed by using data from our previously published, Melatonin Evaluation of Lowered Inflammation in ICU (MELIt) Trial (1). Eligible patients in this trial were ICU patients who could take medicines orally or through a nasogastric tube during the first 48 hours of admission, and received a ramelteon (8 mg/d) or placebo during their ICU stay. In the subgroup analysis, we divided all patients into two groups by the levels of Acute Physiology and Chronic Health Evaluation (APACHE) II score, and evaluated the effect of ramelteon for delirium occurrence in the two groups, respectively.

RESULTS. In all 88 patients, 47 subjects (ramelteon: 26 cases, placebo: 21) were divided into high APACHE II score (≥23), while 41 (ramelteon: 19, placebo: 22) were into low APACHE II score group (< 23). The mean APACHE II score were 30.0 ± 4.7 and 17.1 ± 4.3, respectively. The number of intubated patients was 31 (66%) in the high score group and 7 (17%) in the low score group. In the high score group, the use of ramelteon was associated with a statistically significant decrease in the incidence of delirium (30.8% vs. 71.4%; p < 0.01). On the other hands, in the low score group, no statistical significance was observed (15.8% vs. 22.7%; p = 0.70).

CONCLUSIONS. Ramelteon statistically significantly decreased the occurrence rate of delirium in the patients with APACHE II sore ≥23, while not in those with APACHE II sore < 23. Ramelteon reduced delirium in highly severe ICU patients.

Serum orexin-A concentration and acute brain dysfunction in critically ill patients

J. Oto, N. Nakanishi, Y. Ueno, T. Itagaki
Tokushima University Hospital, Tokushima, Japan
Correspondence: J. Oto
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0524

INTRODUCTION. Acute brain dysfunction is common in critically ill patients. Orexin is one of the neuronal bioactive substances and may play an important role in several neuro-physiological functions such as sleep-wake cycle and cognitive function. Several experimental studies suggest that degeneration of orexinergic (OXergic) neurons occurs during acute critical illness, i.e., sepsis or traumatic brain injury, and the decline of OXergic activity may partly characterize the symptoms of acute brain dysfunction such as delirium or coma, in critical illness (1). However, there are few clinical data that validated this hypothesis.

OBJECTIVES. To investigate the relationship between serum orexin-A concentration and the occurrence of delirium and coma in critically ill patients.

METHODS. In this prospective cohort study, adult patients admitted to ICU at the Tokushima University Hospital (general ICU: 10 beds) for more than 24 hours were recruited. Delirium was assessed with the confusion assessment method for the ICU (CAM-ICU) performed every 2 to 3 hours during the ICU stay. Coma was defined as Richmond Agitation-Sedation Scale of -4 to -5. Serum orexin-A were measured at once daily during daytime (6:00 AM to 9:00 PM) for up to 7 days post-ICU admission by commercial enzyme linked immuno-sorbent assay. We compared the serum orexin-A concentration among the patients with delirium (D Group), or with coma (C group) or without delirium/coma (Non-D/C group).

RESULTS. Sixty-four patients were included and 176 samples were collected. The incidence of delirium and/or coma at the orexin-A concentration measurement was 59.7%. In patients who did not de-velop delirium/coma, serum orexin-A levels were significantly higher than in patients with delirium or coma [median: inter-quartile range: Non-D/C group: 31.0 (22.0, 49.3) pg/mL, D group: 23.1 (14.2, 33.3) pg/mL, C group: 22.6 (12.8, 32.8) pg/mL, p=.003, respectively].

CONCLUSIONS. To our knowledge, this is the first study to investigate the serum orexin-A levels and acute brain dysfunction in critically ill patients. Low serum orexin-A levels are associated with the occurrence of delirium and coma.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0525

INTRODUCTION. ICU delirium occurs frequently and is associated with worse outcomes. A recent delirium prevention study, the REDUCE study, has assessed the prophylactic use of haloperidol [1]. This study showed no effect for any group for all outcomes. Therapeutic serum levels of haloperidol for treatment of schizophrenia are reported to be 3-20 μg/L [2,3]. The pharmacokinet-ics in ICU patients are known to be variable.

OBJECTIVES. To determine haloperidol serum concentrations in ICU patients receiving prophylactic haloperidol.

METHODS. Subgroup analysis of all included patients in the REDUCE study in one participating ICU. A blood sample was drawn immediately before the third dose of the study medication. All results were blinded until the study was ended. Patients received placebo or 1 mg or 2 mg haloperidol q8hrs intravenously. Non-parametric tests were used (Kruskal-Wallis; Mann-Whitney).

RESULTS. We included 139 patients for the REDUCE study of whom in 100 blood was drawn to determine serum haloperidol concentration. 39 patients were discharged early or did not give consent. Baseline characteristics showed no differences between subgroups (Table 1). The median serum level of haloperidol was 0 mg/l for placebo,1.1 mg/L (IQR 0.1-1.6) in the 1mg group and2.6 mg/L (IQR 1.8-3.2) in the 2 mg group (figure 1), p=0.001 for 1 vs 2 mg haloperidol. Two patients had a serum level above 20 mg/L as an indication for poor metabolism.

CONCLUSIONS. In this subset of patients included in the REDUCE study we found a linear dose-concentration relation of haloperidol trough concentrations. The observed haloperidol serum levels were lower compared to those reported when haloperidol was given in a treatment setting for patients with schizophrenia and other psychotic disorders.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0526

INTRODUCTION. The relative effectiveness of different interventions for treatment of ICU delirium remains unclear. To address this knowledge gap, we conducted a systematic review (SR) and network meta-analysis (NMA) to evaluate the comparative benefits and harms of interventions from published trials.

OBJECTIVES. To assess 1) effects of drug interventions on delirium duration and other clinical outcomes (delirium-free and coma-free days, duration of mechanical ventilation, length of stay, mortality) in ICU patients with confirmed or at high risk of delirium; and 2) drug safety.

METHODS. We used well established Cochrane SR and NMA methods. We searched the following databases (inception-April 2018): MEDLINE, Embase, PsychINFO, Cochrane Library, CINAHL, Web of Science, and grey literature. We included all randomized controlled trials (RCTs) of critically ill adults with confirmed or high risk of delirium treated with any drug and compared to any control group (other drug, or placebo).Treatment effects for continuous outcomes were summarized as ratios of means (RoM: mean[expt]/mean[ctrl]) and binary endpoints were summarized as OR. All estimates were reported along with 95% CrI. We performed conventional pairwise meta-analyses and NMA within a Bayesian framework, both using random-effects (RE) models; the reference treatment for all analyses was placebo. This approach enabled the estimation of each drug's probability of being at each possible rank (e.g., 1st,...,n^{th} for n drugs) for each outcome. For NMAs, we estimated the corresponding probability of each drug to be the best, surface under the cumulative ranking curve (SUCRA) values, and the mean rank of each drug.

RESULTS. We screened 4996 papers and included 13 RCTs (n=1278 subjects). Nine RCTs were placebo-controlled; 4 were comparisons of different drugs. Drugs included antipsychotics (n=9), alpha$_2$-agonists (n=3), statins (n=2), opioid (n=1), serotonin antagonist (n=1), and cholinesterase (CHE) inhibitors (n=1). Nine studies (n=964) reported on duration of delirium. The forest plots from pairwise meta-analyses on duration of delirium are shown in figure 1; only alpha$_2$-agonists were significantly better compared to placebo (mean difference -0.53, 95% CI -0.84 to -0.22, P=0.0007). Figure 2 displays the RoM estimates of pairwise comparisons from NMA. The smallest RoM vs. placebo was associated with alpha-2 agonists (mean rank 2.13), followed by atypical antipsychotics (mean rank 2.37), although 95% CrIs of all interventions included 1. None of the secondary outcomes identified differences between therapies. Adverse events were rarely reported, with rates similar between drugs and placebo where available.

CONCLUSION. Secondary effect measures from our NMAs suggest alpha$_2$-agonists and atypical antipsychotics may be most effective in reducing delirium duration. However, corresponding pair-wise comparisons from NMA could not rule out a possible null difference between drugs.

Efficacy of dexmedetomidine in reducing duration of mechanical ventilation in patients with severe burn injury

A. Lavrentieva[1], M. Papaioannou[1], I. Tsioulis[1], E. Sourla[1], C. Giannaki[1], G. Vasileiadou[1], S. Tsotsolis[2], M. Bitzani[1]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0527

INTRODUCTION. Although causal relation between the level of sedation and the patient outcomes is difficult to be determined, many studies suggest that the use of sedatives could account for the prolonged duration of mechanical ventilation in patients with severe burn injury.

OBJECTIVES. The goal of the study was to determine the effectiveness of dexmedetomidine vs. midazolam in reducing duration of mechanical ventilation in patients with severe burn injury.

METHODS. Forty nine burn patients admitted during 2015-2017 in four-bed burn ICU receiving sedation and mechanical ventilation for more than 96 hours were included in the study (mean total body surface area burned 42±23%, mean SOFA score at admission 5.8±4). After four days of mechanical ventilation patients were randomly assigned to 1 of 2 treatment groups: receiving dexmedetomidine (20 patients), titrated to rates between 0.5 and 1.5 µg/kg/h and receiving midazolam (19 patients), titrated to rates between 0.03-0.09 mg/kg/hr) to achieve sedation goals. Sedation was continued until no longer require or up to 5 days. Ventilator-free hours and time to extubation in the 5 days following randomization were assessed and compared between two groups of patients.

RESULTS. Dexmedetomidine increased ventilator-free hours at 5 days compared with midazolam (median, 89 hours vs. 65 hours, respectively; median difference between groups 23.0 hours [95% CI, 6.0 to 29.4 hours]; $p < 0.01$). Patients in dexmedetomidine group had reduced time to extubation (median, 29.5 hours vs. 51.6 hours with midazolam; median difference between groups, 20 hours [95% CI, 8.9 to 32 hours]; $p = 0.01$) and lower rate of delirium (15 % vs. 31.6%, $p <$

0.01). Using Cox modeling to adjust for imbalanced baseline characteristics, allocation to dexmedetomidine was significantly associated with earlier extubation (hazard ratio, 0.5 [95% CI, 0.29-0.83]; *p*= 0.002). Bradycardia was detected in 4 patients (20%) receiving dexmedetomidine. No unplanned extubations were observed in both groups.

CONCLUSIONS. Among patients with severe burn injury receiving prolonged mechanical ventilation the addition of dexmedetomidine to standard burn care compared with midazolam resulted in more ventilator-free hours, lower rate of delirium and reduced time to extubation. Dexmedetomidine seems to be safe and effective for sedation of burn patients on prolonged mechanical ventilation however close cardiovascular monitoring should be used to detect bradycardia.

Weaning from mechanical ventilation: New ideas

INTRODUCTION. The duration of weaning from mechanical ventilation is strongly associated with clinical outcomes. Predicting the duration of weaning may be useful to identify high-risk patients for intervention and for quality assurance benchmarking.

OBJECTIVES. We aimed to develop a prognostic score to predict the risk of prolonged weaning based on readily available clinical characteristics at the onset of weaning readiness.

METHODS. Clinical data were collected twice daily in 5197 invasively mechanically ventilated patients included in the Toronto Intensive Care Observational Registry (iCORE) from April 2014 to October 2016. The onset of weaning readiness was defined as the first day when patients were receiving inspired fraction of oxygen < 50% with positive end expiratory pressure < 10 cmH$_2$O without vasopressor infusions. The two primary outcomes were the proportion of patients requiring 1) > 4 days and 2) > 6 days to be liberated from mechanical ventilation. Multivariable logistic regression modelling with bootstrapping for internal validation was used to create the Weaning score. Then, the score was tested into a validation cohort (n=862) issued from the iCORE registry from November 2016 to July 2017.

RESULTS. After exclusion of patients with missing or inconsistent data, 2814 patients with mechanical ventilation for at least 24h were evaluated. Among them, 673 (28%) never reached readiness criteria. Eventually, 1163 (41%) patients presented simultaneously all three readiness criteria during the ICU stay. From them, 219 patients (19%) required > 4 days and 109 (9%) > 6 days to be liberated from mechanical ventilation. Of more than 30 pre-selected potential predictors, logistic regression identified 3 variables measured on the day of readiness that were independently associated with a duration of weaning > 4 days:

1) time from ICU admission to weaning readiness;
2) lowest Sedation-Agitation Scale (SAS) score on the day of readiness; and
3) lowest respiratory rate on the day of readiness.

The model had good predictive discrimination (c = 0.75; 95% CI 0.72-0.79). Variables independently associated with weaning duration > 6 days were:

1) time from ICU admission to weaning readiness;
2) trauma as a primary reason for acute respiratory failure; and
3) lowest respiratory rate on the day of readiness.

This model also had good predictive discrimination (c = 0.80; 95% CI 0.76-0.84). External validation performed on 862 additional patients confirmed the performance of the score to predict duration of weaning longer than 4 days (c = 0.69; 95% CI 0.64-0.74) and duration of weaning longer than 6 days (c = 0.74; 95% CI 0.67-0.81).

CONCLUSIONS. The Weaning score is a new clinical score employing simple variables available at the time of weaning readiness that predicts the subsequent duration of weaning with acceptable performance.

0529

The effects of pressure support and proportional assist ventilation on metabolic parameters during weaning

M. Arslan, A. Kuntman, K. Demirag, I. Cankayali, M. Uyar
Ege University Hospital, Anesthesiology and Intensive Care, Izmir, Turkey
Correspondence: M. Arslan
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0529

INTRODUCTION. Weaning refers to the process of gradually withdrawing invasive mechanical ventilation. Various spontaneous breathing modes may be used for weaning. The patients respond to these modes by different metabolic and respiratory patterns.

OBJECTIVES. The aim of this study is to compare pressure support (PS) and proportional assist ventilation (PAV+) modes regarding these parameters.

METHODS. After obtaining consent from local ethics committee, 50 intensive care patients who were mechanically ventilated for at least 24 hours, hemodynamically stable and met the criteria for weaning were included. The study was designed as a prospective, cross-over study.

The patients were randomized to start on either PSV or PAV+ mode by Puritan Bennett 980 ventilator and measurements were obtained after an adaptation period of 30 minutes with a PaCO$_2$ value between 35-45 mmHg and PaO$_2$ above 60 mmHg. Patients were then switched to the other mode and the same measurements were repeated. Ventilatory parameters were adjusted during the study period to maintain the blood gas values within clinically acceptable limits. Indirect calorimetry was performed during each ventilatory mode for a period of 30 minutes. Energy expenditure (EE), oxygen consumption (VO$_2$), and CO$_2$ production (VCO$_2$) were measured. Also respiratory rate, pulse rate, mean arterial pressure, oxygen saturation, tidal volume, peak and mean airway pressures and arterial blood gas values were recorded at 10 min intervals during the study period.

RESULTS. The parameters did not differ significantly between the two ventilatory modes, regardless of the patient´s randomization except VO$_2$. All patients tolerated both ventilatory modes without signs of discomfort.

CONCLUSIONS. PSV and PAV+ modes produced clinically similar results in terms of metabolic and other variables. The difference regarding VO$_2$ between PSV and PAV+ was not considered as clinically significant.

INTRODUCTION. Sleep disruption and poor sleep quality are common in critically ill patients. An association between sleep quality and weaning outcome has never been studied.
OBJECTIVES. To investigate whether the level of sleep depth assessed the night before a spontaneous breathing trial (SBT) would be associated with different subsequent weaning outcomes.
METHODS. Mechanically ventilated patients from three ICUs were enrolled if the clinical team planned to conduct a SBT the following day. On the night before, polysomnography (PSG) was performed using an unattended portable sleep diagnostic device (Alice PDx, Philips, Murrysville, USA). Alice PDx includes six electrodes and two bands (thorax and abdomen) and records electroencephalography (EEG), electrooculography, electromyography, electrocardiography, and chest and abdominal effort.
The odds ratio product (ORP) is a new continuous index for evaluating the level of sleep depth: it is calculated from the power of 4 EEG frequency band (delta, theta, alpha-sigma, and beta) relative to each other (1). Its range extends from full wakefulness (2.5) to the deepest sleep (0). ORP was calculated off-line as well as the intra-class correlation between right(R) and left(L) hemispheres' ORP (ICC R/L). Normal ICC R/L is greater than 90%.
The SBT was performed under continuous positive airway pressure set at 0 cmH$_2$O. Average ORP and ICC were compared between patients depending of their weaning outcome (Kruskall-Wallis test): passed SBT followed by extubation, passed SBT without extubation and failed SBT without extubation. Data are given as mean (standard deviation) or median (25th-75th percentiles).
RESULTS. 37 patients (34 PSGs) were enrolled: 11 patients passed the SBT and were extubated, 8 passed the SBT but were not extubated (clinical decision) and 15 failed the SBT.
ORP was significantly higher in patients who passed the SBT as compared both to those who passed the SBT but were not extubated and to those who failed the SBT (Figure 1). Sixty-seven percent of patients who passed SBT and were extubated spent >20%

of recording time with ORP >2.0 (meaning alert); this contrasted with 16% of patients who passed SBT but were not extubated and 13% of patients who failed SBT (Chi2=0.02). The ICC R/L was 0.83 (0.77-0.91), 0.82 (0.75-0.86) and 0.62 (0.49-0.65) in patients who passed the SBT and were extubated, in patients who passed the SBT but were not extubated and in patients who failed the SBT and respectively (p< 0.01).
**CONCLUSIONS.** On the night before weaning, spending little or no time with a high ORP (full wakefulness) is predictive of weaning failure. In addition, hemispheric correlation was higher in patients who passed the SBT. This new analysis shed a new light on the weaning process.

INTRODUCTION. Assessing the ability to clear secretions and protect airway with effective cough is an important part of pre-extubation evaluation in patients who have passed spontaneous breathing trial (SBT). We hypothesized that cough strength and extubation outcome can be predicted by diaphragm ultrasound.
OBJECTIVES. The aim of this study is to investigate the predictive values of diaphragm excursion and max velocity during voluntary cough measured by ultrasound for cough peak expiratory flow (CPEF) measured by ventilator graphics and extubation outcome.
METHODS. All mechanically ventilated patients who passed SBT were enrolled in the study. In the supine position, diaphragm excursion and max velocity were measured during cough by

ultrasound. CPEF was also measured using the ventilator flow waveforms. The primary outcome of this study was extubation failure. Patients who require re-intubation more than 72 hours after extubation were classified as having a failure extubation.

RESULTS. A total of 196 mechanically ventilated patients were included. Both excursion and max velocity of the diaphragm during voluntary cough were significantly correlated with CPEF (r=0.276; p< 0.01 and r=0.464; p< 0.01respectively). The areas under the curves (AUCs) of excursion and max velocity of the diaphragm during voluntary cough for extubation failure are 0.656 (95% Cl 0.389 - 0.924) and 0.517 (95% Cl 0.25 - 0.784) , respectively.

CONCLUSIONS. Excursion of the diaphragm during voluntary cough is a potential predictor of extubation outcome in patients who passed SBT.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0532

INTRODUCTION. Atrophy of diaphragm(DF) fibers is correlated with mechanical ventilation(MV) duration and it is associated with ventilatior-induced diaphragm dysfunction(VIDD). In animal models it typically appears after periods of controlled MV(CMV). Human data are basically available from mechanically ventilated brain-dead organ donors(BD) in controlled modalities. This is the first study to evaluate DF histological characteristics of Maastricht III donors(MS) who can tolerate spontaneous MV(SMV).

OBJECTIVE. To compare DF and quadriceps(QD) histological characteristics of BD donors(ventilated with CMV), MS donors(who can tolerate SMV modalities) and control patients(CTL, ventilated during a thoracic surgery).

METHODS. Unicentric, prospective and interventionist cohort study was conducted in a polyvalent ICU(IRB2017/7183/I). Biopsies from DF and QD were obtained from ICU donor patients(MS and BD) and CTL. Tissue was preserved immediately in alcohol-formol bath to be thereafter embedded in paraffin. Immunohistochemical and morphometric analyses were done:cross-sectional area(CSA), and proportions of type I and II fibers were assessed. Demographic, clinical and relevant mechanical ventilation data(days MV, modality, time in CMV, time in SMV, time with DF stimuli) were collected. Significance was set to p< 0.05.

RESULTS. A total of 35 mechanically ventilated patients(14BD,16MS and 5CTL) were included in the study. BD were younger than MS(56(17)years vs.69(12)years;p=0.03) without differences with CTL(63(6)years). There were no significant differences in other demographic variables among the three groups. MS donors were more hours on MV than BD, and as a result, the number of hours in CMV were higher than in BD. MS donors spent a higher percentage of time in SMV and the percentage with DF stimulus trend to statistical significance(table1).

The size of type I and II fibers were significantly reduced in the DF and QD of both donor groups in comparison with CTL. Although MS donors were significantly more hours under MV, there were no differences in the DF CSA between BD and MS. Size of QD type II fibers were significantly decreased in MS compared to BD. Proportions of type I and II fibers did not differ between the three groups.

CONCLUSIONS. BD and MS donors developed both DF and QD atrophy in comparison to CTL patient. More sever QD atrophy was observed in MS donor as a consequence of more days in MV and

more muscle inactivity. Despite more time spent in MV, MS and BD presented no difference in grade of DF atrophy. Our observations suggest that patients who maintain diaphragm stimulus (MS) could present a protector factor for the development of VIDD, and we speculate that an early switch to an assisted mode or spontaneous mode seems clearly desirable in critical patients to attenuate the progressive instauration VIDD.

INTRODUCTION. Microaspiration of contaminated gastric and oropharyngeal secretions is the main mechanism of entry of bacteria into the lower respiratory tract in intubated critically ill patients.

OBJECTIVES. The aim of this study is to determine the impact of enteral nutrition, as compared with parenteral nutrition, on microaspiration of gastric contents.

METHODS. Planned ancillary study of the randomized controlled multicenter Nutri Réa2 study. Primary objective was to determine the impact of enteral nutrition on abundant microaspiration of gastric contents. Secondary objective was to determine the impact

of enteral nutrition on abundant microaspiration of oropharyngeal secretions. Patients with shock receiving invasive mechanical ventilation were randomized to receive early enteral or parenteral nutrition. All tracheal aspirates were collected during the 48h following randomization. Abundant microaspiration of gastric contents and oropharyngeal secretions were defined as the presence of significant levels of pepsin (>200 ng/ml), and salivary amylase (>1685 UI/ml) in >30% of tracheal aspirates, respectively.

RESULTS. A total of 151 patients were included (78, and 73 patients in enteral and parenteral nutrition groups, respectively), and 1074 tracheal aspirates were quantitatively analyzed for pepsin and amylase. Although vomiting rate was significantly higher (31% vs 15%, p = 0.016, HR 2.33 (95% CI 1.17; 4.62)), constipation rate was significantly lower (6% vs 21%, p = 0.010) in patients with enteral than in patients with parenteral nutrition. No significant difference was found regarding other patient characteristics, including the use of subglottic secretion drainage, cuff pressure, or tracheal tube size.

The percentage of patients with abundant microaspiration of gastric contents was significantly lower in enteral than in parenteral nutrition groups (14% vs 36%, p = 0,004; unadjusted OR 0.80 (95% CI 0.69, 0,93), adjusted OR 0.79 (0.76, 0,94)). The percentage of patients with abundant microaspiration of oropharyngeal secretions was significantly higher in enteral than in parenteral nutrition groups (74% vs 54%, p = 0,026; unadjusted OR 1.21 (95% CI 1.03, 1,44), adjusted OR 1.23 (1.01, 1,48)). No significant difference was found in percentage of patients with ventilator-associated pneumonia between enteral (8%) and parenteral (10%) nutrition groups (HR 0.78 (0.26; 2.28)).

CONCLUSIONS. Enteral nutrition, as compared with parenteral nutrition, is associated with significantly lower rates of abundant microaspiration of gastric contents and significantly higher rates of microaspiration of oropharyngeal secretions. Our results suggest that the route of nutrition should probably not be determined based on the risk of abundant microaspiration.

OBJECTIVES. To analyze the impact of SDD on ICU nosocomial infections (NI) and multiresistant bacteria (MRB) compared to another ICU without SDD.

METHODS. Observational, analytical, cohort study, in ICUs of two different hospitals [Hospital Universitario Dr. Negrín, University of Las Palmas (HUDN): 30 mixed beds] and University Hospital San Agustín de Avilés (HUSA)], with 10 mixed beds. The aim was, to compare the incidence on NI in patients that received SDD (HUDN) with patients whose did not receive SDD (HUSA). In order to compare the NI rates we assessed three groups of patients, the group with SDD (HUDN) from October 1, 2011 to September 30, 2016; the group without SDD (HUDN) from October 1, 2010 to 30 / September / 2011 and the HUSA group, without SDD, from April 1, 2012 to

September 30, 2016. SDD was applied in HUDN to patients in whom mechanical ventilation was considered for more than 48 hours. It consists of an oropharyngeal paste, and a solution of tobramycin, colistin and nystatin and intravenous cefotaxime for 4 days. We analyzed demographic variables, type of admission, comorbidities, according to the ENVIN-Helics database. A multivariate statistical analysis of SDD and MRB was performed, as well as an incidence of IN / 1000 days of exposure for each group and were compared with the Poisson model.

RESULTS. Of the 517 NI patients treated in both ICUs, 342 were given SDD (HUDN) and of the remaining 175 patients without SDD, 110 belonged to HUDN and 65 belonged to HUSA. Regarding the analysis of patients with one or more MRB, *Acinetobacter spp.* was more frequent in HUSA (p < 0.001) while extended spectrum betalactamases (ESBLs) were significantly more frequent in HUDN (p = 0.012), although both of them decreased significantly after SDD (from 34.5 % to 23.7%) (Table 1).

In the multivariate analysis (Table 2)

The proportion of patients without SDD in HUDN was almost 5 times higher compared to those of SDD, OR 4.802 (95% CI 1951-11819) In HUSA, without SDD, the risk of *Acinetobacter* infection was 38.73 times higher, OR 38,773 (95% CI 10.812-139.037). In the multivariate logistic regression analysis it can be observed that, a patient without SDD in the HUDN, the OR of developing *Acinetobacter spp.* infection was OR = 10.072 (3.142; 32.291). Also, a patient without SDD in the HUDN, the OR of developing MRB-GNB (gram negative bacteria) infection was OR = 4.8 (1.951; 11.819).In the multivariate analysis of MRB the risk of acquiring a MRB infection was significantly reduced after the application of SDD: OR 0.438 (95% CI 0.299-0.640) and increased in the presence of septic shock. Moreover, ICU NI (ventilator-associated pneumonia, secondary bacteremias and urinary infections), also decreased after SDD (Table 3).

CONCLUSIONS. The SDD decreases the NIs in an environment of high-level of bacteria resistance, as a protective factor for the acquisition of MRB.

Influence of tracheostomies, sub-glottic suction endotracheal tubes and routine chlorhexidine on the rate of suspected ventilator-associated pneumonia in Scottish intensive care units

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0535

INTRODUCTION. Ventilator-associated pneumonia (VAP) is the most common healthcare associated infection (HAI) in mechanically ventilated patients. VAPs are independently associated with an increased length of intensive care unit (ICU) stay, duration of mechanical ventilation and mortality. For this reason it is important that our ICU´s implement strategies to prevent this serious complication of mechanical ventilation. The influence of tracheostomies and routine chlorhexidine are the subject of debate. The use of sub-glottic suction endotracheal tubes (SGT) is not universal.

OBJECTIVES. We aim to determine whether the presence of tracheostomy, sub-glottic suction endotracheal tube or routine chlorhexidine has an influence on the rate of suspected VAP.

METHODS. A prospective national audit was conducted over a one-month period. Local data collectors were recruited and coordinated by the Scottish Intensive Care Society (SICS) Trainee Committee. All patients ventilated for more than 48-hours were included. Baseline HAI data was gathered for each patient on a daily basis. Additional relevant data, such as the presence of a subglottic tube, tracheostomy or regular chlorhexidine administration was also recorded.

RESULTS. This study included 227 patients and 1751 days of data collection. We successfully recruited 14 ICU sites from 11 Scottish Health Boards. 32 patients were suspected of having a VAP (S-VAP). The incidence of suspected VAP was reduced in patients with a subglottic drainage ET tube in place (5.7% vs 11%, RR 0.36, p=0.12). S-VAP was significant increased in patients with a tracheostomy (35.1% vs 10%, RR 3.51, p< 0.0001). Regular chlorhexidine did not demonstrate a significant reduction in S-VAP (12.2% vs 16.7%, RR0.73, p=0.34).

CONCLUSIONS. VAP is a serious complication of mechanical ventilation therefore preventative strategies should be routine. Tracheostomy was associated with a significant increase in suspected VAP, therefore the decision to site a tracheostomy should be carefully considered. Our study showed a tend toward reduction in S-VAP using SGT and may have been significant if our population was larger. Although SGT are more expensive than standard endotracheal tubes we believe our study interpreted with the existing literature suggests that they are effective in reducing VAP rates. We therefore believe routine SGT use should be encouraged in our units, which is in line with existing guidance from the Intensive Care Society (ICS)[1,2]. We believe our results show there is no role for routine use of chlorhexidine therapy in the prevention of S-VAP.

The introduction of a policy of chlorhexidine washing is not associated with a reduction in rates of intensive care associated bloodstream infections, blood culture contamination, and colonisation or infection with multidrug-resistant microorganisms: an interrupted time series analysis

E. Thoonen[1], R. Kengen[1], K. Daveson[1], B. Loong[2], H. Rodgers[1], W. Beckingham[1], K. Kennedy[1], R. Suwandarathne[1], F. van Haren[1]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0536

BACKGROUND. Healthcare-associated infections (HAIs) are a major cause of morbidity and mortality in intensive care patients. The effect of daily washing with chlorhexidine on HAIs is controversial.

METHODS. Interrupted time series (ITS) analysis in a 31-bed tertiary referral mixed ICU, comparing daily washing with water and soap (January 2011 - August 2013) with chlorhexidine washing (November 2013 - December 2015), following the introduction of a unit-level policy of chlorhexidine washing. All ICU patients were included in the study, except: if they were under 18 years of age; if their ICU stay was less than 24 hours, to ensure that all studied patients had at least one exposure to the daily wash intervention; if patients had a known allergy to chlorhexidine. Outcome measures included: clinically significant positive blood cultures attributable to the ICU stay; contaminated blood cultures; newly acquired multidrug-resistant microorganisms (MDRO): methicillin resistant staphylococcus aureus (MRSA), vancomycin resistant enterococcus (VRE), or multi-resistant

gram-negative (MRGN) isolates attributable to ICU from clinical and screening cultures; and newly acquired Clostridium difficile (CDI) cases.Incidence rates of these outcomes were calculated per 1000 patient days. MDRO acquisition rates were corrected for background hospital period prevalence rates of MDRO.

RESULTS. A total of 6634 patients were included in the study. ITS analysis showed no significant level or slope changes in any of the outcome measures following implementation of chlorhexidine washing. The incidence rate of clinically significant positive blood cultures during the chlorhexidine period compared to the water and soap period was 3.6 vs. 4.7 (p=0.37); blood culture contamination rates were 11.8 vs. 9.5 (p=0.56); incidence rates of new ICU associated MDRO acquisitions were 3.22 vs. 3.69 (p=0.27); incidence rates of new CDI were 2.01 vs. 0.79 (p=0.16). Outcomes after adjustment for known and potential confounders were similar.

CONCLUSIONS. In this real-world long-term ICU study, implementation of a unit -level policy of daily washing with chlorhexidine impregnated cloths was not associated with a reduction in the rates of ICU associated clinically significant positive blood cultures, blood culture contamination, newly acquired MDRO isolates, and CDI.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0537

INTRODUCTION. Carriage of extended-spectrum betalactamase-producing Enterobacteriaceae (ESBL-E) is frequent in ICU patients.The knowledge of previous ESBL-E colonization makes clinicians more prone to empirically start carbapenems if a ventilator-associated pneumonia (VAP) is suspected, pending results of respiratory samples cultures (2,3). Studies suggested that previous ESBL-E carriage did not accurately predict an ESBL-E VAP(4). We hypothesized that the quantification of rectal and throat ESBL-E carriage will allow a better prediction of ESBL-E-associated VAP.

OBJECTIVES. To evaluate the impact of rectal and throat carriage of ESBL-E assessed semi-quantitatively to predict ESBL-E- associated VAP in a single medical ICU.

METHODS. Between May 2014 and May 2017, all patients were screened at admission and weekly for ESBL-E (ChromID ESBL, Biomérieux) throat and rectal carriage. Results were given semi-quantitatively (fFig). We recorded the last positive sample collected at least 48 hours before the VAP. VAP was diagnosed using BAL or PTC quantitative culture.

RESULTS. 1,319 patients were analyzed. 284 (21.5%) were ESBL-E carriers.

79 ESBL-E carriers (rectal only n=54; throat only n=2; both n=48) (SAPS 2, 48 [35-64]; age, 58 [49-70] years) acquired 104 VAP episodes after a median of 13 ICU-days. VAP was not due to ESBL-E in 56 (54%) cases (Klebsiella sp . 28 (50%) P. aeruginosa 5 (9%) E. cloacae, 5 (9%) P. mirabilis, 5 (9%) other). ESBL-E was recovered in 48 cases (28 (58%) Klebsiella, 11 (23%), E. coli, 9 (19%) E. cloacae. The duration of ICU stay after VAP (22 [11.5-41] and 15.5 [8.5-36.5] for no ESBL-E and ESBL-E respectively) was similar between both groups.

Empirical therapy contained carbapenems in 62 (61%) cases including 26 (48%) of the no ESBL-E VAP. Predictors of ESBL-E VAP were: lower albumin level on admission (24 vs 26 g/l, p=0.04), a higher ARDS rate (20 (42%) vs 13 (23%) p=0.04) and SOFA score (8 vs 10 p=0.04) at VAP onset. ESBL E coli carriers developed ESBL-E VAP less frequently (n=16 (34%)) than others (n=37 (67.3%, p< .01) Number of ESBL-E rectal carriers were similar in both groups (ESBL-E

VAP 97.9% vs no ESBL-E VAP 98.2%; p=0.9) whereas ESBL throat carriage was more frequent in ESBL VAP (no ESBL VAP 13 (23.2%) vs ESBL VAP 37 (77.1%); p< .01).

When analysing throat and rectal samples semi-quantitatively, the rectal bacterial semi-quantitative load (fig1A, p=0.0079 test for trend) but not the throat bacterial load (fig 1B; p< .0001) were associated with ESBL VAP.

CONCLUSIONS. ESBL-E throat carriage and a high semi-quantitative ESBL-E rectal carriage predict ESBL-E VAP, and should be used to limit the empiric use of carbapenems in patients suspected of ESBL-E VAP.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0538

INTRODUCTION. Sepsis is one of the main causes of death in ICU and, in almost half of the cases, bacteremia is detected. The early detection of bacteremia is valuable, because an adequate and early treatment is fundamental for the survival of the patient.

OBJECTIVE. To identify a metabolomic profile able to predict early the type of microorganism that causes bacteremia in patients admitted in ICU with a diagnosis of sepsis and septic shock, using H1-NMR spectroscopy in urine samples.

MATERIAL AND METHODS. Prospective observational study of cohorts in patients admitted in the ICU with a diagnosis of sepsis

and septic shock during a period of one year. The urine of 62 patients was analyzed on H1-NMR spectroscopy the day of admission. NMR spectra were obtained for each sample in a Broker AVANCE III 600 spectrometer of 14.1 Teslas at 25ºC. These spectre were analyzed by multivariable analysis (PCA) and discriminatory (PLS-DA) and peak integration. The relevant spectral regions were identified and quantified in arbitrary units (relative spectral area). We calculated the means, standard deviations and statistical significance of them by T-Student between the group that tested positive for bacteremia and those that did not (according to microbiological results) and according to the type of microorganism identified (Gram positive / Gram negative / fungi).

RESULTS. 62 patients. 62.9% were men. Age 61.51(± 17.5). Overall Mortality 28.6%. ICU stay of 5 days (1-61). Urine NMR spectra on admission show signs of more than 50 metabolites. The multivariate analysis PLS-DA relies from the admission, metabolic differences between the patients who present bacteremia and those who do not (TPR 87.5%, FPR 17.77%) (Figure 1) and depending on the type of microorganism causing the bacteremia (Figure 2). The metabolites that contribute to the separation of the most prevalent types of microorganisms are isocaproate, alanine, acetyl-lysine, hydroxyacetone, creatine, creatinine and N-oxide of Trimethylamine.

CONCLUSIONS. The metabolomic profile obtained in urine by H1-NMR spectroscopy is able to identify early type of microorganism causing bacteremia in the first hours of admission to the ICU, which may prove to be a crucial advantage in the evolution of the patient.

INTRODUCTION. Acute brain dysfunction due to the pathologic neuro-inflammatory process associated with sepsis is common in the intensive care unit (1). One of the challenges in studying sepsis-induced brain dysfunction (SIBD) is that without a specific diagnostic test, it remains a syndrome diagnosed by exclusion (2). Brain imaging methods are diagnostic procedures which complement neurologic examination. Magnetic resonance imaging (MRI) provides important information on the primary pathologic mechanism of sepsis associated encephalopathy and structural alterations in the brain (3). Furthermore, morphometric analysis of the MRI data using voxel-based approaches has a potential of providing more detailed information about the structure of the brain structures.

OBJECTIVES. Our objective was to provide findings from MRI and VBM of the brain in patients showing neurological alterations due to sepsis and relate it to the inflammatory and disease severity markers of SIBD.

METHODS. In this prospective observational study, 93 SIBD patients (45 men, 48 women; 50.6±12.7 year-old) were enrolled. Patients underwent a neurological examination and brain MRI. Several
severity-of-disease scoring systems were used for evaluation of patient outcome. Serum levels of a panel of mediators [IL-1 β, IL-6, IL-8, IL-10, IL-12, IL-17, IFN- γ, TNF- α, complement factor Bb, C4d, C5a, iC3b, amyloid-b peptides, total tau, phosphorylated tau (p-tau), S100b, neuron-specific enolase] were measured by ELISA. VBM was employed to available patients for assessment of neuronal loss pattern in SIBD.

RESULTS. MRI of SIBD patients were normal (n=27, 29%) or showed brain lesions (n=51, 54.9%) or brain atrophy (n=15, 16.1%). VBM analysis showed neuronal loss in the insula, cingulate cortex, frontal lobe, precuneus, and thalamus. Patients with abnormal MRI findings had worse APACHE II, SOFA, GOSE scores, increased prevalence of delirium and mortality. Presence of MRI lesions was associated with reduced C5a and iC3b levels and brain atrophy was associated with increased p-tau levels. Multivariate regression analysis identified an association between reduced IL-12 level and occurrence of coma.

CONCLUSIONS. Neuronal loss predominantly occurs in limbic and visceral pain perception regions of SIBD patients. Complement breakdown products, IL-12, and p-tau stand out as adverse neuroimaging and neurological outcome markers for SIBD.

INTRODUCTION AND OBJECTIVES. Patients with septic shock undergo extensive physiological alterations that can alter drug pharmacokinetics. A growing body of evidence indicates that standard dosing of antibiotics is not sufficient in many of these patients. Ciprofloxacin is a fluoroquinolone with a wide spectrum of action and the objectives of this study were to use a population pharmacokinetic approach to define **recommendations for effective ciprofloxacin dosing in patients with septic shock.**

PATIENTS AND METHODS. Adult patients with septic shock treated with ciprofloxacin were eligible for inclusion. A drug concentration curve was created from seven blood samples collected during one dosing interval. Ciprofloxacin concentrations were measured by a validated HPLC-MS/MS method. Pharmacokinetic modelling was performed with Monte-Carlo simulations to define dosing regimens that optimised attainment of AUC:MIC ratio > 125 for different minimal inhibitory concentration (MIC) breakpoints as well as empirical or targeted therapy of Pseudomonas aeruginosa.

RESULTS. We included 48 patients with median SAPS II of 49 and 90-day mortality of 33%. Ciprofloxacin pharmacokinetics was best described by a two-compartment linear model including creatinine clearance (CrCL) and body weight as covariates. With a dose of 400 mg q8 and CrCL of 80 mL/min successful target attainment was reached for bacteria with MICs ≤ 0.25 mg/L. For empirical treatment of P. aeruginosa, 600 mg q8 (the maximal simulated dose) only reached a maximum of 68% target attainment. For directed therapy, against P. aeruginosa, a dose of 400 mg q8 reached a 95% successful target attainment only for patients with a low CrCL of 30 mL/min whereas for patients with normal CrCL of 80 mL/min, a dose of 600 mg q8 was needed to reach sufficient AUC:MIC ratios.

CONCLUSIONS. In patients with septic shock, standard ciprofloxacin dosing only achieves sufficient concentrations to successfully treat bacteria with MICs of ≤ 0.25 mg/L and then only in patients with normal or reduced CrCL. To cover bacterial isolates with higher MICs or in patients with augmented renal clearance, doses should be increased and/or administration should be tailored by therapeutic drug monitoring to optimise drug concentration, increase the likelihood of treatments success and reduce the potential of selection of resistant strains.

INTRODUCTION. Hemodynamic resuscitation of septic shock patients is based on optimization of cardiac output in order to improve oxygen delivery to the tissues. Microcirculatory evaluation of critically ill patients has stressed the possibility of discrepancy between the microcirculation and global flow response to a fluid challenge. On the other hand, some authors have shown that some metabolic markers might better reflect the microcirculatory status than traditional macrocirculatory parameters.

OBJECTIVES. To evaluate the coherence between the macrocirculatory and the metabolic response to a fluid challenge in septic shock patients in the early phase of resuscitation.

METHODS. Single-center, prospective, observational study. Septic shock patients within the first 24 hours of ICU admission, monitored with a cardiac output system (PiCCO$_2$), and receiving a fluid bolus (500 mL of crystalloids within 15 minutes) according to their medical team. We measured hemodynamic variables (trans-pulmonary thermo-dilution, TPTD) immediately before, and 15 minutes after volume infusion. Simultaneously to both TPTD, blood samples were obtained from an arterial and a central venous line. We determined cardiac index (CI), central venous oxygen saturation (S$_{cv}$O$_2$), lactate, central venous-to-arterial carbon dioxide difference (P$_{cva}$CO$_2$), PcvaCO2 corrected by the arterial-to-venous oxygen content difference (P$_{cva}$CO$_2$/C$_{av}$O$_2$), and the global oxygen consumption index (iVO$_2$) before and after the fluid challenge. Comparisons were performed using non-parametric tests.

RESULTS. .We studied 65 fluid boluses. The trigger for fluid administration was S$_{cv}$O$_2$ < 70% (43%) and/or persistence of elevated lactate values (79%). Only 34% of the patients showed an increase in CI > 10% (CI-Responders). Among CI-Responders, only 32% also increased iVO$_2$ values > 10% (VO$_2$-R). The presence of low S$_{cv}$O$_2$ values at inclusion was not associated with VO$_2$-R, regardless of the CI response. Baseline lactate, P$_{cva}$CO$_2$ and P$_{cva}$CO$_2$/C$_{av}$O$_2$ values were not different in VO$_2$-R and non-responders (VO$_2$-NR). In those patients whose CI increased (CI-R), changes in the metabolic parameters did not differ between VO$_2$-R and VO$_2$-NR: S$_{cv}$O$_2$ increased in 80% of VO$_2$-R vs 92% of VO$_2$-NR (*p* ns); lactate decreased in 20% of VO$_2$-R vs

58% of VO$_2$-NR (p ns); and P$_{cva}$CO$_2$/C$_{av}$O$_2$ did not decrease in any VO$_2$-R, while it decreased in 33% of VO$_2$-NR (p ns).

CONCLUSIONS. Increases in CI as results of a fluid challenge do not preclude a positive metabolic response, defined as the increase in VO$_2$, even in low S$_{cv}$O$_2$ situations. The current concept of "Fluid-Responder" might not be the most appropriate, since it does not take into account the evaluation of the VO$_2$/DO$_2$ dependence. No single metabolic parameter seems to accurately reflect the VO$_2$ response to a fluid challenge. Integration of metabolic markers informing of this VO$_2$/DO$_2$ dependence seems complex, but necessary in order to avoid potentially harmful interventions.

INTRODUCTION. Brain natriuretic peptide (BNP) is a well-studied biomarker of heart dysfunction, secreted by cardiomyocytes in response to stretching, in the presence of volume or pressure overload. BNP has been suggested to correlate with left ventricular systolic dysfunction (LVSD) and mortality in sepsis. However, the optimal cut-off level of BNP in the intensive care setting is still unclear.

OBJECTIVES. To determine the optimal cut-off level of BNP rule out the diagnosis of LVSD in septic patients admitted to the Intensive Care Unit (ICU). To create a model to predict LVSD after initial resuscitation in septic patients, based upon biomarkers and easy to obtain echocardiographic parameters.

METHODS. We conducted a single-centre prospective observational cohort study. Patients admitted to the ICU with sepsis over a 20-month period were enrolled, excluding those with ischemic or valvular heart disease and pacemakers. Admission levels of biomarkers were obtained and transthoracic echocardiogram (TTE) was performed within the first 24 hours. Multivariate logistic regression analysis was used to create predictive models. Clinical, echocardiographic and analytical variables with p < 0.1 on univariate analysis were considered for inclusion in the models.

RESULTS. In our analysis, a cut-off level of BNP >400 pg/ml for the diagnosis of LVSD in septic patients showed 82% sensitivity, 68% specificity and 95% negative predictive value (p< 0.0001). We created three predictive models to identify LVSD in the septic patient (see Table and Figure):
• Model 1: Log$_{10}$BNP, OR 7.57 (95%CI: 1.85-39.76) and TAPSE, OR 0.63 (95%CI: 0.47-0.78).
• Model 2: Log$_{10}$BNP, OR 11.72 (95%CI: 2.36-82.74), LVOT VTI OR 0.73 (95%CI: 0.54-0.93) and TAPSE, OR 0.75 (95%CI: 0.55-0.95).
• Model 3: BNP >400 pg/mL, OR 14.62 (95%CI: 3.08-105) and TAPSE, OR 0.62 (95%CI: 0.45-0.78).

CONCLUSIONS.
• Detection of BNP levels < 400 pg/mL after initial resuscitation excludes the presence of LVSD in the septic patient, with a high negative predictive value. Therefore, the optimal cut-off levels of BNP for the diagnosis of LVSD in septic patients should be considered higher than in general population.
• Combination of plasma BNP levels >400 pg/mL and TAPSE < 17 mm can predict the presence of sepsis-induced LVSD in the critically ill patient.
Fig 1 (abstract 0542). Predictive models to identify LVSD in the septic patient: AUCROC comparison

Table 1 (abstract 0542). Predictive models to identify LVSD in the septic patient

	AUCROC	Standard error	95%CI	p
Model 1 (Log$_{10}$BNP, TAPSE)	0.9093	0.03	0.836-0.983	<0.0001
Model 2 (Log$_{10}$BNP, LVOT VTI, TAPSE)	0.9403	0.02	0.892-0.989	<0.0001
Model 3 (BNP >400 pg/mL, TAPSE)	0.9330	0.03	0.882-0984	<0.0001

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0543

INTRODUCTION. After surviving ICU, some patients may experience memories and recollections about his/ her ICU stay. The aim of this study was to report and analyze the memories and recollections of adult patients three months after ICU discharge.

METHODS. Retrospective cohort observational study. The study participants were all patients who were discharged alive from general ICU and from the hospital between february 2012 and November 2017, and who were evaluated by the psychology team in the Multiprofessional Office Clinic (MPOC) three months after ICU discharge. Inclusion criteria: patients > 24 h in ICU; >18 years old and attended the MPOC. The tool used to evaluate memory was a questionnaire applied by the MPOC psychologist. The types of memories were classified as memories of real events (memories related to actual facts regarding treatment, environment, emotional aspects) and illusion memories (related to illusory events such as

nightmares, dreams and hallucinations, or which the patient believes was not real). All memories of any event related to the treatment, environment or emotional experience in which the patient was believed to have occurred during the period of consciousness recovery were accepted as memories.

RESULTS. A total of 749 patients were evaluated (62.8% male, mean age 43.5 years, mean ICU length of time 10.2 days, mean APACHE II 20.7, most common admission causes: trauma and medical).

More than half (56.0%) of the patients reported some type of ICU memory. Of these (n = 419), 61% reported memories of real events, 4% illusion memories and 35% presented a combination of real and illusory memories. As for memories of real events, the most frequent memories were: discharge to the ward (83.2%), family visit (76.4%); presence of confusion / agitation (67.2%), physical restraint (53.7%) and feeling thirsty (51.2%). Remarks related to the endotracheal tube, bronchial hygiene therapy and extubation were reported by only 24.7% of the patients. When comparing patients with or without illusory memories, patients with illusory memories had a lower incidence of male gender (42% x 57%), older age (44.2 x 41.4), higher APACHE II (22 x 17) and longer MV (7.0 x 4.9 days) and ICU (9.8 x 7.6 days) than patients without illusory memories.

CONCLUSIONS. The incidence of memories and recollections in post-ICU survivors is high, including illusory memories. The patient´s own perception of being agitated and confused is frequent. Patients with higher severity of acute disease and longer MV and ICU time tend to have a higher chance of presenting illusory memories after the ICU.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0544

INTRODUCTION. Moral distress occurs when health care professionals are constrained from practicing what they believe to be ethically appropriate actions. It causes feelings of frustration, guilt, anger, sadness, fear, and depression. Previous studies showed high levels of moral distress among intensive care nurses, and association with burnout and attrition. Recent reports on intensive care professionals´ well-being rarely focus on how they cope with this kind of stress.

OBJECTIVES. To examine moral distress among intensive care physicians and nurses, and to explore coping strategies in those who had high levels of moral distress.

METHODS. A survey was done in seven ICUs of five hospitals in Japan. Two of the hospitals were academic, and the other three were non-academic. All ICU physicians and nurses who were directly involved in patient care for more than one year were invited to participate during February and March 2018. The survey included Japanese translations of the Measure of Moral Distress for Healthcare Professionals (MMD-HP, a revised version of the Moral Distress Scale-R), Maslach Burnout Inventory General Survey (MBI-GS), Brief COPE (measures coping strategies), and demographics. We assessed correlations between MMD-HP scores and scores of each MBI domain. Among participants whose MMD-HP scores were greater than the mean, coping strategies were explored stratified by their intention to leave the position due to moral distress ever.

RESULTS. We distributed 274 questionnaires; 215 (79%) were returned, of which 27 (13%) were excluded because the MMD-HP questionnaire was not completed. The overall mean MMD-HP score was 91 (standard deviation 54). The MMD-HP score was correlated with the intention to leave the position due to moral distress (Odds ratio 1.14, 95% Confidence Intervals, 1.07 to 1.22). The mean MMD-HP score of physicians was 82 (SD 57), and that of nurses was 94 (SD 53, p = 0.22). Nurses also had higher MBI scores than physicians (Table1). The MMD-HP score correlated weakly with the MBI exhaustion domain (R = 0.28, p < 0.001) and the cynicism domain (R = 0.36, p < 0.001), but not with the professional efficacy domain (R = 0.005, p = 0.32) (Figure 1). Among those who had a high MMD-HP score, participants with intention to leave their position cope with stressful situations most frequently by behavioral disengagement, self-blame, and less frequently by positive reframing and humor (Table 2).

CONCLUSIONS. This study is the first to demonstrate the level of moral distress and burnout among ICU physicians and nurses in Japan. Moral distress was associated weakly with burnout. Those who had intention to leave their position due to moral distress cope with stressful situations less frequently in positive ways.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0545

OBJECTIVE. To analyze patients who survived the critical illness who presented delirium during ICU admission, and to evaluate the impact on functional independence three months after discharge from the ICU.

METHODS. Adult patients admitted to the general ICU who responded to CAM-ICU and survived to hospital discharge. The evaluation of Confusion Assessment Method scale (CAM-ICU) was performed three times a day until ICU discharge; the Functional Independency Measure (FIM) scale was evaluated at the ICU discharge and at the outpatient clinic (three months later). For the variables that presented normal distribution, the data were presented using mean ± standard deviation and the t student test was performed. For the variables that did not present normal distribution, the data were presented as a median ± interquartile range and the non-parametric Mann Whitney test was performed.

RESULTS. Eighty-one patients were included in the study, of whom 33% had delirium in the ICU. The delirious patients presented higher age, higher incidence of comorbidities, higher SOFA and APACHE II admission score, longer ICU and hospital stay, use and time of MV, time of sedation and total dose of midazolan and fentanyl than non-delirium patients. Regarding GCS and FIM, both were lower in the delirium patients than the non delusional group at ICU discharge and at the outpatient clinic; however, both groups showed improvement in functional Independence (FIM) three months later.

CONCLUSION. Delirium was more common in the ICU in more severe patients, with longer ICU and MV, and with greater use of sedatives. The delirium in the ICU negatively influences the functional independence in the discharge of the intensive care unit, and potentially affecting the recovery of the functionality of these patients three months after discharge.

Table 1 (abstract 0545). See text for description

	Delirium (n=27)	No Delirium (n=54)	p-value
ICU length of stay (days), median (IQR)	10 (6-15)	4 (3-8)	<0.001
Hospital length of stay (days), median (IQR)	25 (20-41)	15.5 (11-21)	0.001
GCS at ICU discharge, median (IQR)	14 (11-15)	15 (15-15)	<0.001
FIM at ICU discharge, mean ± SD	56 ± 26.9	76 ± 26.5	0.003
GCS after 3 months, median (IQR)	14 (11-15)	15 (15-15)	0.0009

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0546

INTRODUCTION. Sleep disruption is a well known problem among critically ill patients in an intensive care unit (ICU) which persist during recovery and after transfer to step down unit (SDU) or wards. Objective. To evaluate 1)patterns of sleep in patients recovering from CCI in ICU and SDU and 2) Effect of environmental factors (noise, light) on sleep.

MATERIALS AND METHODS. 24 hr polysomnography (PSG) study was done in patients recovering from CCI in ICU with simultaneous recording of noise, light and nursing care activities and repeated after shifting to step down unit (SDU).

RESULTS. 26 patients underwent PSG study in ICU and then in SDU. Mean APACHE II and SOFA Score were 19.38 ± 3.72 and 5.11± 1.27. Paired t-test showed reduction in N1% (28.80 ± 7.30, 21.8 ± 4.3: p = 0.0001) and N2% (60.3 ± 8.65, 55.8± 4.0p = 0.021) and improvement in N3% (6.66 ± 2.30, 14.34 ± 3.8 p < 0.0001) and REM% (4.20 ± 3.68, 8.2 ± 3.5 p = 0.01) . Day time sleep and arousal index were reduced (49.55 %, 37.71%; p< 0.0001) and (22.65 ± 10.49, 16.55 ± 5.15: p = 0.006) respectively. The difference in mean illuminance during day and night time in ICU (77.09 ± 3.66, 14.98 ± 2.04 lux) and HDU (160.52 ±6.07, 23.67 ±2.62lux) was significant (p< 0.0001). Mean Sound level was high (59.17±1.69 dB,59.12±1.49 dB:p = 0.904). Mean nursing care activities difference was significant (50.8± 6.34 , 33.96 ± 5.34: p< 0.0001)(table).

REFERENCE(S)

Sleep is highly disturbed and fragmented in ICU and SDU. However, the pattern of sleep shows trend towards recovery as patient recovers from critical care illness.

INTRODUCTION. The PEPaNIC-RCT has shown that withholding supplemental parenteral nutrition for up to one week in the PICU (late-PN) reduced infections and accelerated recovery from critical illness in children as compared with early-PN [1].

OBJECTIVES. The aim of this study was to investigate the impact of withholding supplemental parenteral nutrition early during pediatric critical illness on long-term physical and neurocognitive development.

METHODS. Two years after inclusion in the RCT, the 1440 patients were approached for possible assessment of physical/neurocognitive development as compared with 405 matched healthy children. Assessed outcomes comprised growth, health status, parent/caregiver-reported executive functions and emotional and behavioral problems, tests for intelligence, visual-motor integration, alertness, motor-coordination, inhibitory control, cognitive flexibility, and memory. To handle partial response rates among tested children, multiple data imputation by chained equations was performed prior to multivariable linear and logistic regression analyses adjusted for risk factors.

RESULTS. At 2-years follow-up, 60 late-PN children (8.4%) and 63 early-PN children (8.7%) had died (P=0.81), 68 late-PN patients (9.5%) and 91 early-PN patients (12.6%) were too disabled for neurocognitive assessment (P=0.05) and 786 patients consented for testing. Late-PN did not adversely affect growth, health status or neurological functioning, but improved executive functioning (beta-estimate late-PN versus early-PN -2.258; 95%CI[-4.012;-0.504], P=0.01), more specifically inhibition (-3.422; 95%CI[-5.171;-1.673], P< 0.001), working memory (-2.016; 95%CI[-3.761;-0.270], P=0.02) and meta-cognition

(-1.957; 95%CI[-3.694;-0.220], P=0.02). Also externalizing behavioral problems (-1.715; 95%CI[-3.325;-0.106], P=0.03) and visual-motor integration (0.468; 95%CI[0.087;0.850], P=0.01) were improved. After Bonferroni-correction for multiple comparisons, the effect on inhibitory control remained significant.

CONCLUSIONS. Withholding early-PN in the PICU did not negatively affect survival, growth or health status 2 years later and partially improved neurocognitive development. (clinicaltrials.gov-number, NCT01536275)

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0548

INTRODUCTION. In recent years there has been growing concern about the unnecessary application of certain interventions in critical patients that have proven to be ineffective, consume a significant amount of health resources and are not exempt from yatrogeny.
With the intention of improving the quality of health care and reducing the use of unnecessary interventions, the project Commitment for Quality coordinated by the Ministry of Health of Spain and scientific societies as the Spanish Society of Intensive Care Medicine and Coronary Units (SEMICYUC) established 5 "not to do" recommendations.
OBJECTIVE. The purpose of this study is to measure the extent of unnecessary interventions in our Intensive Care Unit (ICU).
METHODS. We conducted a preliminary observational study in a 16-bed polyvalent intensive care unit from April 2017 to January 2018. A randomized non-consecutive 8-day follow up of the 5 recommendations in all admitted patients to the ICU was carried out.
All attending physicians in the Intensive Care Unit were asked about the need for antibiotic therapy, clinical indications of scheduled blood tests and chest XR, the need to continue isolation measures initiated and the need to red blood cells (RBC) transfusion according to clinical status and hemoglobin (Hb) levels, following the 5 recommendations established for critical patients from the project Commitment for Quality, which are:
1. Do not continue with empirical antibiotic treatment without assessing daily its need and possible de-escalation
2. Do not perform blood tests routinely
3. Do not perform chest x-rays routinely
4. Do not maintain isolation measures when they are no longer needed
5. Do not transfuse RBC in hemodynamically stable, non-bleeding critically ill patients, without cardiological or central nervous system involvement with Hb greater than 7 gr / dl
Descriptive statistics include frequencies and percentages for categorical variables.

RESULTS. Six attending physicians provided input for a total of 114 patient days. Results are shown in the table.
The recommendation in which there was less compliance was not to perform routine blood tests (15% of the patients analyzed), followed by not to perform chest radiographs routinely(3.5%).
A total of 26 recommendations were not achieved from all the patients-day analyzed (23%).
CONCLUSIONS. A significant part of the interventions performed in our patients were not justified with the consequent patient discomfort, work overload and increase in costs.
Health care professionals should carefully strategize and optimize efforts to reduce unnecessary interventions and avoid wasteful clinical practice.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0549

INTRODUCTION. SIRS has been long advocated as a prognosis and triage method to identify patients at high risk of dying. Aging has been suggested to impact host response to stressors such as trauma, surgery and infection and could therefore modulate the presence of abnormal laboratory and vital signs in patients with severe infection.
**OBJECTIVES.** To assess the association between age and presence of SIRS criteria in patients admitted to intensive care units with severe infection.
METHODS. We included critically ill patients admitted to 93 intensive care units (ICUs) in Brazil from January 2014 until December 2015 with suspected infection and admission SOFA score ≥2 points; we excluded patients with missing information on SIRS criteria. We build a Poisson regression model with number of SIRS criteria (0-4) as dependent variable using age, need for urgent surgery, admission source (ward or emergency room), SOFA score, diabetes and cancer as predictors. We also built linear models for each of the SIRS criteria components using the same variables as predictors. Finally, we built a logistic regression model for SIRS higher or lower than 2 points using the same approach.
RESULTS. Out of 18,184 with infection and a SOFA score ≥2 points, 15,971 (89%) had complete data for analysis. Mean age was 68 years (SD 19). 6,490 (40%) patients had less than 2 SIRS criteria. The number of SIRS criteria decreased with increasing age (Figure). Age was independently associated with lower number of SIRS criteria (reduction of 3% on mean SIRS value for each 10 years increase in

age). Increasing age was also associated with lower heart rate (-2.25 beats per minute /10 years), respiratory rate (-0.1 breaths per minute/10 years) and temperature (-.05 °C/10 years) at admission, but not with leukocyte count. In logistic regression, the odds for presence of at least 2 SIRS criteria was 0.90 for each 10-years increase in age.

CONCLUSIONS. Age was associated with lower number of SIRS criteria in patients admitted to ICUs with severe infection. Prospective studies are necessary to assess whether age may impact the use of SIRS criteria for severe infection screening.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0550

INTRODUCTION. Randomised controlled trials have shown that low tidal volume venitlation (TV) (6-8 mL/kg ideal body weight (IBW)), is beneficial in ventilated patients on the intensive care unit (ICU) (1-2), but the adoption of this strategy has been inconsistent.(3-4).

OBJECTIVES. Assess compliance with protective lung ventilation strategies before and after the introduction of display monitors highlighting recommended ventilation in 2 UK general ICUs (total of 22 beds).

METHODS. A prospective observational before-after study was undertaken (2016-2017). The units use a clinical information system (CIS) that automatically collects information relating to patient care including ventilator data. Consecutive patients undergoing controlled mechanical ventilation were included. The intervention consisted of two large display screens at each ICU configured to display TVes derived from the CIS in mL/kg IBW. Warnings were produced when TVe >8ml/kg, which resulted in the TVe cell turning red. We included only patients with at least 24 hours of ventilator data. The first 12-month period acted as the control period. No protocols or quality improvement processes were changed, nor was additional training or education undertaken and ventilation equipment was the same in both the control and intervention period.

RESULTS. From 70,654 data points we included 36,197 from patients meeting the inclusion criteria. There was a small statistically significant fall in median VTe/Kg after the intervention (from 7.7

[interquartile range 6.6-9.0] to 7.5 [6.6-8.6], P< 0.001). Fewer ventilator episodes after the intervention were ≥8ml/kg (38% vs 42%, OR 0.84 95% CI 0.81-0.88, P< 0.001) or ≥10mls/kg (14% vs 18%, OR 1.37 95% CI 1.29-1.44, P< 0.001). PEEP levels were higher following the intervention (6 [5-8] pre vs 7 [5-10] post, P< 0.001) and were more often in the recommended range (79% vs 76%, OR 1.16, 95% CI 1.11-1.22, P< 0.001).

CONCLUSIONS. A simple prominent display improved compliance with best ventilation practice in two non-specialist general ICUs, maintained over a 1-year period. Effects on patient outcomes should be an avenue of future study.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0551

INTRODUCTION. Each day we investigate measures of the circulation to guide diagnosis and treatment. The diagnostic accuracy of clinical examination in diagnosing shock as reflected by an inadequate cardiac output (CO) or cardiac index (CI) has been questioned [1].

OBJECTIVES. To determine whether students and trained clinicians can give an estimate of low cardiac output based on standardized clinical examination in patients acutely admitted to the Intensive Care Unit (ICU).

METHODS. This study describes one of the outcomes of the Simple Intensive Care Studies - I (SICS-I). This prospective cohort study included all consecutive adults who were acutely admitted with an ICU stay expected to last beyond 24 hours. We assessed accuracy scores of cardiac index (CI) estimates and compared them to CI measured by critical care ultrasonography. CI measures were

independently scored by a core laboratory. Investigators were asked to estimate cardiac pump function as 'poor', 'moderate', 'reasonable', or 'good'. For diagnostic test analyses 'poor' and 'moderate' estimates were grouped as 'low', and 'reasonable' or 'good' estimates were grouped as 'high'. The CI measurements were categorized in two groups to match the estimate groups as follows: 'low' CI $\leq$ 2.2 L/min/m^2 and 'high' CI > 2.2 L/min/m^2.

RESULTS. From 27 March 2015 until 22 July 2017, 1075 patients were included in the SICS-I of which 828 patients had CI measurements. Diagnostic test analyses for estimating a low cardiac index is shown in table 1. Sensitivity varied from 47% to 67% and specificity varied from 64% to 76%. Positive likelihood ratio was 1.47 (1.22 - 1.78) and negative likelihood ratio was 0.77 (0.66 - 0.90) for all groups. Level of training had no influence on improvements of estimates.

CONCLUSIONS. The diagnostic accuracy as defined by the positive and negative likelihood ratio for estimation of cardiac pump function indicate that estimating of cardiac pump function in critically ill patients has value. The first step in gathering information on the circulation is clinical examination.

Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0552

INTRODUCTION. Computerized tomography (CT) is the gold standard imaging technique to quantify loss of aeration in ARDS patients and to determine the morphology of lung injury and the consequent response to recruitment manoeuvres. Transfers to radiology ward is time and resource-consuming and implies a significative risk for the patient. The role of LUS in evaluating aeration in comparison to CT scans has not been determined.

OBJECTIVES. The aim of our study was to assess if LUS can be a reliable method to quantify the loss of aeration and to predict lung injury morphology in ARDS patients compared to CT scan.

METHODS. LUS was performed bedside whenever a CT scan was available for comparison. Linear (15-12 Mhz) and convex (5-3 Mhz) probe were used to evaluate pleural line and lung parenchyma.

Twelve sections, corresponding to 6 CT landmarks for hemithorax, were evaluated and a score from 0 (normal) to 3 (consolidation) was given. Total LUS score (LUS_{tot}) and regional cranio-caudal LUS score, derived as the sum of the 4 non-dependent (LUS_{ND}), the 4 intermediate (LUS_{int}) or the 4 dependent (LUS_{dep}) fields, were calculated. CT scans quantitative analysis was performed and expressed in Hounsfield Units and the percentage of air (Pair) was derived. According to CT scans, ARDS pattern was defined as diffuse/patchy or lobar. The optimal cut-offs values of global and regional LUS scores in identifying ARDS pattern were analysed by ROC curve analyses with Youden method for empirical cut-point estimation.

RESULTS. Forty-one LUS evaluations were performed on 26 patients. Study population, mechanical ventilation and extracorporeal support characteristics are described in **Table 1** and **2**. The agreement between LUS score for every field and CT scan evaluation in terms of Pair is shown in **Figure 1**. LUS_{tot} was 24 (18 - 27). Regional LUS score was 7 (4 - 8), 8 (6 - 9) and 10 (7 - 10) for non-dependent, intermediate and dependent fields, respectively (p< 0.01 LUS_{dep} VS LUS_{ND} and LUS_{dep} VS LUS_{int}). Regional LUS_{ND} score could identify diffuse/patchy pattern with an AUC_{ROC} of 0.95 (SE=91% and SP=86% for LUS cut-point=3 - **Figure 2**).

CONCLUSIONS. LUS can reliably quantify loss of aeration and can be used to identify ARDS morphology.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0553

INTRODUCTION. Although arginine vasopressin has been used as an additional drug in refractory shock in worldwide clinical practice, there are no prospective studies using it as a first choice therapy in patients with cancer and septic shock.

OBJECTIVES. The aim of this study is to assess if the use of arginine vasopressin would be more effective on treatment of septic shock in cancer patients than norepinephrine regarding 28-day mortality and organ failure.

METHODS. We performed a single center, randomized, parallel-group, double-blind, controlled trial in Brazil. Patients with septic shock were randomized in a 1:1 ratio to receive either vasopressin or norepinephrine as vasopressor therapy. The vasopressor infusion was titrated to maintain a mean arterial pressure (MAP) of at least 65 mmHg. Eligible participants were all adult patients with cancer, aged 18 yr or more, with septic shock admitted to the intensive care unit (ICU). The primary outcome was defined as all-cause mortality rate at 28 days after randomization. The pre-specified secondary outcomes were defined as all-cause mortality rate at 90 days after randomization and Sequential Organ Failure Assessment (SOFA) score 96 hours after randomization.

RESULTS. A total of 250 patients were randomly assigned, 125 into the vasopressin group and 125 into the norepinephrine group. The duration of the vasopressor therapy was similar between groups. No significant difference was observed regarding hemodynamic data, urinary output and perfusion markers. All-cause mortality rate at 28 days was 56.8% in the vasopressin group and 52.8% in the norepinephrine group (P=0.525). All-cause mortality rate at 90 days was also similar between groups. There was no significant difference between groups in SOFA score within the first 96 hours after randomization.

CONCLUSIONS. In this randomized clinical, the use of arginine vasopressin did not reduced 28-day all-cause mortality in cancer patients with septic shock when compared with norepinephrine (NCT01718613).

Relationship between time to positivity of blood culture and mortality according to the site of infection

Y.W. Um, J.H. Lee, Y.H. Jo, J. Kim, Y.J. Kim, H. Kwon
Seoul National University Bundang Hospital, Emergency Medicine, Seongnam, Korea, Republic of
Correspondence: Y.W. Um
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0554

INTRODUCTION. Sepsis is a life-threatening condition resulting from a dysregulated host response to infection, and the incidence of sepsis is increasing and mortality rate still remains high.

Time to positivity of blood culture (TTP) could reflect the bacterial load of patients, and it was associated with severity and a prognostic factor in bloodstream infection according to previous studies. However, these studies mainly focused on the relationship between TTP and specific microorganisms in blood stream infection. In clinical settings, clinicians could not aware of specific microorganisms until the final report would be made. In addition, the rate of positivity of blood culture and the severity of sepsis were different according to the site of infection. Therefore, the relationship between TTP and the outcomes in sepsis might be different, but it has not been evaluated yet.

OBJECTIVES. This study was performed to evaluate the relationship between time to positivity of blood culture (TTP) and mortality rate in sepsis and septic shock according to the site of infection.

METHODS. We performed a retrospective cohort study of patients with sepsis and septic shock in a tertiary care, emergency department. The rates of positivity of blood culture and mortality and the relationship between TTP and 28-day mortality rate were compared between patients with different sites of infection of lung, abdomen, urogenital and others.
RESULTS. A total of 2668 patients were included and overall mortality rate was 21.6%. The rates of positivity of blood culture and mortality were different between the sites of infection (P < 0.001).

The relationship between TTP and mortality rate of total patients, patients with lung and urogenital infection did not have any relationship. Patients with abdominal infection showed negative correlation between TTP and 28-day mortality rate. In patients with abdominal infection, TTP < 20 h was independently associated with 28-day mortality compared with patients with negative blood culture (hazard ratio. 1.65; 95% confidence interval, 1.12-2.42). However, there was no difference in mortality rate between patients with TTP $\geq$ 20 h and negative blood culture.

CONCLUSIONS. The shorter TTP of the patients with abdominal infection was associated with 28-day mortality rate in patients with sepsis and septic shock.

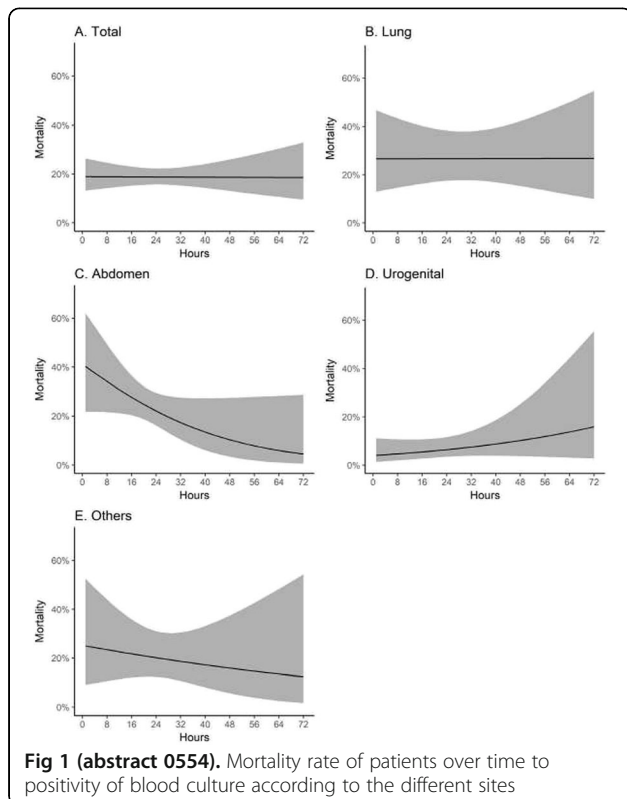
Obstructive sleep apnea increases risk of sepsis, but with improved survival

V. Bansal, T. Weister, R. Kashyap, E. Festic, A. Lee
Mayo Clinic, Jacksonville, United States
Correspondence: A. Lee
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0555

INTRODUCTION. Obstructive sleep apnea (OSA) is a prevalent disorder with an estimated prevalence of 20% in the United States. Animal models have demonstrated sleep deprivation is associated with immune dysregulation and an increased susceptibility to infection, while hypoxic preconditioning may suppress inflammation and theoretically provide a protective effect.

OBJECTIVES. We aimed to investigate whether OSA would predispose patients to sepsis, and whether it would worsen sepsis-related outcomes.

METHODS. Adult residents of Olmstead County that required hospitalization for at least one day in 2013 were eligible. Validated electronic tools were used to identify OSA and sepsis by both sepsis-2 (systemic inflammatory response syndrome) and sepsis-3 (sequential organ failure assessment) definitions. Sepsis-related outcomes included need for invasive ventilation and hospital mortality. Multivariable logistic regression analysis was utilized to determine whether OSA was an independent risk factor for sepsis and hospital mortality; adjusting for age, sex, and the Charlson comorbidity index (CCI), and for those requiring ICU admission, the acute physiology and chronic health evaluation-III score (APACHE-3). Odds ratios (OR) with their 95% confidence intervals (CI) are reported as a measure of risk.

RESULTS. Of the 6131 eligible subjects (median age 56-years, 39% male), OSA was identified in 21% (n=1265), sepsis-2 in 17% (n=1052), and sepsis-3 in 5% (n=319). In univariate analyses, OSA was a significant risk factor for both sepsis-2 (OR=2.3, CI:2.0-2.6) and sepsis-3 (OR=1.4, CI:1.1-1.8). After adjustment for age, sex, and comorbidities, OSA remained a significant risk factor for sepsis-2 (OR=1.8, CI:1.5-2.1), but not sepsis-3 (OR=0.92, CI:0.70-1.2). As expected, sepsis-2 and sepsis-3 were associated with increased mortality, but OSA was independently protective against all-cause hospital mortality (OR=0.50, CI:0.27-0.92), including after adjustment for sepsis-3 (OR=0.50, CI:0.27-0.95) and sepsis-2 (OR=0.47, CI:0.25-0.87). However, for the subset of patients admitted to the ICU (17%) with sepsis, OSA was not significantly protective against death (OR=0.67, CI:0.025-1.8), nor invasive ventilation (OR=1.2, CI:0.70-2.2). OSA patients required less


vasopressors, but this was not statistically significant (4% v. 7%, p=0.11).

CONCLUSION. In this large cohort of patients, OSA was found to be an independent risk factor for sepsis by the more sensitive sepsis-2 criteria, but not the more prognostic sepsis-3 definition. Paradoxically, OSA appeared protective against hospital mortality, even after adjustment for age, gender, comorbidities, and sepsis. The findings are consistent with pre-clinical work and hypotheses that OSA patients may be at an increased risk for infection, but may better endure its complications.

The effect antibiotics duration on mortality and infectious complications in critically-ill septic patients- a meta-analysis

M. Khpal, A. Baheerathan, N. Arulkumaran, M. Singer
UCL, Bloomsbury Institute of Intensive Care Medicine, London, United Kingdom
Correspondence: M. Khpal

OBJECTIVES. To investigate the effect antibiotics duration on mortality and infectious complications in critically-ill septic patients (PROSPERO registration number: CRD42018091566).

METHODS. We carried out a systematic search of Pubmed, Embase, clinicaltrials.gov, and CENTRAL databases to identify randomized clinical studies investigating duration of antibiotics in intensive care units. The primary outcome was mortality. Secondary outcomes were treatment failure, secondary infections, and incidence of antimicrobial resistance. Statistics were performed using Review manager for Mac (version 5.1) software. Data on dichotomous outcomes are presented as (odds ratio (OR) (95% confidence intervals), p-values) and data on continuous outcomes are presented as mean difference (95% confidence intervals) and p-values.

RESULTS. 5018 titles were retrieved from the search. Of these, 20 studies (5373 patients) were included in the final analysis (Figure 1). Strategies to optimise antibiotic use included
(i) biomarker guidance (procalcitonin; PCT) (12 studies),
(ii) clinical algorithms (3 studies), or
(iii) pre-specified fixed antibiotic duration (5 studies).
PCT-guidance (-1.26 (-1.98 to -0.89); p< 0.001) resulted in shorter antibiotics duration, however, clinical-algorithms did not demonstrate a reduction (-3.7 (-11.7 to 4.5); p=0.38). The average number of days of antibiotics use in fixed-duration studies were 6.6±2.6 days and 12.4±3.7 in the short and long duration arms respectively (p=0.021). PCT-guided antibiotics therapy was associated with lower *mortality* (OR=0.85 (0.74-0.99); p=0.03), while clinical algorithm based treatment (OR=0.73 (0.46-1.16); p=0.18) and fixed-duration antibiotic treatment (OR= 1.28 (0.89-1.85); p=0.18) were not.
Treatment failure was not reported in the clinical algorithm studies. Neither fixed duration (OR=1.23 (0.89-1.70), p=0.21) nor PCT-guided antibiotic studies (OR=0.90 (0.78-1.04); p=0.15) were associated with treatment failure.
The incidence of *secondary infections* was reported in all 3 clinical-algorithm studies, 3 of 5 fixed-duration studies, and 4 of 12 PCT-guided studies; no difference was seen between treatment and control arm in any group. Reporting of incidence of antimicrobial resistance was only available in 3 studies.

CONCLUSIONS. Studies using PCT-guidance for antibiotics duration and fixed duration were associated with shorter duration of antibiotic use. The reduction in the number of days of antibiotics use was not associated with greater treatment failure. The fixed duration studies did not factor in biological response to treatment and were not associated with a mortality benefit. The reduction in antibiotics duration seen with PCT- guided treatment was associated with a mortality benefit. Further research is required to investigate the potentially negative impact of prolonged antibiotics duration on the immune cells of patients with sepsis.

INTRODUCTION. The quick Sequential Organ Failure Assessment (qSOFA) has been proposed for prediction of mortality in patients with suspected infection outside the intensive care unit.

OBJECTIVES. To test the hypothesis that the qSOFA can more accurately predict in-hospital mortality than systemic inflammatory response syndrome (SIRS) criteria in patients with suspected infection in the emergency department.

METHODS. This prospective, multi-center, diagnostic accuracy study, initiated in December 2017, included 37 emergency departments in Japan. Patients consecutively participated in the study if they were

suspected of infection, received antibiotics, underwent cultivation of body fluids or imaging for detecting sites of infection, and were hospitalized in the study hospitals or died in the emergency department. Study index tests included the qSOFA and SIRS criteria based on information at the time of suspected infection. The study reference standard was defined as in-hospital death. Predefined statistical analysis plans included multiple imputation for all the study variables, comparison of area under the receiver-operating characteristic (AUROC) curve as the primary analysis, and net reclassification improvement (NRI) analysis as the secondary analysis. Interim analysis was planned to determine the final study sample size after the number of study participants exceeded 900, which was within the upper limit of 2,000.

RESULTS. This study was terminated in February 2018 after the number of participants reached 1,065. Of these, 407 (38%) and 915 (86%) participants were qSOFA >1 and SIRS criteria > 1, respectively. A total of 160 participants (15%) died in the hospitals. The primary analysis demonstrated greater diagnostic accuracy for in-hospital death with qSOFA than with SIRS criteria (AUROC 0.65 versus 0.51, difference +0.14 95% confidence interval (CI) [+0.08, +0.19]). Sensitivity and specificity to predict in-hospital mortality at the given thresholds (qSOFA >1 and SIRS criteria >1) were 0.58 and 0.65 with the qSOFA and 0.87 and 0.14 with SIRS criteria, respectively. The secondary analysis also demonstrated positive NRI between the qSOFA and SIRS criteria (+0.45 95% CI [+0.22, +0.62]).

CONCLUSIONS. In patients who visited the emergency department and were suspected of infection, this prospective, multi-center study for external validation demonstrated that the qSOFA improved diagnostic accuracy and reclassification in predicting in-hospital death compared to those with SIRS criteria. However, early prediction of subsequent in-hospital death with the qSOFA in those patients remained insufficient.

INTRODUCTION. Since the introduction of qSOFA, concerns have been raised. None of the elements in qSOFA are specific for the detection of infection, and subsequent validation studies showed suboptimal overall discrimination and sensitivity (reported sensitivity 32%) under the recommended cutoff.

OBJECTIVES. To investigate whether procalcitonin can improve the performance of quick SOFA score in sepsis mortality prediction.

METHODS. We conducted a multicenter retrospective cohort study with prospective validation in an independent cohort. Patients who presented to the emergency department or hospital floors with suspected severe infection and complete data on procalcitonin were eligible for inclusion. The derivation cohort include 1318 patients with presumed sepsis between June 1, 2015, and December 31, 2016 and the validation cohort included 493 prospectively collected patients in 2017. Serum procalcitonin levels were measured at admission with the commercial assay (VIDAS, bioMerieux, Marcy, France). Quick SOFA score and SIRS (Systemic Inflammatory Response Syndrome) criteria were calculated for each patient. PCT levels were assigned into 0, 1, 2 points for a serum level of < 0.25, 0.25-2, and >2 ng/mL and added to the qSOFA score. The incremental value of PCT to qSOFA was then evaluated by logistic regression, ROC curve, and reclassification analysis. Lastly, we calculated the sensitivity, specificity, positive predictive value, and negative predictive value of SIRS, qSOFA, and qSOFA_PCT in predicting in-hospital mortality.

RESULTS. A total of 1318 patients with presumed severe infection were enrolled with a 30-day mortality of 13.5%. Serum level of procalcitonin showed a high correlation with qSOFA score and 30-day in-hospital mortality. The area under the ROC curve in predicting mortality was 0.56 for SIRS criteria, 0.67 for qSOFA score, and 0.73 for qSOFA_PCT. The risk prediction improvement was reflected by a net reclassification improvement of 35% (17%-52%, p=0.00011). At a cut-off of 2 points, qSOFA has a sensitivity of 32.6% (95% CI: 25.8%-40.0%) and a specificity of 87.0% (87.3%-91.0%) to predict 30-day mortality. Incorporation of PCT into the qSOFA model could raise the sensitivity to 86.5% (95%CI: 80.6%-91.2%) with a specificity 47.5% (95%CI: 44.6%-50.5%). In the validation cohort, we confirmed qSOFA_PCT greatly improve the sensitivity to 90.9%.

CONCLUSION. A simple modification of qSOFA score by adding the ordinal scale of PCT could greatly improves the sensitivity of qSOFA. The highly sensitive qSOFA_PCT score can used as a quick screening tool for early identification of sepsis patients. Prospective multicenter studies are needed to validate our findings.

INTRODUCTION. The systemic inflammatory response following on-pump cardiac surgery is related to post-operative hemodynamic instability and impairment of renal function [1]. Pregnancy is associated with immunotolerance and an increased glomerular filtration rate (GFR).

EA-230, a linear tetrapeptide (AQGV), derived from the human chorionic gonadotropin hormone (hCG), has shown immunomodulatory and renal protective properties in several pre-clinical animal models of systemic inflammation. Also, an excellent safety profile of EA-230 was observed in phase 1 studies in humans. Furthermore, the immune modulating effects of EA-230 were recently demonstrated during human experimental endotoxemia.

OBJECTIVES. To investigate immunomodulatory and renal protective effects, as well as safety and tolerability of EA-230 in patients with systemic inflammation following on-pump cardiac surgery.

METHODS. We designed a prospective, double-blind, placebo-controlled, randomized trial in 180 patients undergoing elective CABG-surgery with or without valve surgery. Patients were randomized to receive either 90 mg/kg/hour EA-230 or placebo (1:1 ratio) during the surgical procedure. The primary endpoint is the modulation of the inflammatory response by EA-230, quantified as the change in IL-6 plasma concentrations. Key secondary endpoints are changes in glomerular filtration rate as measured with iohexol plasma clearance (iGFR) [2] and safety parameters.

The trial is conducted in two parts to enable an (unblinded) interim safety analysis by an independent data safety monitoring board (DSMB) at n=60. Second, an adaptive design is used to re-assess power at n=90 with intrinsic data. All study procedures are summarized in figure 1.

RESULTS. Last patient last visit was February 22 2018. 158 Male and 22 female patients were enrolled with an median [IQR] age of 68 [62-74] years and BMI of 25 [26-29] kg/m^2. During the DSMB interim analyses no safety concerns were raised. Following adaptive sample size re-assessment, the group size did not need adjustments.
Median [IQR] iGFR prior to surgery was 94 [77-104] mL/min/1.73m^2. Efficacy data will be available after database lock in May 2018.
CONCLUSIONS. A large randomized double-blind placebo-controlled phase II study in patients undergoing elective on-pump cardiac surgery was conducted with the hCG-derivative EA-230. It was designed to study the safety, tolerability and immunomodulatory and renal protective effects of EA-230 during systemic inflammation. Results will be available in May 2018.

INTRODUCTION. Epigenetic alterations may provide important insights into the regulation of gene expression in sepsis and the genetic pathways that drive the critical illness phenotype.
METHODS. A nested case-control pilot study of whole blood DNA methylation profiling in 68 critically-ill septic ICU patients vs 66 critically-ill non-septic ICU patients with similar severity of illness and mortality.
RESULTS. Epigenome-wide DNA methylation profiling identified 668 differentially methylated regions (DMRs) corresponding to 443 unique differentially-methylated genes (DMGs). Analysis of transcriptomic data from human sepsis cohorts reveals that DMGs are overrepresented amongst genes showing differential expression in sepsis. Functional analysis of all DMGs showed enrichment for antigen processing and presentation, methyltransferase activity, cell adhesion proteins, cell junction proteins, and metal-binding proteins. A text-mining tool, the "SepsisScore", identified those DMGs most associated with sepsis in the literature including complement component 3, angiopoietin 2, myeloperoxidase, HLA-A, HLA-DRB1, HLA-C, and HLA-DQB1. Intriguingly, a large number of genes are both differentially-methylated and differentially-expressed in sepsis yet do not appear in the sepsis literature. Weighted gene correlation network analysis (WGCNA) was performed using the same patient dataset and identified gene methylation modules associated with important clinical traits including multiple organ dysfunction score, need for vasopressors, length of ICU stay and length of hospital stay.
CONCLUSIONS. Whole blood DNA methylation profiling of critically-ill patients reveals a "sepsis" phenotype corresponding to differential methylation of multiple sepsis-associated genes. We also identify DNA methylation modules that correlate with features of critical illness including multiple organ dysfunction score, need for vasopressors, length of ICU stay and length of hospital stay. DNA methylation profiling of whole blood is a powerful new method for characterizing critically ill patients and may have utility as both a diagnostic and prognostic tool.

INTRODUCTION. Capillary Leak Index (CLI) reflects endothelial damage most of the time associated with certain pathologies such as sepsis, severe trauma, extracorporeal circulation, etc. Described as systemic edema, hypoproteinemia, reduction of effective arterial blood volume and hemoconcentration.
Capillary Leak Index increases mortality in septic patients. Currently, there is not effective treatment, so early recognition and staging its crucial in medical prognosis. An objective score such as CLI, can reasonably infer the integrity and functionality of endothelial barrier. This index proposed by Condermans et al[1], is obtained as a ratio of C reactive protein (CRP) over albumin times 100, with normal range values between 2.5 to 25.
OBJECTIVE. Validate CLI as a tool in septic patients for severity and outcome. Determine a cut-off value related to mortality.
**METHODOLOGY.** Observational prospective trial conducted in two tertiary centers in Mexico which included ICU patients admitted with diagnosis of severe sepsis and septic shock. The study was divided in two phases: generation and validation. In first phase we analyzed CLI, SOFA, APACHE, CRP, albumin, hospital length of stay and mortality. Student´s t test was used to compare data and ROC curve analysis was performed to validate CLI as a prognostic factor. On second phase the cut-off point obtained from previous stage, was compared with all variables to validate it as a prognostic scale.
RESULTS. 116 patients included. ROC curve analysis on generation phase (n=62 patients), set a cut-off point (85.55, AUC 0.88) as mortality predictor. On phase two, based on cut-off point, complete group was analyzed obtaining a 100% sensibility, 89% specificity, PPV 67% and a NPV of 100%. Kaplan Meier survival curve and Log Rank test analysis compared 28 days mortality, based on CLI cut-off point, resulting in survival of 88.6% vs 11.4% (P< 0.001).

CONCLUSION. CLI is a useful tool to predict poor prognosis in septic shock patients. Cut-off point of 85.55 reflects better sensitivity and specificity. This scale is simple, accessible and low cost.

Clinical usefulness of modified CRB-65 score compared to SIRS and qSOFA as a screening tool for sepsis in initial emergency department: a propensity score matching study

H. Oh, J. Lee
Jeju National University School of Medicine, Internal Medicine, Jeju-si, Korea, Republic of
Correspondence: H. Oh
Intensive Care Medicine Experimental 2018, **6(Suppl 2):**0562

INTRODUCTION. A revision of sepsis definitions proposed the Quick Sequential Organ Function Assessment (qSOFA) as a bedside indicator of sepsis. But practical application is not well established in the Emergency Department (ED).

OBJECTIVES. We aimed to elucidate modified CRB-65 (mCRB-65)score in recognizing sepsis compared to systemic inflammatory response syndrome (SIRS) and qSOFA.

METHODS. A retrospective chart review was performed among patients with suspected or documented infection between January 2014 and December 2015. We assigned each patient into the sepsis and the no-sepsis group by the presence of predefined organ dysfunction. The number of SIRS, qSOFA, mCRB-65 criteria was calculated for each patient. And we then calculated the sensitivity and specificity of predefined criteria for each score for prediction of sepsis in our data set, and compared an area under the curve (AUC) for each score. In addition, we performed the matched case-control study through using the propensity score matching method. More than 2 points in three tools was considered as positive for risk of sepsis.

RESULTS. A total of 4,253 patients with pneumonia were assessed for eligibility, and 2,441 of whom(933 with sepsis and 1,508 with no-sepsis) were included in the study. Of these patients, the rate of patients met mCRB-65, qSOFA, and SIRS positive criteria was 37.6%, 12.3%, and 52.3%, respectively. The crude AUC value of mCRB-65 positive criteria in predicting sepsis was significantly higher than that of qSOFA and SIRS positive criteria (0.728 vs. 0.633. vs. 0.608, respectively). After the propensity score matching process, the rate of pa-

tients met mCRB-65, qSOFA, and SIRS positive criteria was 49.2%, 15.8%, and 56.5%, respectively. With respect to mCRB-65, qSOFA, and SIRS positive criteria, the sensitivity for sepsis were 0.66 (95% CI, 0.63 to 0.69), 0.29 (95% CI, 0.26 to 0.32), and 0.66 (95% CI, 0.62 to 0.69), respectively. And for positive criteria of three tools, the specificity for sepsis were 0.72 (95% CI, 0.69 to 0.75), 0.96 (95% CI, 0.95 to 0.97), and 0.54 (95% CI, 0.50 to 0.57), respectively. And mCRB-65 positive criteria still showed higher discrimination for prediction sepsis compared to qSOFA and SIRS positive criteria (adjusted AUC 0.688 vs. 0.630 vs. 0.596, respectively).

CONCLUSIONS. Proposed mCRB-65 score seemed to provide better discrimination than SIRS and qSOFA for predicting sepsis. After adjustment of baseline variables, high discrimination of mCRB-65 was still maintained.This may have quality improvement implications in predicting sepsis. Our finding suggest that this simple screening tool might be helpful for physicians to identify sepsis promptly and to escalate therapy appropriately in initial ED.

Predictor of developing type 2 diabetes mellitus: glycosylated hemoglobin in patients with coronary disease and without known diabetes
A.M. González González, A.M. Garcia Bellon, M. Cano García, M. De Mora Martin
Regional Hospital of Malaga, Cardiology, Malaga, Spain
Correspondence: A.M. González González
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0563

INTRODUCTION AND OBJECTIVES. To analize the value of glycosylated hemoglobin (HbA1c), determined at admission, as predictor of developing type 2 diabetes mellitus in non-diabetic patients, hospitalized for coronary disease.

METHODS. We collected 578 consecutive patients, admitted for Acute Coronary Syndrome (ACS) in our Cardiology department, from May 2016 to September 2017. Their levels of Hb1Ac were requested at admission systematically. Finally, 199 patients (34%) were included with diagnosed coronary disease and without known diabetes. We collected clinical data, cardiovascular risk factors (CVRF), anthropometric and laboratory values (fasting glucose and HbA1c).

Two months after hospital discharge, all patients were reevaluated clinically and analytically undergoing an oral glucose tolerance test (OGTT). Patients were grouped into four categories according to the criteria of the American Diabetes Association (ADA): a) normal fasting glucose < 110 mg / dL and OGTT < 140 mg / dL, b) altered basal glucose (ABG): fasting glucose 110 - 126 mg / dL, c) glucose intolerance (GI): a 2-h OGTT 140-200 mg / dL, d) ABG + IG, e) DM: fasting glucose> 126 mg / dL and 2 hours OGTT> 200 mg / dL

We conducted a descriptive analysis of the data. We determine the odds ratio (OR) of having DM or any disorder of carbohydrate metabolism in relation to the values of HbA1c at admission.

RESULTS. Mean age was 68.3 years. 69.2% were male and 30.8%, female. Mean body mass index (BMI): 28.4 kg / m². Regarding the prevalence of cardiovascular risk factors: 74.6% hypertensive, 34.7% dyslipidemic, 32.9% active smokers. Prior history of heart disease: 26.5% acute myocardial infarction (AMI), 19.3% prior stable angina, 41.6% with no history of heart disease. Mean fasting blood glucose 104 mg / dL ± 24, and 6% on HbA1c.

The evaluation at 2 months by fasting glucose and OGTT: normal result 24.1%, 3.5% GBA, IG 33.7%, 11.1% GBA + IG, 27.6% DM. The OR of having any disorder of carbohydrate metabolism in terms of

HbA1c levels was 6.65 (95% CI, 1.25-35) (p < 0.029). The cutoff point that best discriminated Hb1Ac was Hb1Ac risk = 6.5%.

CONCLUSIONS. HbA1c level at admission is a good predictor for the risk of developing DM or other alterations in carbohydrate metabolism. This small measure would be useful for an early detection of DM, allowing to start a suitable dietary and pharmacological prevention.

INTRODUCTION. Loss of skeletal muscle during early critical illness can be profound[1], with major functional sequelae[2]. In contrast to continuous enteral feeding, which may inhibit muscle anabolism through the muscle-full effect, intermittent feeding may promote anabolism and preserve muscle mass. In the current study, we investigated the safety and feasibility of intermittent feeding.

OBJECTIVES. We sought to determine whether intermittent enteral feeding was safe and feasible during the first ten days of intensive care unit (ICU) stay.

METHODS. Mechanically ventilated adults with multi-organ failure were recruited within 24 hours of admission to one of 8 UK ICUs, and randomised to receive four-hourly intermittent feed (intervention) or continuous (control) enteral feed for 10 days.

For participants who received feed for $\geq$48 hours, we recorded the days during which feed was received, reasons for any missed days, average daily energy and protein intakes, and percent target energy and protein intakes received. Patients were excluded if extubated $\leq$48 hours or discharged from ICU $\leq$7 days. Data are reported descriptively and analysed using two sample t-tests or Mann-Whitney U-tests as appropriate.

RESULTS. Participants (mean ± standard deviation age 57.4 ± 15.8 years; 68%:32% male:female) received intermittent (n=52) or continuous (n=47) enteral feed on a mean of 77% and 74% of total possible feed days (10 days per patient), respectively; ICU discharge prior to Day 10 was the main reason for missed feed days. No intermittent feed-related serious adverse events were reported. Two participants transferred from intermittent to continuous feed, and one from intermittent to total parenteral nutrition, due to gastric residual volumes $\geq$300 mls or vomiting. There was significantly greater daily energy intake from intermittent feed (median ± interquartile range (IQR):1539 ± 427 kCal) versus that from continuous feed (median ± IQR: 1363 ± 384 kCal; p=0.02). Groups did not differ for median percent energy requirements met or protein intake (either percent daily requirements met or daily intake) (Table 1).

CONCLUSIONS. Delivery of intermittent enteral feed to ICU patients appears feasible and safe, and associated with greater median energy intake than is continuous enteral feeding.

Continuous Feed, n=47	77.2	29.2		1363	384	
	Protein Requirements Met, %			Daily Protein Intake, g		
	Mean	95%CI	p value	Mean	95%CI	p value
Intermittent Feed, n=52	77.9	83.1-72.8	0.12	70.66	75.06-66.26	0.58
Continuous Feed, n=47	71.6	77.9-65.3		68.65	74.55-62.75	

mean morning blood glucose were the primary outcomes of interest. Secondary observations included ventilation period, mortality, and length of ICU stay (LOICUS).

RESULTS. Groups were comparable in baseline clinical and demographic characteristics, and nutrition practices. Volume delivered to the VBF group increased significantly by 11.2% ($p=<$ 0.001) compared to the RBF group, and did so significantly every day of the study (Fig 1). Energy increased in the VBF group by 13.4% ($p=<$ 0.001) and protein by 8.4% ($p=0.02$), compared to the RBF group. In the VBF group, patients meeting >90% of energy requirements increased significantly from 47.8% to 84.8% ($p=<$ 0.001); those meeting >90% of protein requirements changed from 56.5% to 73.9% ($p=0.134$).

VBF did not increase symptoms of feed intolerance. Adjusted binomial logistic regression found each additional 1% of prescribed feed delivered decreased the odds of vomiting by 0.942 (5.8%), 95% CI [0.900-0.985], $p=0.010$.

There was no difference in mortality or LOICUS. Kaplan-Meier found a significantly increased extubation rate in patients receiving >90% of protein requirements compared to those meeting < 80%, ($p=0.006$) (Fig 2). Adjusted Cox regression found the daily probability of extubation tripled in patients receiving >90% of their protein needs compared to the group receiving < 80%, hazard ratio 3.473, $p=0.021$, 95% CI [1.205-10.014].

CONCLUSIONS. VBF safely and effectively increased the delivery of nutrition to critically ill patients. Increased protein delivery may improve extubation rate which has positive patient and financial implications, warranting larger confirmatory trials. This investigation adds weight to the ICU literature supporting VBF, and the growing evidence which advocates for enhanced protein delivery to improve patient outcomes.

INTRODUCTION. Underfeeding in critical illness is common and associated with poor outcomes. According to large prospective hospital studies, volume-based feeding (VBF) safely improves nutrition delivery to critically ill patients compared to traditional rate-based feeding (RBF) (Heyland et al. 2015), and confers the potential to improve patient outcomes.

OBJECTIVES. A before-and-after study was designed to evaluate the safety, efficacy and clinical outcomes associated with VBF compared to RBF in an Intensive Care Unit (ICU).

METHODS. The sample included consecutively admitted critically ill adults, mechanically ventilated for at least 72 hours and fed enterally for a minimum 48 hours. The first cohort ($n=46$) were fed using RBF, the second ($n=46$) using VBF, and observed for 7 days, or until extubation or death. Statistical comparison of percentage feed-volume, energy and protein delivered, plus indices of feed intolerance including diarrhoea, vomiting, gastric residual volume and

INTRODUCTION. Critical illness-related corticosteroid insufficiency (CIRCI) is a condition in which endogenous cortisol levels are relatively low compared to illness severity. Cortisol has to bind to the glucocorticoid receptor (GCR) to be biologically active. Sepsis and septic shock are major healthcare problems with a very high mortality rate in critically ill patients. Hydrocorticosteroid administration is recommended in the Surviving Sepsis Campaign Guidelines 2016 if adequate fluid resuscitation and vasopressor therapy are unable to restore hemodynamic stability (Rhodes et al., 2017). However, each patient responds differently to steroids, and as yet there is no agreement as to who would benefit from their use and how to accurately identify these patients.

OBJECTIVES. To assess glucocorticoid receptor expression in peripheral polymorphonuclear cells of critically ill patients.

METHODS. Thirty two (32) critically ill patients suffering from medical, surgical and trauma-related pathologies were included in the study. Patients who received corticosteroids at ICU admission were excluded. GCR-α and GCR-β expression were measured in our critically ill cohort at four time points: at admission to the intensive care unit (ICU - baseline), and twice weekly for up to two weeks or until discharge from the ICU or death. Polymorphonuclear cells were isolated from the peripheral blood of the patients at all time points, total RNA was extracted, and GCR-α and GCR-β mRNA levels were quantified by real-time PCR (RT-PCR). At admission, demographics, APACHE II & SOFA scores were recorded.

RESULTS. Among the 32 critically ill adult patients studied, approximately one third were female. The median patient age in our sample was 54 years {interquartile range (IQR): 37-73}, the median acute physiology and chronic health evaluation (APACHE) II score was 17 (IQR: 14-22) and the median SOFA score was 8 (IQR: 7-10). The mean ICU stay was 26 days. GCR-α expression decreased from its baseline value at all three time points ($p < 0.05$), while GCR-β expression, which is expressed in lower copies at baseline compared to the α receptor, remained stable until the second measurement, and afterwards decreased ($p < 0.05$) during the remaining ICU stay.

CONCLUSIONS. Our results indicate that critically ill patients have a very variable expression of the glucocorticoid receptor that cortisol has to bind to in order to enter the nucleus and inhibit transcription of inflammatory genes. Therefore, the extent to which patients respond to cortisol treatment may be dependent on the levels of GCR receptors.

INTRODUCTION. Studies and guidelines suggests that in the critically ill patient indirect calorimetry is the most appropriate form to establish adequate caloric intake and some observational studies suggests that a high protein intake could improve outcomes (1).

OBJECTIVES. To evaluate the effects of an optimized nutrition with caloric expenditure determined by indirect calorimetry and a high protein intake compared to standard of care nutrition, primarily on physical component (PCS) of quality of life after 3 and 6 months of randomization and secondarily on short term outcomes in critically ill adult patients.

METHODS. We randomized mechanically ventilated critically ill adult patients expected to stay in the ICU for at least 3 days. In the optimized caloric-protein nutrition (OCPN) group caloric intake was determined by indirect calorimetry and protein intake was established in 2.0 to 2.2 g/kg/day. The control group received 25 kcal/kg/day and 1.4 to 1.5 g/kg/day of protein.The primary outcome was the PCS score at 3 and 6 months. Secondary outcomes included handgrip strength at ICU discharge, duration of mechanical ventilation, ICU and hospital mortality.

RESULTS. We randomized 138 patients and 120 were included in the analysis. Demographic and clinical data were comparable between the 2 groups (Table 1). There was no difference between the two groups in relation to calories received ($p = 0.70$). On the other hand, the amount of protein received by the OCPN group was significantly higher compared to control group (1.69; 1.33 -1.80 vs. 1.13; 0.97 - 1.39, $p < 0.0001$) (Table 2).The PCS score at 3 and 6 months did not differ between the two groups, neither did handgrip strength at ICU discharge, ICU LOS, duration of mechanical ventilation, and ICU and hospital mortality (Table 3). However, after adjusting for demographic and nutrition covariates a negative protein balance was associated to a lower PCS score at 3 months (OR, 2.63, 95% CI, 1.02 - 6.76; p= 0.045), and 6 months (OR, 3.26, 95% CI, 1.21 - 8.80; p= 0.019) after randomization, while a negative caloric balance did not influencePCS score at 3 months (OR, 1.91, 95% CI, 0.63 - 5.78; p= 0.255), and 6 months (OR, 2.67, 95% CI, 0.86 - 8.24; p= 0.089).

CONCLUSIONS. In this study an optimized caloric and high protein strategy did not appear to improve physical quality of life and other important outcomes compared to a standard nutrition care. However, after adjusting for important covariates a negative protein balance was associated to a lower PCS score at 3 and 6 months after randomization.

INTRODUCTION. Patients undergoing major abdominal surgery for cancer treatment are at substantial risk for postoperative complications. The impact of a strategy based on early parenteral nutrition on postoperative outcomes is unknown.

OBJECTIVES. The objective of this study was to compare the incidence of postoperative complications in surgical patients submitted to different parenteral nutrition strategies: Early vs. Late.

METHODS. Phase III study of superiority, unicentric, prospective and randomized, performed at the Cancer Institute of the State of São Paulo, Faculty of Medicine, University of São Paulo, Brazil. We included adult patients with gastrointestinal neoplasia (esophagus, stomach and / or intestine), metastatic or not, submitted to non-palliative elective oncologic surgery. Patients were randomized into two groups: Early parenteral nutrition or Late parenteral nutrition. In the Early group, total parenteral nutrition was started on the second postoperative day, and in the Late group, patients received supplemental parenteral nutrition on the 7th postoperative day if necessary. Patients and outcome assessors were blinded to the treatment group. The analysis was performed according to intent to treat. The primary outcome was a composite endpoint of postoperative complications in 30 days including respiratory, cardiovascular, renal, neurological, infectious and surgical complications. Secondary outcomes were 30-day mortality, need for intensive care unit, total length of hospital and intensive care unit stay, intensive care unit readmission, duration of mechanical ventilation, duration of vasopressors, hepatic dysfunction and hospital readmission.

RESULTS. Between May 8, 2013 and October 7, 2017, 658 patients were assessed for eligibility and 335 patients were enrolled, 167 patients randomized to the Early group and 168 patients to the Late group. At 30 days, the Early group had 46 complications (27.5%) and the Late group had 68 complications (40.5%) - [absolute difference, 95% Confidence Interval of the absolute difference -12.9 (-22.7 to -2.8), p = 0.013]. The secondary outcomes were not different between the groups.

CONCLUSIONS. In patients with cancer undergoing elective gastrointestinal surgery, early parenteral nutritional strategy was superior than the late strategy in avoiding postoperative complications. Registration: www.clinicaltrials.gov: NCT01839617.

INTRODUCTION. Individualized supplemental parenteral nutrition (SPN) improved clinical outcome in a cohort of 305 patients by reducing energy deficit and infectious complications (1). Importantly feeding targets were individually set by indirect calorimetry.

OBJECTIVES. We reproduced the conditions of the prior SPN-1 trial to investigate the metabolic and immune response underlying the results.

METHODS. Randomized controlled trial starting on day4 (D4) of ICU admission. Inclusion: receiving < 60% of energy target by EN. Patients were randomised to either continued EN or to SPN to cover the indirect calorimetry target. Protein and glucose metabolism were investigated on D4 and D9 of the ICU stay with ^{13}C-Leucine, ^{2}H$_2$ glucose and ^{13}CO$_2$ HCO3. Immune response was investigated in stimulated peripheral blood mononuclear cells and by serum cytokines. Nosocomial Infections were recorded. Muscle mass was measured by ultrasound of the thigh cross-sectional area (CSA). Data as medians.

RESULTS. Twenty-three patients completed the trial: SPN patients were better fed (Table). Baseline data were similar (age 65 years, SAPS 48). Protein and glucose kinetics did not differ. Immune response differed significantly: on D9, compared to EN patients, TNFα (p=0.018) and IL-6 (p=0.024) decreased more in SPN patients, and response to phytohemagglutinin was stronger, with trend to less infections (p=0.12). Length of stay and mortality did not differ.

CONCLUSIONS. Feeding patients to cover an indivualised energy target with SPN from D4 improved the energy balance, and was associated with an improved immunity, attenuation of inflammation, and a lesser muscle mass loss, confirming the results of the SPN-1 trial.

INTRODUCTION. Diarrhea is a frequent concern in the Intensive Care Unit (ICU) and incidence varies from 2-95% in previous studies. This variation is due to lack of a consistent definition of diarrhea and scientific inattention to this clinical problem.

OBJECTIVES. The objectives of this study were to describe the epidemiology of diarrhea in critically ill patients including the incidence, risk factors, and consequences of diarrhea, and the incidence of Clostridium difficile-associated diarrhea.

METHODS. This prospective cohort study was undertaken over 10 weeks in 9 ICUs in Canada and the United States. We included all patients >18 years old who were admitted to the ICU for >24 hours and followed them daily until ICU discharge. The bedside nurse documented all bowel movements, classifying them using the Bristol and Bliss Stool Charts. We defined diarrhea 3 ways: 1) WHO Criteria of >3 liquid bowel movements per day (Bristol type 7), 2) any Bristol type 6 or 7 stool, and 3) any Bliss score of 4. We collected daily data on life support, laboratory values (e.g., electrolytes), treatment (e.g., medications, fecal management devices, nutrition), and outcomes (overall mortality).

RESULTS. Among 865 patients, the incidence of diarrhea varied based on the definition (WHO Criteria: 77.3%; 95% CI 774.4-80.0, Bristol Stool Chart definition: 56.8%; 95% CI 53.5-60.1, Bliss Stool Chart definition: 39.9%; 95% CI 36.7-43.2). Risk factors associated with diarrhea on multivariate analysis included total number of antibiotic days (p< 0.001), use of sorbitol-containing medications (p< 0.001) and enteral nutrition (< 0.001), while opiates were associated with a lower risk (OR 0.22, 95%CI 0.13-0.36, p< 0.001). Diarrhea often prompted cessation of enteral nutrition, prokinetics or stool softeners, or fecal management device insertion. Diarrhea was not associated with increased overall mortality (78.6% in those with diarrhea and 73.8%% in those without, p=0.184). Clostridium difficile toxin was identified in 56 patients but only 18 (2.0%) met the definition of Clostridium difficile-associated diarrhea concurrently requiring >3 liquid bowel movements per day.

CONCLUSIONS. In this multicenter cohort of critically ill patients, diarrhea occurred frequently, and the incidence varied based on the definition employed. Clostridium difficile-associated diarrhea was an uncommon cause for diarrhea. Antibiotics, hyperosmolar medications and enteral nutrition decreased the risk of diarrhea, while opiates decreased the risk. Further research is needed to identify feasible cost-effective interventions that prevent or reduce this problem.

Does parenteral nutrition affect liver function in the critically ill patient: a retrospective study

INTRODUCTION. Nutrition support in critical care is complex with a reported 15.6% of patients requiring parenteral nutrition (PN). Liver dysfunction has been observed in 30% of critical care patients receiving PN. This study sought to review current evidence and investigate the relationship between liver function, inflammation and PN in a cardiorespiratory tertiary critical care centre.

METHODS. There was a two phased approach comprising of a systematic review of published evidence, followed by a retrospective service evaluation. The systematic review of NICE Healthcare databases (AMED, BNI, CINAHL, Cochrane, EMBASE, HBE, HMIC, Medline, PsycINFO and Pubmed) found nine full text observational studies written in English, published in the past 20 years which assessed the relationship between critical care adults, PN and liver function. The retrospective service evaluation captured data of all adult critical care patients who received PN from April 2009 to July 2017. Biochemistry results, length of say, outcome on leaving intensive care and anthropometry data were collated before statistical analysis to establish significant associations.

RESULTS. The systematic review found observed liver function changes may be a result of PN or sepsis but was not able to clarify which, if either

was responsible. The retrospective service evaluation found 147 patients, of which 62.6% were male, mean age was 56.8 years and 63.9% left intensive care alive. Biochemistry data were analysed for the initial 5 feeding days. An elevated Bilirubin was significantly associated with increased mortality (p=0.0001). Other biochemical markers analysed showed no significant difference associated with outcome. Despite no significant association, elevated Inflammatory and infection markers C reactive protein (64%) and white blood cells (76%) suggests that liver function is affected by sepsis rather PN. This lack of association is consistent with published systematic review evidence. Females were found to have a 41% lower risk of death compared to males. Underweight (BMI < 18.5kg/m^2) or obese (BMI >30 kg/m^2) patients, had a relative risk of death increased by 13% and 30% respectively. The risk of death increased by 0.3% with each increased year of age.

CONCLUSION. This review suggests that liver dysfunction and inflammation in adults receiving PN are a common occurrence and likely to be related to sepsis. Consequently, liver function should not affect the decision to initiate PN as no associated risk on liver function or mortality outcome has been seen in this or bigger studies for this patient group. For optimal outcome in this patient group the dietetic treatment should focus on minimising malnutrition and sepsis through PN formulation. Elevated Bilirubin is a predictor of mortality outcome, however more work should be done to assess the relationship with sepsis or severity scores.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0572

INTRODUCTION. Metabolic rate after major surgery is modulated by inflammation, metabolically active drugs[1] and patient factors. In small patient groups with a pulmonary artery catheter (PAC) the reversed Fick method was used to investigate the link between oxygen transport and consumption[2,3] despite concerns about mathematical coupling[4]. Multivariate modeling of the postoperative course of metabolic rate has not been done so far in a large cohort.

OBJECTIVES. We investigated the metabolic rate and its association with intraoperative hyperlactatemia within the first week after major cardiac surgery using continuous PAC measurements.

METHODS. We included all consecutive patients with a PAC after major surgery treated at our ICU between Jan. 2012 and Dec. 2015. Data was stored every 10 minutes in the patient data management system. Median oxygen consumption (VO2) was calculated using the Fick equation (VO2 = CO × (CaO2 - CvO2)) over 1-hour periods. Resting energy expenditure (REE) was calculated with VO2 × 7 assuming a RQ of 0.83. A multivariate regression model with patients as random factors was used to estimate the association between metabolic rate and patient characteristics, intraoperative lactate level and duration of surgery. Patient weight and height were centered on the overall mean and analyzed for 10 cm and 10 kg increments. Age was analyzed in 10-year increments with age 60-70 as reference.

RESULTS. We analyzed a total of 634 (475 male, 159 female) patients with median age 65a (IQR 56;72) and median SAPS2 score 35 (IQR 13;65). Hospital mortality was 9.31%. In total, 39044 hourly VO2 measurements were used. Median PAC monitoring lasted 66.5 hours (IQR 34;101). Median VO2 was 236 ml.min^{-1} (IQR 199;272). Median REE was 1650 kcal.d^{-1} (IQR 1391;1901) and 20.4% lower in women (1392 kcal.d^{-1} (CI95 1330;1453)) than men (1751 kcal.d^{-1} (CI95 1715;1787)). REE increased by 329 kcal.d^{-1} (CI95 146;513) in patients aged 30-40 (p< 0.001) and decreased by 89 kcal.d^{-1} (CI95 11;166) in patients aged 80-90 years (p=0.025). REE increased by 108 kcal.d^{-1} (CI95 81;135) per 10 kg patient weight (p< 0.001) but not with height (p=0.368). REE decreased by 24 kcal.d^{-1} (CI95 3;46) per 1 mmol/l

increase in intraoperative lactate (p=0.028). An additional anesthesia hour decreased REE by 30 kcal.d^{-1} (CI95 13;48) (p=0.001). REE was only decreased by 83 kcal.d^{-1} (CI95 37;129) (p< 0.001) on the first postoperative day, but remained stable during further ICU stay (Fig.1). REE was more than 20% higher in survivors (Fig.2).

CONCLUSIONS. Postoperative metabolic rate is affected by patient characteristics, prolonged surgery and intraoperative hyperlactatemia. A slight hypometabolic state is commonly present early after ICU admission and persists in non-survivors.

INTRODUCTION AND OBJECTIVES. Delirium is the most common postoperative complication of the central nervous system (CNS). Its underlying mechanism is still unclear, but previous reports suggest its association with dysfunction of the blood-brain barrier (BBB).
By measuring serum levels of the neuronal axonal damage biomarker, phosphorylated neurofilament (pNF-H), we demonstrated objective CNS anatomical damage in moderate to severe delirium patients, but not in mild delirium patients. These findings indicate postoperative delirium can induce the irreversible CNS damage and pNF-H has a potential to objectively evaluate the severity of the CNS damage. Focusing serum biomarkers of the BBB, we investigated relationship between postoperative CNS damage and the BBB dysfunction in reference to pNF-H.
METHODS. After approval at the Ethics Committee, we measured following serum biomarkers: five BBB biomarkers (ICAM-1, PECAM-1, VCAM-1, E-selectin, P-selectin), 3 proinflammatory cytokines (TNF-alpha, IL-1beta, IL-6) and pNF-H. Blood samples were collected within 14 postoperative days after major surgery in 117 patients. Among these, postoperative delirium was clinically diagnosed by using CAM-ICU. At first, we performed a multilinear regression analysis on all of the participants to identify independent contributing biomarkers for pNF-H positive during postoperative periods. Next, we performed a multivariable logistic regression analysis in the stepwise manner to determine whether biomarkers contribute to severity of the pNF-H level in patients with pNF-H positive.
RESULTS. Of the 117 subjects, 41 were clinically diagnosed of delirium during postoperative periods, and 30 were pNF-H positive (delirium positive:23, negative:7). P-selectin was only revealed as the independent variable to associate with presence of pNF-H by the multilinear regression analysis ($p < 0.0001$). Further, PECAM-1 only was positively associated with serum levels of pNF-H ($p = 0.02$).
DISCUSSION AND CONCLUSIONS. Clinical diagnosis of delirium based on CAM-ICU or other conventional tools usually demonstrate high specificity but low sensitivity, and the hypoactive-type delirium is frequently misdiagnosed. In order to compensate such insufficient clinical diagnosis of delirium, we here used serum pNF-H as an objective CNS damage biomarker. In the process where immunocompetent cells invade into the central nervous system through the BBB and exert the CNS cytotoxicity, there are several steps. P-selectin is an adhesion molecule involved in the very early "capture" step, in which of the immunocompetent cells adhere to vascular endothelia of the BBB. PECAM-1, also known as an adhesion factor, works in the terminal "transmigration" step, in which the immunocompetent cells finally pass the BBB and invade into the CNS. Our findings suggest that P-selectin might be a potential target for preventing the CNS damage and that PECAM-1 should be referenced when treating delirium to protect the CNS.

INTRODUCTION. The pharmacokinetics (PK) of drugs is dramatically altered in critical illness. Augmented renal clearance (ARC), a phenomenon characterized by creatinine clearance (CrCl) greater than 130ml/min, is commonly described in critically ill patients. Levetiracetam, an antiepileptic drug commonly prescribed for seizure prophylaxis in the neurosurgical ICU, undergoes predominant elimination via the kidneys. Hence, we hypothesize that current dosing practice of intravenous (IV) levetiracetam 500mg twice daily is inadequate for patients with ARC due to enhanced drug elimination.
OBJECTIVES. The objectives of our study were to describe the population PK of levetiractam using a nonparametric approach and design an optimal dosing regimen for critically ill neurosurgical patients with and without ARC.
METHODS. his was a prospective, observational, population PK study. Serial blood samples were obtained from neurosurgical ICU patients who received at least one dose of IV levetiracetam. We used uHPLC to analyze these samples and Pmetrics software to perform PK analysis.
RESULTS. Nineteen subjects were included, with a median age of 57 years and CrCl of 99ml/min. A one-compartment model with linear elimination adequately described the profile of levetiracetam. Mean clearance (CL) was 3.12 L/hr and volume of distribution (V) was 14.92 L. Significant covariates included in the final model were CrCl and body weight. Monte Carlo simulations showed a low probability of target attainment (PTA, trough at steady state of ≥ 6 mg/L) with a standard dose of 500mg twice daily. A dose of 1000mg every 8 hours and 1000mg twice daily is required for subjects with or without ARC respectively to achieve 80% PTA. Two subjects developed early onset seizures despite therapeutic trough concentrations.
CONCLUSIONS. We found that subjects with ARC required higher doses to achieve target levels. Our study was the first to provide recommendations for levetiracetam dosing in neurosurgical ICU patients with ARC.

INTRODUCTION. Traumatic brain injury (TBI) is one of the main causes of morbidity and mortality. Immobilism generates acquired myopathy, neuropathy or a combination of both, called muscle weakness acquired in the intensive care unit (ICU-AW). Ultrasound (US) has been shown to be effective because it allows the identification of changes in muscle structure and morphology.

OBJECTIVE. To compare muscle thickness and echo intensity changes in upper and lower limbs of TBI patients submitted to mechanical ventilation on admission and after 14 days of ICU admission.

METHODS. The present study is observational prospective. TBI adults victims were admitted by automobile accident using mechanical ventilation (MV) at a trauma reference unit in the capital. Patients underwent muscle US (SonoSite, M-Turbo®) of biceps brachii (BB), tibialis anterior (TA) and rectus femoris (RF) to obtain measurements of muscle thickness and echogenicity for all the muscles refered between day 1 and day 14 was analyzed. Measurements were performed by us on the upper and lower limbs of patients in the RF, TA and BB muscles on the first day and 14 days thereafter. Quantitative and qualitative analyzes of the images were performed through the ImageJ program.

RESULTS. 9 patients were enrolled (age 34.22 ± 6.83 years; 89% male; 22,2% surgery after brain injury; 100% neuro protective). The BB muscle had a loss thickness significant (P = 0.0023) and the RF had a loss echo intensity significant (P= 0.0124) in 14 days. For the evaluation of variation between muscles, a significant difference was observed in echo intensity of BB was bigger RF and TA (P< 0.05).

CONCLUSION. The loss of muscle thickness in patients with TBI submitted to MV was higher in the upper limb than lower limb and the variation of the echo intensity was shown to be lower in the upper limbs.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0576

BACKGROUND. Myasthenia gravis (MG) crisis and Guillain-Barre Syndrome (GBS) are immune mediated diseases that may require mechanical ventilation as part of their management if severe. Comparative analysis of outcomes in terms of length of stay, disability and mortality between these two disease entities at national level is not reported.

DESIGN/METHODS. Mechanically ventilated patients with primary diagnosis of Guillain-Barre Syndrome and Myasthenia Gravis were identified from the nationwide in-patient sample database for the years 2012 to 2014.

RESULTS. Mechanically ventilated MG patients (n= 2330, mean 62.0 ±19.5 years) were older compared to GBS patients (n=2060, mean 55.9 ±20.0 years, p= 0.001). Medical Comorbidities were significantly higher in MG patients (diabetes mellitus, congestive heart failure, coagulopathy, chronic lung disease and dyslipidemia) whereas significantly higher nicotine dependence and alcohol abuse was noted in GBS. Significantly higher in hospital complications of pneumonia and urinary tract infection were noted in GBS. Disease severity measured by APDRG severity index and rate of treatment with intravenous immunoglobulin and plasma exchange were comparable. Length of stay (25.3 ± 18.2 days , p < 0.0001); hospital charges (\$353361.2 ± 293863.2 vs 232160.12 ± 222881.3 p = 0.001) ;moderate to severe disability (86.6% vs 46.2% p < 0.001) were significantly higher for GBS patient compared to MG. In-hospital mortality was comparable (8.7% GBS vs 8.6 % MG, p =0.93).In multivariate analysis after adjusting for confounders including treatment, myasthenia gravis patients had significantly less disability (OR 0.06 (95% CI 0.03-0.10) and shorter length of stay (OR 0.32, 95% CI 0.16-0.61).

CONCLUSIONS. Mechanically ventilated GBS patients have higher in-hospital complications, length of stay and disability compared to MG. This may reflect delay in diagnosis of GBS at admission and poor response to immunotherapy in certain GBS variants.

Migraine and its relation to other risk factors in patients with acute ischemic stroke and acute coronary syndrome

H. Enas[1], O. Momtaz[2]
[1]Minia University, Neurology, Minia, Egypt; [2]Faculty of Medicine, Fayoum University, Critical Care, Fayoum City, Egypt
Correspondence: H. Enas
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0577

BACKGROUND. Cerebral ischemia and ischemic heart diseases are the main manifestation of circulatory diseases with shared identifiable risk factors. Migraine has been recently studied as a risk factor for ischemic stroke (IS) and a possible link to a broader range of ischemic vascular disorders including angina and myocardial infarction is suggested.

OBJECTIVES. We aimed to study migraine and its relation to other risk factors in patients with acute IS and acute coronary syndrome (ACS).

METHODS. We studied 200 patients, 114 patients had acute IS and 86 patients with ACS collected from the inpatient department of neurology and coronary care units of El-Minia Insurance Hospital in addition to 850 control participants. All patients were subjected to detailed clinical and laboratory evaluation including evaluation of traditional risk factors. All stroke patients were subjected to CT scan. Assessment of stroke severity was measured by National Institute of Health Stroke Scale (NIHSS). Diagnosis of acute coronary syndrome was established clinically as well as by ECG and cardiac specific enzymes. Migraine was diagnosed in all patients and control according to the international headache society and assessment of migraine severity was measured by the Migraine Disability Assessment (MIDAS) questionnaire.

RESULTS. Risk ratios (RR) of migraine were adjusted for gender, age, BMI, smoking, physical inactivity, hypertension (controlled and uncontrolled), diabetes mellitus and abnormal lipid profile in both cerebrovascular and cardiovascular groups. In patients with ischemic stroke, RR of migraine was 3.3 for all migrainous patients, 4.97 for MA and 2.14 for MO. In the cardiovascular group, RR of migraine was 2.75 in all migranous patients, 4.12 for MA and 1.88for MO. Other risk factors and their relation to migraine had been discussed. A positive correlation between migraine severity and both stroke severity and cardiac affection severity was found though non-significant in the cardiovascular group. There was no significant difference in hospital outcome in migrainous patients in both groups.

CONCLUSION. Patients with migraine (with and without aura) have higher risk than non-migrainous patients for both cerebrovascular and coronary vascular diseases. Risk is stronger in MA in both conditions. Considering migraine in risk stratification of cerebrovascular and cardiovascular diseases is recommended.
KEYWORDS. Migraine, risk factors, ischemic storke, coronary artery disease.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0578

INTRODUCTION: Many instruments have been developed to evaluate hospital mortality, but less attention has been paid to the long-term functional status and quality of life (QOL) of traumatic brain injury (TBI) patients.
OBJECTIVES: To study the evolution of functional situation in the follow-up period between 1 year and 3-4 years and the related variables in traumatic brain injury (TBI).
METHODS. Prospective cohort study of traumatic brain injury admitted to the Carlos Haya Hospital (Málaga) between 2004-2008. Evaluated functional situation with Glasgow Outcome Scale (GOS) .
Data were expressed as the mean and standard deviation for quantitative variables and percentages for qualitative variables. We used ANOVA and Newman Keuls test to compare means, Pearson coefficient for correlation and logistic regression for multivariate analysis. . Statistically significant differences $p < 0.05$.
RESULTS. 531 patients. Mean age 40.35±19.75 years, APACHE-II 17.94 ±6.97, admission GCS 7.53±3.83 points. Computerized tomography (CT) on admission by Marshall score was: diffuse injury type I (10.4%), type II (28.1%), type III (24.5%), type IV (8.3%), mass evacuated (22.6%), mass not evacuated (6.2%). Hospital mortality 28.6%.
171 patients died at first year (32.2%) (6.6% missing) and at 4 years 175 died (33%) (16.2% missing). Of the 264 live and followed up at 3-4 years, 10 patients (3.8%) were in vegetative state, 54 (20.5%) were not self-sufficient, 68 (25.8%) were self-sufficient but dysfunctional, and 132 (50%) did not present dysfunction.
Normal functional status or with dysfunction but self-sufficient: 1st year 65.3% of the 325 patients alive and 3-4 years, 75.76% of the 264 alive and followed. Of these, 65 (24.6%) patients improved their functional situation, worsened 1 (0.4%) and 198 (75.3%) same.
The patients that improved their functional situation were younger (28.38±12.83 vs. 35.73±17.42 years, p=0.002), longer stay in ICU (15.43±12.55 vs. 12.56±12.88 days, p=0.038).
Multivariate analysis by multiple logistical regression found association between the improvement in functional situation(between 1 year and 3-4 years) with age OR: 0.97 (0.95-0.99) and with previous functional status (vegetative or not self-sufficient vs. without or with dysfunction but self-sufficient) OR 1.92 (1.06-3.50).
CONCLUSIONS. Approximately 75% of TBI that survive are self-sufficient at 3-4 years approx. Between 1 year and 3-4 years, the functional situation modifies favorably at 25% of the survivors, being greater in the youngest patients with functional situation dysfunction at first year.

Table 1 (abstract 0578). Improved situation functional (%)

Injury Type	Type I	11.6	p = 0.017
	Type II	23.9	
	Type III	40	
	Type IV	21.4	
	mass evacuated	18.8	
	Not evacuated	0	
Functional situation first year	vegetative	9.1	p<0.001
	Not self-sufficient	34.2	
	dysfunction but self-sufficient	46.2

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0579

INTRODUCTION. The presence of the physiotherapist in the Intensive Care Unit (ICU) with the
extended assistance from 12 to 24 hours, reduces the number of respiratory complications and the time of the individuals´ hospitalization, as well as the financial costs to the instituition.
OBJECTIVE. To verify if physiotherapy care (PTc) provided within 24 h/day for Cardiac patients in the Intensive Care Unit (ICU) reduces the length of stay, mechanical ventilation (MV) support and mortality compared to a physiotherapy care provided within 18 h/day.
METHODS. A longitudinal study was designed to assess differences between first three months of the year (2016) hospital where patients were given physiotherapy care for 18 h/day and last 3 months of 2016 with 24 h/day. We considered the following as outcome measurements: clinical diagnosis, APACHE II, ICU and mechanical ventilation length of stay and survival. T test of student was made to compare differences between two groups.
RESULTS. 103 patients were enrolled in this study (60% male, age 55 ± 18 years, APACHE II 20 (17-26). Patients admitted during 24h/day of PTc showed a lower length of stay in ICU (7 ± 3.1 days X 11.1 ± 3.9 days respectively, p = 0.03) and mortality rate (31% versus 39% respectively, p =0.04) , No difference was found for APACHE II score (p = 0.8) and MV length of stay (4.5 ± 3.4 X 5.5 ± 3.3 days, p > 0.05) between two groups.
CONCLUSION. The presence of a PTc contributes decisively to reduce number of hospitalization days and mortality of ICU clinical cardiac patients.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0580

INTRODUCTION. The determination of brain death is based on a comprehensive clinical assessment which includes catastrophic structural brain injury, absence of confounders, absence of motor response, absence of brainstem reflexes, and a formal apnea test. Several methods of apnea testing have been proposed, and each of them may have concerns. Physicians may be apprehensive about performing apnea test due to potential hypoxia, hypotension, and cardiac arrhythmias due to acidemia. Failure to perform the apnea test may lead to additional ancillary tests and possibly delay in organ procurement.
OBJECTIVES. To evaluate the safety profile of apnea test using oxygen diffusion method performed by neurointensivists.
METHODS. We reviewed 114 consecutive patients (16 years or older) who underwent an apnea test in the setting of brain death determination from 2008 to 2017 at Mayo Clinic.
RESULTS. 114 patients had a single apnea test to complete a brain death determination. Mean age was 48 years. Apnea test was terminated in only two patients (1 due to hypoxemia associated with pulmonary edema and one due to hypotension associated with chest trauma), and diagnosis of brain death was confirmed with a cerebral angiogram showing no intracranial circulation. In all but four patients (96 %), the apnea test was performed by a neurointensivist. The protocol included 10 minutes of pre-oxygenation and placement of the endotracheal catheter at the carina with 6 L/min. The baseline arterial blood gas showed median pCO2 of 41 mmHg, median pO2 of 302 mmHg and median pH of 7.38. After 8-12 minutes of disconnection from the ventilator, targets were reached with a median pCO2 of 72 mmHg, median pO2 of 306 mmHg and median pH of 7.19. Pretest mean arterial pressure of 90 mmHg (interquartile range: 78-100) decreased to 76 mmHg (interquartile range: 68.5-85) after the test. Median heart rate remained stable (91 to 94 beats/min). 100 patients (89 %) were on vasopressors before the apnea test, of which 39 patients required an increase in pressor dose during the test. None of the patients developed cardiac arrhythmia or cardiac arrest.
CONCLUSIONS. With preoxygenation and tracheal oxygen insufflation, less than 2% of the apnea tests are terminated. When compared with prior series of patients in our institution (1), without a consistent strict protocol, a marked decline (from 10%) in discontinuation of apnea tests was noted. Apnea testing using a predefined protocol and performed by neurointensivists is safe.

Correspondence: C. Sánchez Ramírez
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0581

OBJECTIVES. To evaluate the factors associated with disability and mortality six month after discharge in patients with decompressive craniectomy (DC) in the ICU.

METHODS. Prospective study of patients admitted from January 1, 2013 to march 2018 who required DC. DC was performed by intracranial hypertension (ICH) refractory to medical treatment. We analyzed: main diagnosis at admission; demographic data; neurological data (clinical examination and Glasgow Coma Score: GCS); hypotension: at the site, at hospital admission, in ICU and at hospital discharge; type of craniectomy and DC complications; Rankin scale, and Glasgow outcome scale (GOS) at 30 days after UCI admission, at ICU and 6 months after ICU discharge ; preoperative serum lactate levels and number of hours with intracranial pressure (ICP)> 20, 25 or 30 mmHg before DC; hypo and hyperglycemia; application of mannitol or hypertonic saline solution before and after DC; dose of catecholamines needed; leukocytes and platelets previous and after to DC and other factors related to prognosis. Categorical variables were summarized as frequencies and percentages and the continuous variables as medians and interquartile ranges (IQR) or means and standard deviations. Univariate analysis of disability (Rankin > 3) and mortality in ICU, 30 days after DC and 6 months after ICU discharge were performed. Statistical significance was set at p ≤ 0.05.
RESULTS. Twenty two DC patients were collected. Demographic data and types of admission are shown in Table 1.
Most were subarachnoid haemorrhages (SAH) (59,1%) and 68,2% of DC were hemicranial. The most frequent complications were reoperation due to complications (54.5%), hydrocephalus (50%) and extraaxial hematoma (36,4%). Five patients died at the ICU discharge (22,7%), 4 (80%) of them were SAH. Rankin mean at ICU discharge was 4 and GOS was 3. Rankin mean 6 months after ICU discharge was 2 and GOS was 4. Abcess after DC, number of platelets post DC and GCS at admission was associated with disability 30 days after DC (Table 2).
Mortality 6 months after discharge was significantly associated with bilateral pupillary reactivity prior DC (Table 3).
We found no significant factors associated with mortality in ICU or disability in ICU and six months.after discharge.
CONCLUSIONS. Preliminary data show low mortality (22,5%) of DC patients. Rankin and GOS reflect moderately severe disability of DC patients at ICU discharge. Rankin and GOS showed an improvement in disability.six months after ICU discharge.The presence of abcess after DC, number of platelets post DC and GCS at admission were significantly associated with disabiliity thirty days after DC. The presence of bilateral pupillary reactivity prior DC (with lower mortality), was significantly associated with mortality six months after ICU discharge.

The frontal bone window for transcranial Doppler ultrasonography in intensive care units: a new approach

P. Sentenac[1,2], J. Charbit[1], C. Maury[1], P. Bory[2], G. Dagod[1], F. Greco[2], X. Capdevila[1], P.F. Perrigault[2]

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0582

INTRODUCTION. The standard temporal bone window (TBW) for transcranial Doppler (TCD) is most often inadequate to insonate the anterior cerebral artery (ACA) because of a unfavourable angle of insonation. By improving the insonation rate of the ACA [1], the frontal bone window (FBW) is a promising alternative approach but has never been evaluated in intensive care units (ICU).

OBJECTIVES. To determine the ability of the FBW to assess ACA velocities in comatose populations admitted to ICU and the reproducibility of the technique.

METHODS. A prospective study was conducted at the University Hospital of Montpellier (France). Patients 18 years of age or older, admitted to ICU for neurological disease with GCS score less than 13, were enrolled within the first three days after admission, provided that they were clinically stable. Brain deaths were excluded. According to a standardized protocol (Fig1), a first TCD exam was carried out bilaterally through the TBW and FBW by an expert examiner categorizing patients into two groups: the FBW success (unilaterally or bilaterally) or FBW failure group. A second TCD exam was performed 15 min later by the same examiner. A third TCD exam was performed 30 min later by a blinded non-expert examiner. Intra and interobserver concordance of FBW measurements were analysed according to the limits of agreement (LOA) method. The correlation between ACA measurements recorded by TBW and FBW was expressed using correlation coefficient (r) and its 95% confidence interval (CI). P-values < 0.05 were considered significant.

RESULTS. Between Nov 2014 and Sept 2016, 147 patients were included. The first TCD exam was able to measure ACA velocities through the TBW in 91 patients (62%, CI[54-70]), 70 bilaterally and 21 unilaterally, and through the FBW in 66 patients (45%, CI[37-53]), 45 bilaterally and 21 unilaterally (Fig2). For 16 out of the 147 patients included (11%), the FBW was the only acoustic window allowing to measure ACA velocities. By combining the TBW with the FBW, the overall proportion of patients with at least one-sided ACA velocities measurements increased from 62% CI(54-70) to 73% CI(65-79) (p< 0.05). No risk factors for FBW failure were found. Intra and interobserver mean bias and 95% LOA for ACA systolic velocity measurements were similar, 1 (-33 to 35) and 2 (-34 to 38) cm.s^{-1} (Fig3). ACA systolic velocity was lower on average when measured through the FBW than TBW, 79±3 vs. 93±3 cm.s^{-1} (p< 0.05). ACA systolic velocities recorded by the FBW were not well correlated with those measured in the same patient by the TBW, r=0.47 CI(0.28-0.62).

CONCLUSIONS. This study was the first to evaluate the FBW in ICU. About one in two patients had an adequate FBW. Reproducibility was good. By insonating the ACA in a more distal segment (A2) than the TBW (A1), the FBW may enhance the monitoring of cerebral vasospasms.

Social media at international intensive care medicine conference - are the voices of nurses and AHPs being heard? A three-year analysis across continents

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0583

INTRODUCTION. The use of social media (SoMe) such as Twitter and Facebook has become ubiquitous at medical conferences including that for intensive care medicine (ICM). The perceived benefits of SoMe include increase interaction, enhanced learning and networking opportunities beyond the physical boundaries of the conference. Critics of SoMe have often cited that such online discussions are often heavily biased and without meaningful educational benefit. In a multi-disciplinary specialty of ICM, where nurses and Allied Health Professionals (AHPs) make up a numerically larger proportion of the team, we sought to assess their contributions, engagement and impact to such online conversations.

OBJECTIVES. To analyse the SoMe engagement of Nurses and AHPs at ICM conferences.

METHODS. The largest ICM conferences were identified by group consensus. The hashtags unique to the individual conferences were identified and analysed using proprietary Symplur algorithms. Quantitative and qualitative measures were collected and comparisons made across the various conferences in 2015 to 2017.

RESULTS. The annual conference of five main societies/organisations were identified during 2015 to 2017. These were the Society of Critical Care Medicine congress, European Society of Intensive Care Medicine congress, the International Symposium on Intensive Care & Emergency Medicine, the Social Media and Critical Care (SMACC) Congress and the UK's Intensive Care Society Congress. The number of tweets at each conference increased annually between 2015 to 2017 with the exception of SMACC 2017; although this had the most number of tweets of all the other organisations. The increase ranged from -12.1 to 267.7%. Tweets from nurses/AHPs made up an average of 10.8% of tweets (4.9 - 21.7%). Quantitative measures in the form of a Healthcare Social Graph (HSG) score showed that that tweets from nurses/AHPs were of lower impact compared to physicians. Average HSG score for nurses/AHPs was 6.6 (1.9 - 14). The average physician score was 57.0 (30.8 - 82.9). There was a significant difference when comparing European and American conferences.

CONCLUSIONS. Although utilisation of SoMe in ICM conferences have increased, the online conversation is dominated by physicians. Despite the possibilities of improved discussion and accessibility that SoMe offers, nurses and AHPs lag behind their physician colleagues. There is a risk that their opinions are not heard and that conferences do not provide any meaningful educational attraction to them. ICM is a multidisciplinary specialty and it is important that this is addressed. Professional societies have dedicated Nurses/AHP committees with involvement in conference organisation. Dedicated conference SoMe teams should consider the composition of the team to be more reflective of the specialty.

An evaluation of the role of occupational therapy within a United Kingdom multi speciality critical care unit

E. Felton[1], T. Downey[1], C. Hassan[1], D. McWilliams[2]
[1]Queen Elizabeth Hospital NHS FT, Therapy Services, Birmingham, United Kingdom; [2]Queen Elizabeth Hospital NHS FT, Birmingham, United Kingdom
Correspondence: E. Felton
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0584

INTRODUCTION. There is an increasing awareness of the benefits of Occupational Therapy (OT) within the intensive care setting, with a number of studies demonstrating the safety and feasibility of early OT input whilst patients are still invasively ventilated. When introduced at this early part of the patient pathway, OT has been associated with improved function at hospital discharge, reduced incidence and duration of delirium, reduced ICU and hospital length of stay, and reduced hospital costs (Pohlman et al, 2010; Schweickert et al, 2009). As these studies were completed predominantly in the United States, further research into the role of the OT within critical care in the UK is needed.

OBJECTIVES. To establish a general overview of the role and potential impact of the OT within a UK based critical care unit over a 6 month period.

METHODS. A new OT post was created on the 1st January 2017 to work within the already established critical care physiotherapy and rehabilitation team. Data was collected for a period of 6 months to evaluate the number of referrals received for OT assessment and any subsequent interventions provided.

RESULTS. A Total of 262 referrals were received from a range of specialities during the study period. Approximately half of these (n=135, 52%) were assessed by an OT prior to ward transfer, with reasons for a lack of OT assessment in critical care due to a lack of service capacity or patients being transferred to ward < 48 hours after referral. A range of different interventions were provided by the OT within critical care (See box 1), including the early assessment and diagnosis of Post Traumatic Amnesia (n=46) and earlier establishment of specialist seating and postural programmes (n=51).

CONCLUSIONS. A large number of referrals were received during the trial period highlighting a significant need for OT within critical care. When available, OT's can fulfil a range of positive roles for patients admitted to critical care including the earlier diagnosis of PTA which otherwise would remain undiagnosed until ward transfer. The OT was also able to assess and provide specialist seating where required to facilitate earlier mobilisation. The overall impact was limited however as a large number of patients were not assessed due to capacity issues. Further research should aim to review the impact of OT input on length of stay, delirium and enhancing patient experience.

The impact of a 7 day working model on physiotherapy intervention and outcomes in the abdominal surgical patient group compared to a traditional 5 day service

P. Piper[1], O. Gustafson[1], J. Ede[2], S. Vollam[2]
[1]Oxford University Hospitals NHS Trust, Adult Intensive Care Unit, Oxford, United Kingdom; [2]University of Oxford, Nuffield Department of Clinical Neurosciences, Oxford, United Kingdom

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0585

INTRODUCTION. Physiotherapy services in critical care are traditionally delivered Monday-Friday, with the provision of an acute respiratory service at weekends and overnight. Early goal-directed rehabilitation has been shown to improve short term clinical outcomes in patients following abdominal surgery[1]. The effect of a 7 day physiotherapy critical care rehabilitation service on this patient group is unknown. This prompted a mixed methods evaluation of the implementation of 7 day working in critical care on patients following abdominal surgery, and the multidisciplinary staff involved in their care. This evaluation is part of a larger retrospective evaluation of 7 day working in critical care.

OBJECTIVES. To assess the impact of a limited 7 day model on the provision of physiotherapy and rehabilitation interventions to patients following abdominal surgery.

To assess the impact on the level of mobility achieved on ICU discharge, post-ICU length of stay and hospital discharge destination.

METHODS. A service change which included an additional 1.5 physiotherapists and an adjustment to the ICU physiotherapy team working patterns was instigated at a UK general tertiary adult ICU in July 2017. An emergency respiratory physiotherapy weekend service was replaced with a limited critical care physiotherapy service that provided both rehabilitation and respiratory interventions. Data was collected for all patients following abdominal surgery admitted to the ICU between September and December 2017, and was directly compared to all patients undergoing abdominal surgery in the same time period in 2016. The primary outcomes were the number of physiotherapy and rehabilitation interventions. Secondary outcomes were: post-ICU length of stay, level of mobility on ICU discharge and hospital discharge destination.

RESULTS. There were no statistically significant differences in patient characteristics between the two groups. Following the service change there was a significant improvement in: the number of rehabilitation interventions received by patients (p= 0.015), level of mobility on ICU discharge (p=0.042) and number of patients discharged home (p=0.014). There was a reduction in post-ICU length of stay of 2.5 days and an increase in the median number of physiotherapy interventions per patient. These did not reach statistical significance.

CONCLUSIONS. Following the instigation of a 7 day critical care physiotherapy model, patients undergoing abdominal surgery received more rehabilitation interventions. They achieved a higher level of mobility on ICU discharge with a greater number discharged home from hospital.

An Investigation into the use of ultrasound as a surrogate measure of respiratory muscle function

S. Holtzhausen, A. Lupton-Smith, M. Unger, S. Hanekom
Stellenbosch University, Cape Town, South Africa
Correspondence: S. Hanekom
Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0586

INTRODUCTION. Sonographic measurements of diaphragm thickness may be a surrogate for interpreting diaphragm function in a mechanically ventilated population, where volitional measures of respiratory muscle function may not be possible. Given the effects of mechanical ventilation and critical illness on respiratory muscle function, early identification of "at risk" patients may help earlier, targeted interventions to optimise respiratory muscle function and improve outcomes. To understand what happens in illness, we first need to understand what happens in health.

OBJECTIVE. This study aimed to determine the correlation between respiratory muscle strength, fatigue, endurance and diaphragm thickness in a healthy population.

METHODS. A descriptive correlational study using a sample of convenience was conducted. University students were stratified according to three activity-levels (sedentary; endurance- and strength related sporting activities), gender and body mass index (BMI).

Diaphragm thickness was determined by sonographic measurement. Respiratory muscle strength, fatigue and endurance was determined using a mouth pressure manometer and calculating the maximal inspiratory pressure and fatigue resistance index and time to fatigue.
RESULTS. 55 subjects with a mean (SD) age 21.16±1.55 years were studied. The mean (SD) diaphragm thickness was 1.92 mm (0.61), mean fatigue resistance index was 0.93 (0.13) and median (IQR) time to fatigue was 3:00:00 minutes (12:28:51). Diaphragm thickness moderately correlated with strength (r=0.52; r2=0.27; p< 0.001) and BMI (r=0.57; r2=0.33; p< 0.001). There was a weak independent correlation between strength and BMI (r=0.37; r^2=0.14; p=0.01). Respiratory muscle fatigue was not correlated with thickness (r=-0.15; r^2=0.02; p=0.29) or strength (r=-0.19; r^2=0.04; p=0.16).
CONCLUSION. Diaphragm thickness was moderately correlated to strength but not to fatigue or endurance in healthy individuals. Sonography may be a surrogate measure of volitional respiratory muscle strength, and requires confirmation in the critically ill population. Whether the sonographic measures will facilitate early identification of patients at risk of poor respiratory muscle function and allow for earlier, more targeted interventions, needs further work.

Intensive Care Medicine Experimental 2018, **6**(Suppl 2):0587

INTRODUCTION. More patients survive critical illness in intensive care due to advanced medical technology. The last years there has been an increased focus on post intensive care. Patients and their family experience post intensive care symptoms, defined as PICS and PICS-F (1). The spouse is the primary caregiver and plays a significant role in helping and supporting the patient after discharge to home.
OBJECTIVES. The aim of this study was to describe experiences of patient and their spouse following discharge from intensive care to home.
METHODS. Within a phenomenological-hermeneutical framework, a qualitative interview study was conducted. The study had an inductive, explorative approach. Three patients (age 72-74) and their spouses, 3 men and 3 women, were recruited from a Danish general ICU. Patients had been mechanical ventilated between 93 and 140 hours, with APACHE II scores between 28-48. All the Patients were following a no sedation strategy during mechanical ventilation in the ICU. Patients and spouses have been married between 49-51 years. Semi-structured individual interviews were conducted 8-11 weeks after discharge from the ICU. Five interviews were conducted in private homes of the participants and one patient participant was interviewed at a community rehabilitation facility. Data was analysed with a thematic analyses based on Interpretative Phenomenological Analyses (IPA) approach.
FINDINGS. The findings give an insight to patients and spouses experiences and the post intensive care when recovering during and after hospital admission. Three themes have emerged: "Spouse as continuity", "Need to be accommodated" and "Turning point - Road to recovery". "Spouse as continuity" describes the spouse as a continuous figure in the patient's illness trajectory where illness has first priority and the spouse has a caregiver role. The second theme, "Need to be accommodated", describes patient and spouse experiences when meeting healthcare professionals, feelings of helplessness, post intensive symptoms and transitions in post intensive care. The third theme, "Turning point - Road to recovery" contributes descriptions into patient and spouse experiences of the patient getting better and more positive about the future in the illness trajectory and includes perspectives on rehabilitation and needs of professional follow-up.

CONCLUSION. Perspectives of patients and spouse's experiences gives healthcare professionals a unique insight, which can be used in future planning of supporting initiatives to patients and near relatives in the post intensive care.

INTRODUCTION. Nurses are present at the bedside 24/7 in the intensive care unit (ICU) and carry the responsibility for patient mobilization when other healthcare professionals are absent (1). Lighter sedation has enabled early mobilization of mechanically ventilated patients (2), but little is known regarding the nurses' role and interaction with critically ill patients in relation to mobilization.
OBJECTIVES. We aimed to explore the nurse-patient interaction in relation to mobilization of non-sedated and awake mechanically ventilated patients in the ICU.
METHODS. The study had a qualitative design using an ethnographic approach within the methodology of Interpretive Description. Data were generated in two intensive care units in Denmark where a strategy of no sedation was applied. Participant observation was conducted during nurse-patient interaction in relation to mobilization with nurses (n=44) and mechanically ventilated patients (n=25). We conducted individual, semi-structured interviews with nurses (n=16), and patients (n=13), who had been mechanically ventilated for at least three days. Data were analyzed using inductive, thematic analysis.
RESULTS. We identified three themes: *"Diverging perspectives on mobilization"* showed that nurses had a long-term and treatment oriented perspective on mobilization while patients had a short-term perspective and regarded mobilization as overwhelming in their present situation. *"Negotiation about mobilization"* demonstrated how patients actively negotiated the terms of mobilization with the nurse. *"Inducing hope through mobilization"* captured how nurses encouraged mobilization by integrating aspects of the patient's daily life as a way to instill hope for the future.
CONCLUSIONS. Exploring the nurse-patient interaction illustrated mobilization as more than physical activity. Mobilization is accomplished in nurse-patient collaboration as a negotiated, complex and meaningful achievement, driven by logic of care and leading to hope for the future. The study demonstrated the important role of nurses in achieving mobilization in collaboration and negotiation with mechanically ventilated patients in the intensive care unit.

INTRODUCTION. The use of a specialized skin care devices reduces the risk of pressure ulcers in comparison with the traditional methods of skin cleansing using water and soap[1]. However it is unclear whether these methods are effective in the prevention microdamage of the patient´s skin, as well as in reducing the physical effort of medical personnel in the ICU.

OBJECTIVES. Comparison of the use of specialized washcloths and the traditional skin care method for ICU-patients in terms of efficacy and safety.

METHODS. We conducted a monocentric, open-label, randomized, controlled trial (Sept. 2016 - Jun. 2017) to compare two skin care regimes. The traditional method including cleansing with water, liquid soap, cotton napkins and towels was used in group I. In group II patients' skin was cleaned by hygienic single use washcloths pre-moistened with a hypoallergenic cleansing lotion with an extract of chamomile, aloe, glycerin, panthenol, vitamin E; the lotion did not contain irritants (soap, alcohol). After every skin cleaning procedure nurses filled in the form, where they had to rate the simplicity of the method, the intensity of the physical effort, the necessity of additional personnel and the duration of the procedure. We used 5-step scale - from 1 (very bad) to 5 (very good). Both groups were assessed for the frequency of skin damage (maceration, intertrigo, excessive dryness, microdamage, dermatitis) and pressure ulcers (stages I-IV).

RESULTS. Thirty patients were enrolled in each group. The groups were comparable in Waterlow scale 13,8±5,2 in group I vs. 14,9±5,2 in group II, p=0,18; use of mechanical ventilation 15 (50%) vs. 20 (66,7%), p=0,3, use of catecholamines 14 (46,6%) vs. 17 (56,7%), p=0,6. The significant differences were identified in SOFA scale: 3,4 ±2,4 in group I vs. 4,2±3,7 in group II, p=0,012. No statistically significant differences in skin damage 52 (34,7%) vs. 53 (35,3%) cases, p=0,998, in frequency of pressure ulcers of I-II stages 7 (23,3%) vs. 12 (40%), p=0,267 were detected. The pressure ulcers of III-IV stages were not recorded. Eighteen nurses took part in the survey, 676 forms were processed. The results of survey are reflected in the table.

Special skin care devices made it possible to reduce the time of skin care from 16 mins. to 9 mins.

CONCLUSIONS. The use of a hygienic pre-moistened washcloths is safe for skin care. It's time-saving and ergonomic effective while not negatively affecting the skin.

INTRODUCTION. The level of expertise with a surgical procedure are often proportional to the amount of experience. The effect of case volume on postoperative outcomes is well established for surgical procedures including cardiac surgery, pyloromyotomy, and inguinal hernia in pediatric patients.

OBJECTIVES. The purpose of this study was to evaluate whether institutional case volume affects clinical outcomes after pediatric liver transplantation.

METHODS. We conducted a nationwide retrospective cohort study using the database of Korean National Healthcare Insurance Service. Between January 2007 and December 2016, 521 pediatric liver transplantations were performed at 22 centers in Korea. Centers were categorized according to the average annual number of liver transplantations: >10, 1-10, and < 1.

RESULTS. In-hospital mortality rates in the high-, medium-, and low-volume centers were 5.8%, 12.5%, and 32.1%, respectively. After adjustment, in-hospital mortality was significantly higher in low-volume centers (adjusted odds ratio, 9.693; 95% CI, 4.636-20.268; *P*< 0.001) and medium-volume centers (adjusted odds ratio, 3.393; 95% CI, 1.980-5.813; *P*< 0.001) compared to high-volume centers. Long-term survival for up to 9 years was better in high-volume centers.

CONCLUSIONS. Centers with higher case volume (>10 pediatric liver transplantations/year) had better outcomes after pediatric liver transplantation, including in-hospital mortality and long-term mortality, compared to centers with lower case volume (≤10 liver transplantations/year).

INTRODUCTION. Paediatric patients who underwent cardiac surgery are prone to postoperative infectious complications. For β-lactams, the time interval during which plasma concentration is above the minimal inhibitory concentration (fT>MIC) should be at least 50% of the dosing interval and ideally 100% to treat severe infections in critically ill patients [1,2]. Cardiac surgery with cardiopulmonary bypass, critical illness and intensive care therapies can significantly alter antibiotic disposition in the postoperative period.

OBJECTIVES. The aim of this study was to determine whether adequate antimicrobial plasma concentrations of amoxicillin-

clavulanate were obtained with a standard dosing regimen of 25 to 50 mg/kg every 6 hours in paediatric intensive care patients after cardiac surgery.
