• **Background and Aims** An understanding of mycorrhizal variation, orchid seed germination temperature and the effect of co-occurring plant species could be critical for optimizing conservation translocations of endangered plants with specialized mycorrhizal associations.
• **Methods** Focusing on the orchid *Thelymitra epipactoides*, we isolated mycorrhizal fungi from ten plants within each of three sites; Shallow Sands Woodland (SSW), Damp Heathland (DH) and Coastal Heathland Scrub (CHS). Twenty-seven fungal isolates were tested for symbiotic germination under three 24 h temperature cycles: 12 °C for 16 h–16 °C for 8 h, 16 °C for 16 h–24 °C for 8 h or 27 °C constant. Fungi were sequenced using the internal transcribed spacer (ITS), nuclear large subunit 1 (nLSU1), nLSU2 and mitochondrial large rRNA gene (mtLSU). Orchids were grown to maturity and co-planted with each of ten associated plant species in a glasshouse experiment with tuber width measured at 12 months after co-planting.
• **Key Results** Two *Tulasnella* fungal lineages were isolated and identified by phylogenetic analyses, operational taxonomic unit 1 (OTU1) and '*T. asymmetrica*'. Fungal lineages were specific to sites and did not co-occur. OTU1 (from the SSW site) germinated seed predominantly at 12–16 °C (typical of autumn–winter temperature) whereas '*T. asymmetrica*' (from the DH and CHS sites) germinated seed across all three temperature ranges. There was no difference in the growth of adult orchids germinated with different OTUs. There was a significant reduction in tuber size of *T. epipactoides* when co-planted with six of the commonly co-occurring plant species.
• **Conclusions** We found that orchid fungal lineages and their germination temperature can change with habitat, and established that translocation sites can be optimized with knowledge of co-occurring plant interactions. For conservation translocations, particularly under a changing climate, we recommend that plants should be grown with mycorrhizal fungi tailored to the recipient site.

Key words: Orchidaceae, mycorrhizae, *Tulasnella*, translocation, *Thelymitra epipactoides*

INTRODUCTION

Globally, one in five plant species are under threat of extinction (Pimm *et al.*, 2014; Anderson *et al.*, 2016) from a diversity of threats such as habitat destruction (Tilman *et al.*, 1994), invasive species (Mack *et al.*, 2000), overexploitation (Brook *et al.*, 2008) and climate change (Thomas *et al.*, 2004). Human intervention is required to prevent extinctions, and increasingly conservation translocations (see definition in IUCNS, 2013, i.e. the deliberate movement of organisms intended to yield a conservation benefit at a population, species or ecosystem level) offer the last hope for species' survival. One possible factor increasing the likelihood of extinction is specialization with a partner organism (Harcourt *et al.*, 2002). Where specialists lose an essential symbiosis from part of their range, such as pollinators (Robertson *et al.*, 1999; Anderson *et al.*, 2011; Pauw and Hawkins, 2011; Reiter *et al.*, 2017) or mycorrhizal fungi (Shefferson *et al.*, 2005; Swarts *et al.*, 2010), a range retraction is inevitable. Conversely, generalists are more likely to be resilient to losing a symbiotic partner as they may be able to switch to another association in part of

their range (Johnson and Steiner, 1997). Therefore, conservation translocations of plants with specialized ecological interactions require not only a thorough knowledge of the threats and threat management (Vallee, 2004), but also a detailed understanding of the ecology (Reiter *et al.*, 2016) of the pollinators (Phillips *et al.*, 2014; Reiter *et al.*, 2017) and mycorrhizal fungal associations (Batty *et al.*, 2001). Yet specialized ecological interactions are rarely specifically addressed in plant conservation translocations (Reiter *et al.*, 2016). Addressing this gap in both knowledge and conservation practice has the potential to increase the long-term success of plant translocations.

The Orchidaceae is a charismatic and diverse plant family with approx. 26 567 species globally (World Checklist of Selected Plant Families, 2017). With high levels of geographic endemism and complex relationships with other organisms (Swarts and Dixon, 2009; Orejuela-Gartner, 2012), it has been predicted that many orchids may be among the first to decline when a habitat is degraded (Backhouse, 2007). All orchids are reliant on mycorrhizal associations in order to germinate in the wild (Warcup, 1971;

Rasmussen, 1995, 2002). However, their level of dependence may change throughout their life cycle (Rasmussen, 2002; Cameron *et al.*, 2006). For example, there is evidence in some species that dependence on mycorrhizal fungi for nutrition and survival differs between seedlings and mature plants (Waterman and Bidartondo, 2008), achlorophyllous (Selosse and Roy, 2009) and chlorophyllous species (Stöckel *et al.*, 2014). Furthermore, orchids differ in their specificity for mycorrhizal symbionts (Swarts *et al.*, 2010), which may affect their predisposition to extinction, through limiting suitable sites at local or regional scales.

Orchids most commonly form mycorrhizal associations with fungi belonging to three groups (Tulasnellaceae, Sebacinaceae and Ceratobasidiaceae) of the basidiomycetes (Taylor *et al.*, 2002; Weiss *et al.*, 2004). The Tulasnellaceae are widespread orchid mycorrhizal fungi (OMFs) in both temperate and tropical regions (Dearnaley *et al.*, 2012), and yet their ecology remains largely unstudied (Selosse and Martos, 2014); but see Fochi *et al.* (2017). Orchids forming mycorrhizal relationships with Tulasnellaceae may form relationships with either a phylogenetically narrow group of fungi, e.g. *Cypripedium* spp. (Shefferson *et al.*, 2005, 2007) or a phylogenetically broad group of fungi (e.g. *Tipularia discolor* associations; McCormick *et al.*, 2004).

Given their reliance on fungi for germination and in many cases annual growth, the distribution of OMFs could theoretically affect the geographic ranges of orchids. Orchids that are generalists (associating with a phylogenetically broad group of fungi), e.g. *Dactylorhiza majalis* (Jacquemyn *et al.*, 2012), may have a broad distribution due to less specific niche requirements of their fungi. On the other hand, orchids that are specialists may have fewer fungal associations, but if the OMFs have a wide geographic distribution, e.g. in *Pheladenia deformis* (Davis *et al.*, 2015), the orchid's distribution is not limited by the OMF with which it associates. Those orchids that have a specific mycorrhizal relationship, but only associate with fungi that also have limited distribution, are likely to be restricted in range (Swarts *et al.*, 2010), though in practice there has been limited evidence for orchid mycorrhiza with restricted ranges. Therefore, high mycorrhizal specificity (i.e. an orchid only forming symbiosis with one or a few lineages of mycorrhizal fungi from a narrow phylogenetic lineage) is not necessarily associated with orchid rarity. For example, narrow phylogenetic groups of tulasnelloid mycorrhizal fungi were found in threatened and common species of *Drakaea* (Phillips *et al*., 2011, 2014; Linde *et al.*, 2014) and *Chiloglottis* (Roche *et al.*, 2010; Linde *et al.*, 2017), but because the OMFs are widely distributed (covering the range of the entire orchid genus), no impact on species distribution is expected. It is likely that factors other than OMF specificity and distribution impact on orchid distribution, as some rare orchids such as the highly endemic terrestrial *Teagueia* morphospecies in Ecuador, associate with a Tulasnellaceae OMF that has a worldwide distribution (Suárez *et al.*, 2016).

To be confident that fungi associated with orchids are mycorrhizal, it is important to show an effective symbiosis between orchid and fungus. Although direct sequencing from orchid roots and soil allows for a complete picture of those organisms present, it does not enlighten us on the ability of these organisms to form an effective mycorrhizal association. Some caution is needed in the interpretation of patterns of specificity in previous papers, where the fungi identified have not been tested directly for the ability to form symbioses (see papers cited in the review of McCormick and Jacquemyn, 2014). More useful for orchid

conservation are studies that both sequence and test germination ability (McCormick *et al.*, 2004; Roche *et al.*, 2010; Smith *et al.*, 2010; Phillips *et al.*, 2011; Linde *et al.*, 2014; Mujica *et al.*, 2016). In most orchids, we do not know if the mycorrhizal fungi that germinate seed also sustain adult plants. Tests for mycorrhizal compatibility with orchids typically are conducted with seed germination studies, where the production of rhizoids or a green leaf constitutes a positive interaction (Batty *et al.*, 2001; Roche *et al.*, 2010; Davis *et al.*, 2015; Phillips *et al.*, 2016). Longer term trials that compare the efficacy of different fungal species on orchid growth with maturation are rare, but showed that OMFs which induced the most seed to germinate were not necessarily those that resulted in the best survival of orchid seedlings (Rasmussen, 1995; Huynh *et al.*, 2009). Furthermore, Smith *et al.* (2010) cautioned that long-term success in orchid survival under field conditions may be dependent on highly specific host–fungus interactions that may prove to be significant in the long term.

To date, the surrounding non-orchid flora's effect on orchid growth, either detrimentally by competing for resources or positively by providing nutrients or suitable microclimate, is underexplored. If we are to conduct conservation translocations on species that are reliant upon mycorrhizal fungi for germination and to sustain populations in the wild, we require the fungi to be cultivable, able to germinate the seed and sustain adult plants. We need to understand whether these symbiotic associations change with different habitats and whether the ability of the mycorrhizal fungi to germinate orchid seed changes under different climatic conditions. Mycorrhizal distribution may be limited by edaphic conditions, including: soil chemistry, moisture, pH, organic content and nutrient availability (Perkins and McGee, 1995; McCormick *et al.*, 2004; Bunch *et al.*, 2013; McCormick and Jacquemyn, 2014). In arbuscular mycorrhiza, the associated vegetation or even invasive plant species may affect the mycorrhizal community abundance (Zubek *et al.*, 2016). Therefore, tests of mycorrhizal symbiosis may benefit not only from the evaluation of short-term seed germination but also from longer term growth alone and with associated species from the sites where the orchids occur. We are not aware of any study with orchids that have utilized pot trials with naturally co-occurring plant species to investigate how they affect orchid growth.

Here we investigate aspects of mycorrhizal ecology useful for optimizing germination and conservation translocations. We use *Thelymitra epipactoides* (Orchidaceae), a species previously widespread across south-eastern mainland Australia, as our study species. Due to habitat destruction, *T. epipactoides* is now endangered under the federal Environment Protection and Biodiversity Conservation Act (1999) and is considered a high priority for conservation translocation (Coates *et al.*, 2002). It now has a discontinuous distribution ranging from coastal to near-desert habitats across its range (Jeanes and Backhouse, 2006). *Thelymitra epipactoides* associates with *Tulasnella asymmetrica* based on morphological culture identification (Warcup, 1981). In order to optimize germination and conservation translocations, we investigate the OMF associations from *T. epipactoides* growing in ecologically and climatically different sites. Furthermore, we investigate whether OMFs from the different sites differ in their optimum temperature requirements for seed germination. Specifically, we ask the following questions. (1) Is there habitat-driven variation in *Tulasnella* associated with *T. epipactoides*? (2) Do *Tulasnella* operational taxonomic units (OTUs) from climatically different sites have

different temperature requirements for orchid seed germination? (3) Do symbiotically grown *T. epipactoides* plants benefit from co-planting with associated flora?

MATERIALS AND METHODS

Study species

The genus *Thelymitra* consists of approx. 110 species, with a distribution across Australia, New Zealand, Indonesia, New Caledonia, New Guinea and the Philippines (Jeanes, 2013). *Thelymitra epipactoides* is a summer-dormant herbaceous geophyte that survives over summer as an underground tuber. Each tuber produces a single leaf and a flowering stalk to 18–30 cm tall with a raceme of between six and 25 flowers (Fig. 1) with a metallic lustre coloured pink, bronze, green, blue or red (Jeanes, 2011). The orchid is thought to be food deceptive and pollinated by native bees (*Nomia* and *Lasioglossum* sp.) (Cropper and Calder, 1990).

Sites

Thelymitra epipactoides populations growing in three habitats were studied: Shallow Sands Woodland (SSW), Damp Heathland (DH) and Coastal Heathland Scrub (CHS) (Table 1; Fig. 2). All three sites have a Mediterranean climate with cooler wetter winters and hotter drier summers. These sites represent the range of habitats and climate in which the species is known to occur, with variation in soil types, rainfall and temperature between sites. The SSW site is the driest with the most extreme temperature ranges, whereas the CHS site is the wettest with the least temperature range (Table 1; Fig. 2). The SSW vegetation is open with an overstorey of *Eucalyptus leucoxylon*, *Callitris gracilis* and *Allocasuarina verticillata*, a middle storey of a variety of acacias and a diverse understorey of *Astroloma*, bulbs including *Arthropodium fimbriatum* and *Bulbine bulbosa*, and 15 orchid species. The DH site is dense and consists predominantly of *Leptospermum continentale* and a variety of acacias with a diverse understorey of *Lepidosperma*, *Stackhousia*, *Thomasia petalocalyx*, *Kennedia prostrata* and a variety of legumes (Fabaceae). The CHS site is dense and consists of an overstorey of *Melaleuca lanceolata* and *Allocasuarina verticillata*, with a middle storey of *Leptospermum continentale*. The understorey included *Poa poiformis*, *Lomandra longifolia*, *Correa reflexa* and *Dianella brevicaulis*. The grass *Rytidosperma* occurs at all sites.

Fungal isolation

In winter, when plants were actively growing, ten plants from each site had sections of lateral roots above the tubers removed, and fungi were isolated from these roots within 4 h of collection. Roots were gently rubbed by hand and rinsed for 15 min in running water before selected regions were surface-sterilized in 0.05 % NaOCl for 3 min and rinsed with sterile water. Root tissue was sliced open with a glass blade to release pelotons. Pelotons were rinsed in a series of sterile water droplets (Rasmussen *et al.*, 1990) in a laminar flow cabinet. Individual pelotons were plated onto fungal isolation medium (FIM) (Clements *et al.*, 1986) containing 0.05 g L^{-1} streptomycin. Three isolates per plant were grown, of which 32 isolates were sequenced across all regions.

Fungal sequencing

Fungal isolates were sub-cultured into 40 mL aliquots of liquid oatmeal broth (25 g of rolled oats, boiled, strained and made up to 1 L with water) and grown in shake-culture at 25 °C for 4 weeks. Fungal pellets were removed from the liquid medium, blotted on tissue and DNA was extracted from approx. 100 mg of each fungus using a Qiagen Plant DNeasy kit according to the manufacturer's instructions, including the optional centrifugation step (Qiagen, Hilden, Germany), and elution into 2 × 50 μL instead of 2 × 100 μL.

Sequences of four regions [internal transcribed spacer (ITS), nuclear large subunit 1 (nLSU1), nLSU2 and mitochondrial large rRNA gene (mtLSU)] were obtained using the primers and thermocycling conditions listed in Table 2. Thirty-two isolates across all sites were sequenced across all regions: with 13 isolates from SSH, eight from DH and 11 from CHS sites. For the initial PCR amplifications, each 25 μL reaction contained 12.5 μL of Promega GoTaq Green Master Mix, 8.5 μL of nuclease-free water, 1 μL each of forward and reverse primers (10–25 μM) and

2 µL containing 5–20 ng of genomic DNA or sterile nuclease-free water. After amplification in a G-Storm thermocycler using the PCR conditions in Table 2, a 5 µL aliquot of the products was electrophoresed at 80–100 V alongside a GeneRuler™ 100 bp Plus ladder in a 1.4 % agarose gel either in TBE [Tris-borate-EDTA: 10.8 g L⁻¹ Tris base, 5.5 g L⁻¹ boric acid, 4 mL of 0.5 M EDTA pH 8.0] or in TAE (Tris-acetate-EDTA: 4.84 g L⁻¹ Tris base, 1.142 g L⁻¹ glacial acetic acid, 2 mL of 0.5 M EDTA pH 8.0), stained with ethidium bromide and imaged using a Bio-Rad Gel Doc system with Quantity One software.

The PCR products were purified using a Qiagen QIAquick PCR Purification Kit according to the manufacturer's instructions. Purified products were sequenced using the BigDye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems, www.thermofisher.com). Each 20 µL reaction contained: 2 µL

of 10× buffer, 14 µL of nuclease-free water, 1 µL of Big Dye mix (Version 3.1), 1 µL of the appropriate primer (0.16 µM) and 2 µL of cleaned PCR product (5–20 ng). Cycling parameters were as in Table 2. DNA was precipitated using the Applied Biosystems ethanol-precipitation protocol 1, and products were electrophoresed and sequenced at Micromon, Monash University (https://platforms.monash.edu/micromon/).

Analysis of DNA sequence data

Alignments of the four DNA sequence regions were performed in Geneious V10.0.8 (Kearse *et al.*, 2012). A Maximum Likelihood analysis for each individual DNA region, as well as a concatenated four-region alignment, was run in RAxML

ITS, nuclear ribosomal internal transcribed spacer region; nLSU1, nuclear large subunit (28S) region 1; nLSU2, nuclear large subunit (28S) region 2; and MtLSU, mitochondrial large RNA gene

(Stamatakis *et al.*, 2008) through Geneious with 1000 bootstrap replicates. Furthermore, a Bayesian analysis was run in MrBayes 3.2.2 (Ronquist *et al.*, 2012), also through Geneious. Analyses were run for 2 million generations (first 25 % discarded as burn-in, Markov chain sampled every 1000 generations) with four chains, using the GTR + G model. Although trees were rooted to *T. albida*, trees were later visualized and midpoint rooted in Figtree v 1.4 (Rambaut and Drummond, 2012). Convergence was considered to be sufficient if the s.d. of the split frequencies was <0.02.

The maximum level of sequence divergence at the ITS was calculated within a putative species using Geneious V10.0.8 (Kearse *et al.*, 2012). To establish the level of divergence within species, minimum and maximum sequence divergences within a clade were calculated. Also, the maximum sequence divergence within a species was compared with the minimum genetic divergence with any of the individuals in the sister clade. Closely related sequences from GenBank were included in Figs 3 and 4.

Symbiotic germination: general methods

Seed collected from 7–10 hand-pollinated *T. epipactoides* individuals from each of the above three sites was combined and thoroughly mixed, air-dried and stored with dried silica crystals at 4 °C for up to 6 months for use in symbiotic seed germination tests. Seeds were surface-sterilized with 0.5 % NaOCl (10 % Domestos®) for 3 min, drained by vacuum onto a 3 µm pore filter, rinsed with sterile water and plated onto sterile filter paper on plates of oatmeal agar (OMA) (Clements and Ellyard, 1979) with 2 g L⁻¹ sucrose and 0.1 g L⁻¹ yeast extract in a laminar flow cabinet. A 1 cm OMA agar block colonized with an isolated fungus was placed on two ends of the filter paper. Plates were sealed with Parafilm® and incubated in the dark.

Symbiotic germination temperature trial

Sequencing results confirmed only two fungal OTUs, with only one OTU isolated at any given site. To test if temperature affected germination in OTU1 and '*T. asymmetrica*', 27 fungal isolates (nine isolates from the SSW pertaining to OTU1, and 18 isolates pertaining to '*T. asymmetrica*' which included nine isolates from each of the DH and CHS sites) were tested for symbiotic germination under three temperature cycles: 12 °C for 16 h–16 °C for 8 h, 16 °C for 16 h–24 °C for 8 h, or 27 °C constant. There were three replicated germination plates per fungal isolate per temperature treatment [thus a minimum of 27 replicates were tested of OTU1 (SSW) and 54 replicates for '*T. asymmetrica*' (DH and CHS)]. Germination was scored as the presence or absence on the production of leaf primordia (Stage 5 of Warcup, 1981).

Symbiotic germination effect of fungal OTU on growth of adult plants

To test the effect of site of isolation of fungi and the effect of fungal OTU on growth of adult plants, germinated seedlings from the above trial were flasked using the methods of Reiter *et al.* (2016), and grown for a further 8 weeks before de-flasking. We de-flasked 35 *T. epipactoides* germinated with
FIG. 3. Phylogenetic tree for the ITS region of *Tulasnella* isolates from the Shallow Sands Woodland, Damp Sands Heathland and Coastal Heathland sites. The sequences clustered into two well-supported (bootstrap = 100 %) OTUs ('*Tulasnella asymmetrica*' and OTU1), based on a 5 % sequence divergence cut-off (Linde *et al.*, 2014, 2017). Warcup's (1981) isolates of *T. asymmetrica* were separated into *T. asymmetrica* and '*T. asymmetrica*' based on phylogenetic divergence (Cruz *et al.*, 2014). We have kept this separation and refer to '*T. asymmetrica*' in the text. GenBank numbers are listed in Supplementary Data Table S3.

OTU1 from the SSW site and 70 *T. epipactoides* germinated with '*T. asymmetrica*', 35 from each of the DH and CHS sites. Each seedling was de-flasked into Bio Gro Terrestrial Orchid Conservation Mix in 12 inch diameter plastic pots (one plant per pot) and watered in the glasshouse as required. We measured the diameter of the tuber of adult plants (12 months after deflasking) at the widest point as our growth measurement (plants lose there leaves annually so leaf measurements are not ideal). Thus symbiotically germinated *T. epipactoides* with fungi from the SSW as well as fungi from DH and CHS, were compared with a one-way analysis of variance (ANOVA) using the Analysis ToolPak, Microsoft Excel 2013. Potted plants were randomized in their positioning on benches throughout the glasshouse amongst the below co-planting trial

and thus were also able to be used as controls in the co-planting experiment.

Co-planting with associated flora

We conducted a controlled glasshouse experiment with ten species of plant that were selected on the basis of co-occurring with *T. epipactoides*. The plants consisted of three species that naturally occurred at the SSW site, six species that naturally occurred at the DH and CHS sites, and one species, *Rytidosperma caespitosum*, that occurred at all sites. The number of co-occurring plants available to use of each species varied between 12 and 64 (Table 3). Seedlings from the above *T. epipactoides* germination trial germinated with either OTU1 (SSW) or '*T. asymmetrica*' (DH and
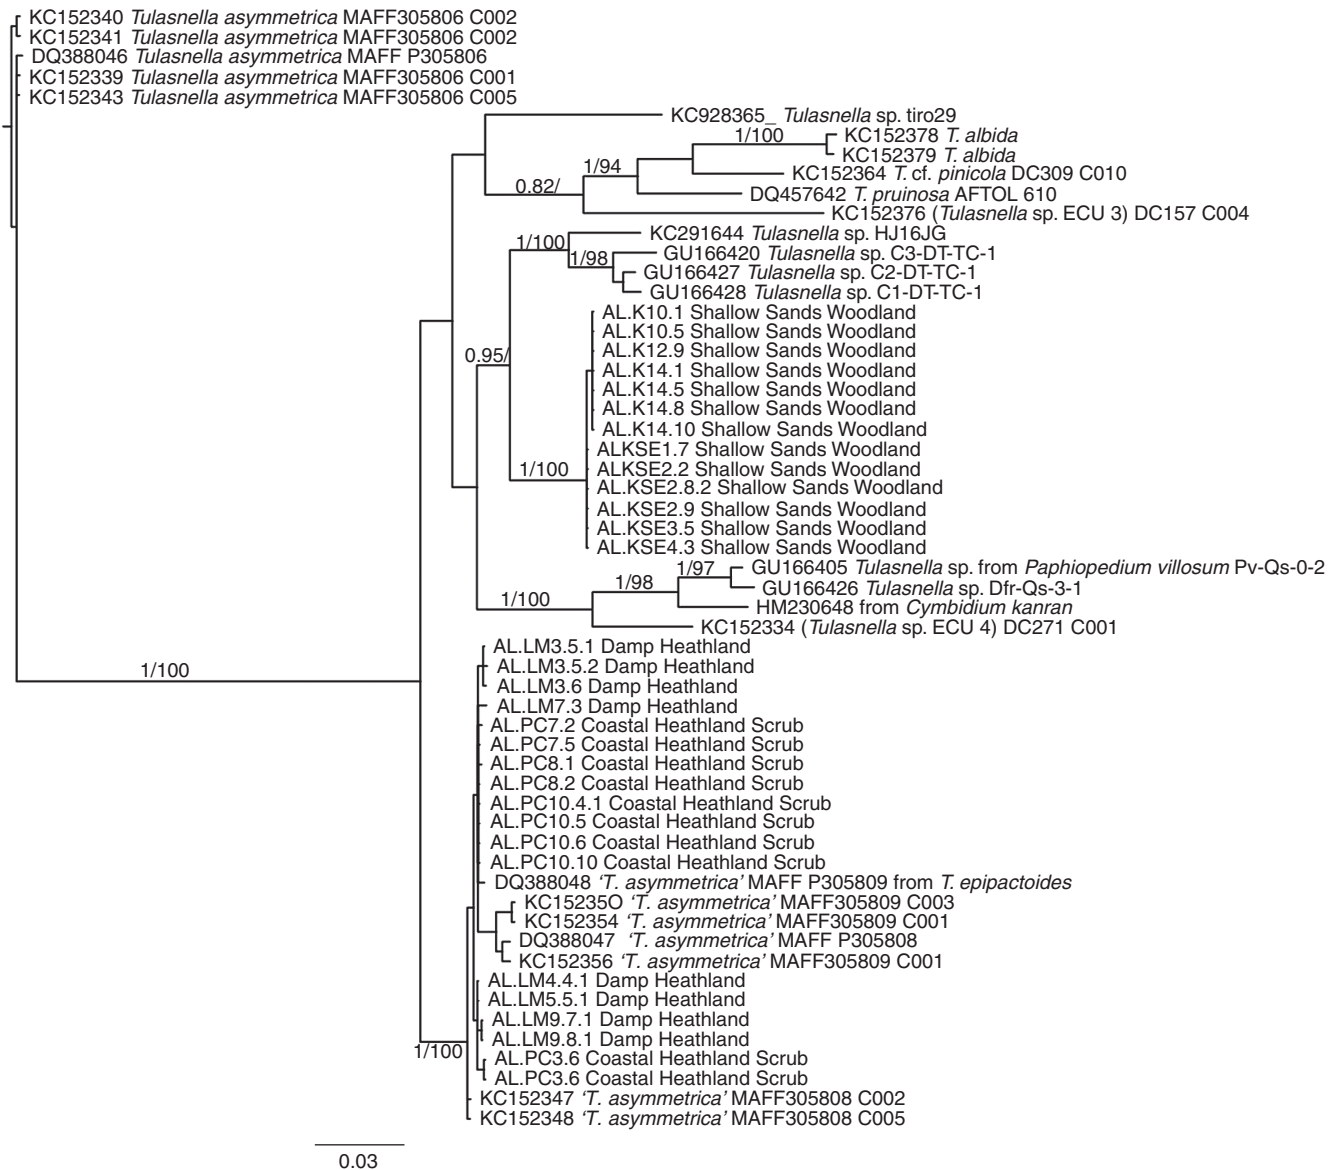

FIG. 4. Concatenated phylogenetic tree for the ITS, nLSU1, nLSU2 and mtLSU region of *Tulasnella* isolates from the Shallow Sands Woodland, Damp Sands Heathland and Coastal Heathland sites. The sequences clustered into two well-supported (bootstrap = 100 %) OTUs ('*Tulasnella asymmetrica*' and OTU1), based on a 5 % sequence divergence cut-off (Linde *et al.*, 2014, 2017). Warcup's (1981) isolates of *T. asymmetrica* were separated into *T. asymmetrica* and '*T. asymmetrica*' based on phylogenetic divergence (Cruz *et al.*, 2014). We have kept this separation and refer to '*T. asymmetrica*' as such in the text. Data are available from the Dryad Digital Repository: https://doi.org/10.5061/dryad.7sb22cb

CHS) were used for the co-planting experiments. Thus each pot had one orchid seedling, grown with one fungal species, and one co-occurring plant species (Table 3). Plants naturally occurring at the SSW site were co-planted with *T. epipactoides* grown with OTU1, plants naturally occurring at the DH and CHS were co-planted with *T. epipactoides* grown with '*T. asymmetrica*', and *R. caespitosum* which occurs across all three sites received in separate pots *T. epipactoides* grown with either OTU1 or '*T. asymmetrica*'. This experiment was conducted at the same time as the effect of fungal OTU experiment, allowing the potted plants grown with either OTU1 or '*T. asymmetrica*' alone (without co-plants) to be used as controls.

Potting was in winter while the orchid was actively growing. Seedlings were potted into Bio Gro Terrestrial Orchid Conservation Mix in 12 inch diameter plastic pots. Pots were randomized across glasshouse benches and incubated in a temperature-controlled glasshouse with 12 °C night and 25 °C day temperatures. Plants received natural light and were watered as required for 12 months. After 12 months of co-planting, tuber width (at the largest dimensions) of each orchid was measured. Results were analysed using a one-way ANOVA; subsequently a two-tailed *t*-test assuming unequal variance was performed to compare each pair of means (e.g. the respective *T. epipactoides* OTU without co-planted species control group mean compared

with that of *T. epipactoides* OTU with specific co-planted species group mean) using the Analysis ToolPak, Microsoft Excel 2013.

RESULTS

Is there habitat-driven variation in Tulasnella *associated with* T. epipactoides*?*

Thirty-one *Tulasnella* isolates were successfully sequenced across all four regions. For the nLSU1 region, all fungi had amplicons of about 650 bp. For the nLSU2 region, all fungi had amplicons of about 350 bp. The DH and CHS isolates had mitochondrial amplicons about 100 bp larger than those from SSW. This was due to an insert at the 3' end that was removed for the alignment and so had no influence on the relationships shown. Isolate ALPC3.4 was sequenced but not included in the trees because it had a short sequence (non-overlapping ITS1 and 4).

The ITS sequences formed two well-supported (bootstrap = 100 %) OTUs, based on a 5 % sequence divergence cut-off (Linde *et al.*, 2014, 2017) (Fig. 3; Supplementary Data Table S2). A similar topology and clustering resulted for nLSU and mtLSU regions (data not shown). Consequently, a phylogenetic tree representing a concatenated data set is presented (Fig. 4). In all trees, sequences representing isolates from DH and CHS clustered together (Figs 3 and 4). Warcup's (1981) isolates of *T. asymmetrica* were separated into *T. asymmetrica* and '*T. asymmetrica*' based on phylogenetic divergence (Cruz *et al.*, 2014). We have kept this separation and refer to '*T. asymmetrica*' as such throughout this manuscript. Furthermore, these sequences [including seven reference sequences from GenBank, suggested as '*T. asymmetrica*' (Cruz *et al.*, 2014)], showed <3 % sequence divergence and therefore were considered '*T. asymmetrica*' (Fig. 3; Supplementary Data Table S2). Sequences of isolates from SSW clustered into a unique, well-supported OTU (OTU1), with no close match to any GenBank sequence. All isolates from *T. epipactoides* clearly separated into two clades representing two fungal OTUs separated according to habitat, with isolates from the SSW pertaining to OTU1 and those from the DH and CHS pertaining to '*T. asymmetrica*'.

Do OTUs germinate orchid seed under different temperatures?

Symbiotic germination was successful at one or more temperatures with the majority of the 27 isolates tested. The number of plates showing germination was significantly affected by temperature (ANOVA, $F = 6.76$, $P = 0.001$). *Tulasnella* isolated from orchids in SSW (OTU1) germinated seed at the lower tested temperature cycles (12–16 °C and 16–24 °C) (Table 4). '*Tulasnella asymmetrica*' from DH and CHS germinated seed at all three temperature ranges (Table 4).

Symbiotic germination effect of fungal OTU on growth of adult plants

We found no effect of fungal OTU on growth of adult plants. There was no significant difference in tuber size between mature orchids when comparing sites of OTU isolation (SSW, DH and CHS) on growth (ANOVA, $F = 3.08$, $P = 0.652$). There was no significant difference in tuber size between mature orchids grown with isolates of OTU1 (SSW) or '*T. asymmetrica*' (DH and CHS) (ANOVA, $F = 0.428$, $P = 0.652$) when planted without associated flora.

Do symbiotically grown T. epipactoides *plants benefit from co-planting with associated flora?*

Tuber size of *T. epipactoides* co-planted with associated plant species was significantly different between treatments (ANOVA, $F = 5.374$, $P < 0.001$). Six associated species: *Rytidosperma caespitosum*, *Kennedia prostrata*, *Pultenaea canaliculata*, *Poa poiformis*, *Leptospermum continentale* and *Thomasia petalocalyx* co-planted with *T. epipactoides* grown with '*T. asymmetrica*' isolates had a significant ($P < 0.005$) detrimental effect on the tuber size of *T. epipactoides* compared with those grown without companion plants (Supplementary Data Table S1). Co-planting with *R. caespitosum* resulted in significantly ($P < 0.05$) smaller tuber widths of *T. epipactoides* when orchid seed was grown with '*T. asymmetrica*' compared with seed grown with OTU1

TABLE 4. *Germination as a percentage of plates that germinated* T. epipactoides *seed to stage 5 with 27 isolates (nine from OTU1 and 18 from '*T. asymmetrica*') under three temperatures*

| Vegetation community	OTU	No. of isolates	Germination %		
			Low (12–16 °C)	Medium (16–24 °C)	High (27 °C)
Shallow Sands Woodland	1	9	66.6 % (n = 27 plates)	22.2 % (n = 27 plates)	0 % (n = 27 plates)
Damp Heathland and Coastal Heathland Scrub	'*T. asymmetrica*'	18	77.7 % (n = 54 plates)	83.3 % (n = 54 plates)	66.6 % (n = 54 plates)

FIG. 5. Mean tuber width of seedlings of *T. epipactoides* grown with either fungus OTU1 or fungus '*T. asymmetrica*', co-planted with co-occurring plant species after 12 months in a pot trial against control without co-planted species. Lines represent the 95 % confidence interval calculated for each individual treatment. Significant differences ($P \leq 0.05$) between control and co-occurring plant treatments are indicated by asterisks.

(Supplementary Data Table S1). *Thelymitra epipactoides* tuber size germinated with fungal OTU1 and subsequently grown by co-planting with associated plant species from the OTU1 site (SSW) (Fig. 5) did not differ significantly from control tubers grown without any co-plants.

DISCUSSION

Highlights

This study provides clear evidence for two tulasnelloid OMFs associated with *T. epipactoides*. These two tulasnelloid fungi were not detected to co-occur at the same sites within pelotons isolated from *T. epipactoides* roots and were found in different habitats. *Tulasnella* OTU1 occurs in the drier SSW site while '*T. asymmetrica*' occurs in the wetter DH and CHS sites. In addition, this is the first study to grow orchid seed to adult plants to test fitness differences with the use of different OMFs. However, the two OTUs tested did not result in differences in orchid tuber widths in adult plants. This study shows that the growth (measured by tuber width) of *T. epipactoides* germinated with OTU1 and '*T. asymmetrica*', was significantly ($P < 0.005$) reduced when co-planted with five of ten tested co-occurring plant species compared with controls without co-occurring plant species. Furthermore, this study is the first to

show that a terrestrial orchid has different optimal germination temperatures depending on the OMF species present.

Is there ecologically driven variation in Tulasnella *associated with* T. epipactoides*?*

Fungi isolated from *T. epipactoides* were tulasnelloid, as expected from a previous study on *Thelymitra* species in south-eastern Australia by Warcup (1981). Warcup (1981) isolated 79 *Tulasnella* strains from 15 of the then 35 *Thelymitra* species (*Thelymitra* was revised by Jeanes, 2002) showing that *Thelymitra* associated with seven species of *Tulasnella*, namely *T. calospora*, *T. asymmetrica*, *T. cruciata*, *T. irregularis*, *T. violea*, *T. alantospora* and an undescribed species.

The ITS region provides species delineation in *Tulasnella* that is equivalent to that from multiple nuclear and mitochondrial sequences (Cruz *et al.*, 2011; Linde *et al.*, 2014). The research presented here supports this conclusion, as sequences from the nLSU (28S) and mitochondrial ribosomes supported the same phylogenetic pattern as with the ITS region. All the *Tulasnella* fungi isolated in this study grouped into two distinct OTUs. One of the OTUs (OTU1) was only isolated from the SSW site, whereas isolates identified as '*T. asymmetrica*' were obtained from the DH and CHS sites. Warcup's (1981) isolates from Australian *Thelymitra* species named as *T. asymmetrica*,

were separated into *T. asymmetrica* and '*T. asymmetrica*' based on phylogenetic divergence (Cruz *et al.*, 2014). We show that '*T. asymmetrica*' and a new, but related lineage (OTU1), are associated with *T. epipactoides*. The percentage sequence divergence between '*T. asymmetrica*' and OTU1 in the ITS region, exceeded a 5 % cut-off, as suggested from other *Tulasnella* studies (Linde *et al.*, 2014, 2017). The maximum sequence divergence within each of OTU1 and '*T. asymmetrica*' is <3 %, in line with the arbitrary figure of 97 % similarity for an OTU (McCormick *et al.*, 2006; Nilsson *et al.*, 2008; Peay *et al.*, 2008) used by others (Roche *et al.*, 2010; Jacquemyn *et al.*, 2011; Kartzinel *et al.*, 2013; Pandey *et al.*, 2013).

The two *Tulasnella* symbionts found in this study did not co-occur at any of the three sites in the root samples, with OTU1 only detected in the SSW site (dry – forest), while '*T. asymmetrica*' was found at sites DH and CHS (wetter – heathland). There are three possible explanations for the apparent habitat-driven switch of *Tulasnella* symbionts. The first is that a reduced suite of tulasnelloid fungi is present in each type of habitat; all may have been present initially but some may have declined due to intolerance of drier conditions or a decline in, or competition for, available resources for saprophytic growth (Brundrett *et al.*, 2003; Mehra *et al.*, 2017). This would suggest that fungal ecological specificity (Perkins and McGee, 1995) is the over-riding determinant of which fungi the orchid encounters and then orchid phylogeny determines whether or not a symbiosis is possible, rather than absolute specificity (Curtis, 1939). The second is that the entire suite of tulasnelloid fungi is present, but the orchid preferentially forms mycorrhizal symbioses with only one of the fungi depending on the environment, as shown in *Goodyera pubescens* (McCormick *et al.*, 2006), which switch fungal associations in drought years. In other studies, *Cypripedium acaule* had a broad association between soil chemistry, elevation and root-associated fungi (Bunch *et al.*, 2013) and *Bipinnula* species, which have soil nutrients modulating mycorrhizal associations (Mujica *et al.*, 2016). A third possibility is that the orchid forms mycorrhizal associations predominantly with different fungi as it matures (McCormick *et al.*, 2004; Otero *et al.*, 2005; Bidartondo and Read, 2008). This is deemed unlikely as all orchids sampled were mature and seeds germinated equally with the fungi from mature plants from each site. All tested fungi were also able to maintain the orchids in pot trials to 18 months maturity. In other studies, with *Tulasnella*, Phillips *et al.* (2011) found the same fungi in mature orchids, seedlings and protocorms, whereas McCormick *et al.* (2004) found fungal diversity to be greater in adult plants than in protocorms.

Thelymitra epipactoides at the SSW site are exposed to lower rainfall, higher temperatures (Table 1; Fig. 1) and fewer nutrients (Grundy *et al.*, 2015) than at the two mesic sites. *Thelymitra epipactoides* has a predominantly coastal distribution, and either expansion inland from the more mesic sites or remaining in these relict sites from a wetter time period may have been possible only because of the ability to form mycorrhiza with fungi that could also survive there, as discussed for tropical epiphytes (Martos *et al.*, 2012). As conditions become less mesic (Hughes, 2003), it is likely that the range of fungi available to the orchid changes due to 'environmental filtering' (Kraft *et al.*, 2015). Drought is suggested to have induced a switch in *Tulasnella* symbionts associated with *Goodyera pubescens*

(McCormick *et al.*, 2006). Kartzinel *et al.* (2013) found that a decrease in seasonal precipitation correlated with a decrease in diversity of the Tullasnellaceae in a tropical epiphytic orchid. Similarly, Phillips *et al.* (2016) found that OTUs of *Sebacina* associated with *Caladenia* stem-collars varied across soil types and rainfall in South West Australia Bio regions, with the Northern Wheatbelt only showing one *Sebacina* OTU and the Swan Coastal Plain (wetter than the Northern Wheatbelt) a larger diversity with six OTUs present (although sampling across each region was limited). Additionally, decreases in soil P and N decreased OTU richness from *Bipinnula* species in Chile (Mujica *et al.*, 2016). The above findings suggest that some fungal OTUs are adapted to different environmental conditions. It is also possible that the mycorrhizal fungi are adapted to different habitats (Oja *et al.*, 2015; Jacquemyn *et al.*, 2016; Ruibal *et al.*, 2017), though habitat and environmental conditions are difficult to tease apart. In the SSW habitat, which has more stressful environmental conditions (for fungi), it is likely that these limitations on available compatible fungi resulted in the orchids forming mycorrhiza with an available fungus different from that at the more mesic near-coastal sites.

The presence of two OTUs of *Tulasnella* forming effective mycorrhizal associations in climatically different sites of *T. epipactoides* is not surprising given the formerly widespread distribution of this endangered species. This is contrary to the hypothesis that threatened orchids have greater mycorrhizal specificity than common orchids and become rare because their compatible fungi are restricted geographically (Swarts *et al.*, 2010). It also contrasts with high fungal specificity in all the *Drakaea* (*Tulasnella secunda*) (Phillips *et al.*, 2011), *Caleana* (*T. secunda*) (Linde *et al.*, 2014) and *Chiloglottis* (*Tulasnella prima* and *T. sphagneti*) species, which are mostly common (Linde *et al.*, 2017). Furthermore, the rare *Diuris fragrantissima* was shown to associate with a range of closely related *Tulasnella* OTUs (Smith *et al.*, 2010), and several OTUs have been found in some rare (Kartzinel *et al.*, 2013; Pandey *et al.*, 2013) and locally endemic orchids (Suárez *et al.*, 2016). Therefore, we suggest that mycorrhizal specificity in *T. epipactoides* does not cause orchid rarity. The germination of *Tipularia discolor* only in the presence of wood colonized by specific fungi at a limited range of decomposition stages (McCormick *et al.*, 2004) suggests that substrate and nutrition are important for determining the distribution of orchid mycorrhizae. It is thus feasible that fungal ecology (temperature, habitat, nutrient or pH requirements) may drive the differences in mycorrhizal fungi isolated from the three study sites of *T. epipactoides*.

Do Tulasnella *OTUs have different temperature requirements for orchid germination?*

The isolates from the hotter, drier SSW site (OTU1) supported germination only at cooler temperatures (12–16 °C and 16–24 °C) and not at all under the higher temperature conditions (27 °C). In contrast, '*T. asymmetrica*', which was only present in the more mesic sites, supported germination at all tested temperatures (Table 4). These temperature ranges coincide best with temperatures when the majority of the precipitation is expected

at each site. The SSW site is characterized by extreme temperatures regularly well in excess of 40 °C over the summer months, and is dry on average with only 400 mm of rainfall annually (Australian Government Bureau of Meteorology, 2017), with the greatest rainfall occurring in the cool wet winter. Thus, it is beneficial for orchid seed to germinate at winter temperatures, with seed germinated in summer unlikely to survive during the hot, dry summer conditions. At the mesic sites (DH and CHS), the cooler temperatures and greater coastal rainfall throughout the year may be more conducive to survival after germination, throughout the year.

Temperature can affect plant fungal symbiosis (Staddon *et al.*, 2002; Kivlin *et al.*, 2013) and has been shown to affect arbuscular mycorrhizal performance (Gavito *et al.*, 2003). Seed from higher elevation locations often germinate at higher temperatures (Cavieres and Arroyo, 2000), though this is not consistent among species. Optimal germination temperatures may vary not only with altitude but also with other factors including light, seed batch and water (Giménez-Benavides *et al.*, 2005; Bauk *et al.*, 2016). While there are no orchid mycorrhizal relationships currently reported that are temperature dependent, this study suggests that high temperatures affect the ability of OTU1 to germinate *T. epipactoides*, with no germination seen at 27 °C.

The high (60–80 %) percentages of *T. epipactoides* plates that germinated with the optimal combination of fungi and temperature emphasizes that both OTUs were highly effective in germinating seed. Other germination trials with closely related tulasnelloid fungi isolated from *Drakaea, Chiloglottis* and *Diuris* species (Roche *et al.*, 2010; Smith *et al.*, 2010; Phillips *et al.*, 2011) had relatively low germination success (42, 23 and 30 %, respectively). Those germination trials were only conducted at one constant temperature. It is possible that varying conditions might have increased germination, as suggested elsewhere (Phillips *et al.*, 2011).

Do symbiotically grown T. epipactoides *plants benefit from co-planting with associated flora?*

There was no benefit from co-planting with any of the species that were tested, suggesting the absence of any benefit by providing a suitable microsite for the *Tulasnella*. The detrimental results due to co-planting with five of the ten co-planted species may be from restrictions in light and competition by the roots of the other species (Wilson, 1988; Calder *et al.*, 1989), though competition between their associated micro-organisms cannot be excluded. Interestingly there was a significant ($P < 0.005$) difference in tuber width of *T. epipactoides* when grown with *Rytidosperma caespitosum*, with those germinated with OTU1 significantly ($P < 0.05$) larger than those germinated with '*T. asymmetrica*', suggesting that '*T. asymmetrica*' negatively affects *T. epipactoides* growth under those conditions. When grown without associated companion plants, orchids with different fungal isolates as inocula had the same tuber width. This suggests that fungal isolates belonging to the two OTUs do not differ in terms of the benefit they provide to the plant, except when grown with other plants. There are no other studies to our knowledge on long-term trials on the effect of fungal isolates on adult orchid plants. Such differences in growth caused by co-occurring plants may be

examples of subtle interactions that affect long-term success in orchid conservation in the wild (Smith *et al.*, 2010). Further investigation of the effects of different OTUs may support these observations.

Conservation implications

'*Tulasnella asymmetrica*' is globally distributed (Cruz *et al.*, 2016), and many orchid mycorrhizal fungi are more widely distributed than the orchids with which they form symbiotic associations (Waud *et al.*, 2017). Our results support previous research suggesting that mycorrhizal specificity is not the driving force for rarity in some orchids (Phillips *et al.*, 2011; Kartzinel *et al.*, 2013; Pandey *et al.*, 2013).

There are three important conservation translocation considerations arising from this research: (1) with more than one species of mycorrhizal fungi able to germinate seed, it may be beneficial to introduce multiple fungal species in a conservation translocation; (2) alternatively, with differences in orchid germination temperatures between OMFs, the OMF has to be site matched to avoid recruitment losses; and (3) associated plants in a site may be detrimental to the growth of an orchid and need to be taken into consideration when selecting sites for conservation translocation at the microhabitat level.

SUPPLEMENTARY DATA

Supplementary data are available online at https://academic.oup.com/aob and consist of the following. Table S1: summary of significance values from two-sample *t*-tests. Table S2: pairwise minimum and maximum sequence divergences (percentage) between *Tulasnella* clades.
