ABSTRACT Cells within mechanically dynamic tissues like arteries are exposed to ever-changing forces and deformations. In some pathologies, like aneurysms, complex loads may alter how cells transduce forces, driving maladaptive growth and remodeling. Here, we aimed to determine the dynamic mechanical properties of vascular smooth muscle cells (VSMCs) under biaxial load. Using cellular micro-biaxial stretching microscopy, we measured the large-strain anisotropic stress-strain hysteresis of VSMCs and found that hysteresis is strongly dependent on load orientation and actin organization. Most notably, under some cyclic loads, we found that VSMCs with elongated in-vivo-like architectures display a hysteresis loop that is reverse to what is traditionally measured in polymers, with unloading stresses greater than loading stresses. This reverse hysteresis could not be replicated using a quasilinear viscoelasticity model, but we developed a Hill-type active fiber model that can describe the experimentally observed hysteresis. These results suggest that cells in highly organized tissues, like arteries, can have strongly anisotropic responses to complex loads, which could have important implications in understanding pathological mechanotransduction.

INTRODUCTION

Many tissues undergo dynamic deformations, with strain rates ranging from \sim 30% per second during cardiac contraction ([1\)](#page-8-0) to \sim 1% per year during aneurysm growth ([2\)](#page-8-1). As a result, cells within the tissue are exposed to constantly changing forces. Mechanical stimulation has been shown to influence a wide range of cellular functions $(3-6)$ and alter gene expression and cell fate $(7-10)$. The process by which the cell converts extracellular mechanical stimuli into biochemical signaling, known as mechanotransduction, is implicated in a number of diseases, from traumatic brain injury (11) (11) to cancer metastasis $(12,13)$ $(12,13)$ $(12,13)$. A cell's mechanical properties, which relate its deformation to its internal forces [\(14](#page-9-3)), likely influence mechanotransduction. Thus, it is important to determine the dynamic material behavior of cells in mechanically responsive tissues.

Compared to most materials, cells have complex mechanical properties. Most notably, cells display temporally dynamic mechanical behaviors. For example, when a cell is rapidly stretched, its stress will initially increase but with time will decay back to a basal level $(15,16)$; and when cyclically stretched, cells display stress-strain hysteresis,

Editor: Kinneret Keren.

with higher stresses during extension than during subsequent compression ([17\)](#page-9-5). These behaviors are well characterized in viscoelastic polymeric materials, which exhibit both fluid-like (viscous) and solid-like (elastic) properties. Thus, cells are often characterized as viscoelastic [\(18](#page-9-6)). However, unlike standard polymers, cells can actively adapt their stress state via actomyosin contraction and cytoskeletal remodeling, which could produce viscoelastic-like stress relaxation and hysteresis. The interplay between passive viscoelastic energy dissipation and active adaptive processes in regulation of cell stress is not fully understood.

Time-dependent properties of cells have been characterized, but existing studies either measure small strain properties or do not account for structural anisotropy of the cell ([19–22\)](#page-9-7). Recently, using cellular micro-biaxial stretching $(C\mu BS)$ microscopy, we demonstrated that vascular smooth muscle cells (VSMCs) with native-like architecture have highly anisotropic mechanical properties under large strains due to their highly aligned actomyosin cytoskeleton ([23\)](#page-9-8). Here, we expand on that study to examine hysteresis in cyclically stretched VSMCs. Using the $C\mu BS$ method, we find that hysteresis depends on the cellular architecture and that, surprisingly, under some complex loads we observed hysteresis loops that are inverse to those observed in energy-dissipating materials. We modeled VSMC anisotropic hysteresis using quasilinear viscoelasticity (QLV)

theory and a Hill-type contractile fiber model and found that only the contraction model was able to capture the experimentally observed behavior. These results have important implications in in vivo mechanotransduction, when cells are exposed to complex loads, and in the development of models for better understanding cell physiology and biomechanical function within tissues.

MATERIALS AND METHODS

Substrate fabrication and cell micropatterning

Micropatterned $C\mu BS$ substrates were prepared as previously described [\(23](#page-9-8)). Briefly, VSMCs were micropatterned with aspect ratios (ARs) 4, 2, and 1 (AR4: $32 \times 128 \mu m$; AR2: $91 \times 44 \mu m$; AR1: $63 \times 63 \mu m$) on polyacrylamide gels with Young's moduli of 13.5 kPa, which were adhered to elastomer membranes. Passages four to seven VSMCs were used for all experiments and the cells were serum starved in serum-free media for 24–48 h before experiments to induce a physiological phenotype [\(24](#page-9-9)).

Cell structure

Cells were fixed, stained for F-actin, and imaged using standard methods. Fiber distributions measured from two-dimensional projections of F-actin confocal stacks were fitted to a von Mises distribution function of the form

$$
f(\theta; \kappa, \theta_p) = \frac{e^{\kappa \cos[2(\theta - \theta_p)]}}{\pi I_0(\kappa)},
$$
\n(1)

 \mathbb{R}^2

where κ is the fiber concentration factor, describing the spread of the fiber distribution around preferred orientation θ_p , and $I_0(\kappa)$ is the modified Bessel function of the first kind of order 0.

Cell stretching and traction measurement

 $C\mu$ BS experiments were conducted using our custom-built microscope-mounted biaxial stretcher [\(Fig. 1](#page-1-0), A and B; Fig. S1 A) at 37° C in Tyrode's buffer. Cell-seeded $C\mu$ BS substrates were exposed to either uniaxial or equibiaxial stretching protocols to 25% grip strain for uniaxial or 20% grip strain for equibiaxial stretches (Fig. S1, B and C). First, a priming stretch and cell location stretch were performed. Then, active cell stretch was performed by increments of 5% loading strain (0.1%/s ramp rate) to the substrate with 2-min hold periods for image acquisition (Fig. S1, B and C). After reaching the maximal prescribed strain, cells were unloaded by performing 5% unloading strain, and images were acquired. After one cycle, cells were passivated with $100 \mu M$ HA-1077, and the load-unload cycle was repeated on the passive cells. Finally, cells were lysed with 0.1% sodium dodecyl sulfate, and the stretching protocol was repeated to acquire cell-free deformation of beads.

The total deformation F was referenced to the prestretched configuration (Fig. S2 A), and the total substrate deformation was given by substrate stretch ratios, λ_x and λ_y , which were taken as the measured cell-free substrate deformations. Cell-induced substrate displacement was given by u and determined using particle image velocimetry to compare the celladhered and cell-free bead position at the top surface of the gel for each applied stretch value (25) (25) ([Fig. 1](#page-1-0) C; Fig. S2 A).

Cell-induced substrate displacement was used to calculate the midplane stresses in the cells as a function of stretch. Substrate traction stress vectors were determined from cell-induced gel displacement (u) using an unconstrained Fourier transform traction cytometry algorithm (regularization

factor: 1E-9, Poisson's ratio: 0.5), which yielded a grid of n substrate traction stress vectors given by $T^n = T^n_x e_x + T^n_y e_y$, where e_i is the unit vector in the *i* direction (Fig. S2 *B*). Substrate traction forces were given by $T^n a^n$, where a^n is the area T^n acts on (Fig. S2 B). Substrate forces are balanced at the cell-substrate interface by cell forces (f^n) , so that $f^n = f_x^n e_x + f_y^n$ f_{y}^{n} $\boldsymbol{e}_{y} = -T_{x}^{n} a^{n} \boldsymbol{e}_{x} - T_{y}^{n} a^{n} \boldsymbol{e}_{x}$. Next, forces were defined as tensile (positive) if they were oriented away from the cell midline and the total tensile forces f_x and f_y are given as $2f_x = \sum_{n} f_n^p r_x^n / |r_x^n|$ and $2f_y = \sum_{n} f_y^p r_y^n / |r_y^n|$, where $r^n = r_x^n e_x + r_y^n e_y$ is the vector that described the location of surface n with respect to the cell center (Fig. $S2$ B). The first Piola-Kirchhoff (PK1) stresses (force per unit undeformed cross-sectional area) at the cell's midline were calculated as $P_x = (f_x/A_x)$ and $P_y = (f_y/A_y)$, where A_x and A_y are the cell midline cross-sectional areas (Fig. S2 C), measured in a previous study to be $A_x = 78 \ \mu m^2$ and $A_y = 278 \ \mu m^2$ for VSMCs with an AR of 4, $A_x = 94 \mu m^2$ and $A_y = 190 \mu m^2$ for VSMCs with an AR of 2, and $A_x = A_y = 117 \ \mu m^2$ for VSMCs with an AR of 1 [\(23](#page-9-8)).

Modeling cell hysteresis

Two models were used to describe cell biaxial hysteresis: a QLV model and a Hill-type active fiber model.

Cell deformation and elastic constitutive description

The cell was assumed to undergo isochoric planar biaxial deformation (i.e., no shear). The deformation tensor $\mathbf{F} = \text{diag}[\lambda_x, \lambda_y, \lambda_z]$ was taken as the observed deformation of the cell, where λ_i are stretch ratios in the *i* direction (x: parallel to the long of the cell, y: parallel to the short axis of the cell, z: perpendicular to the gel surface). Stretch ratios mimicked those of the experiments, both spatially and temporally. In a previous study, we found that cell volume does not significantly change in stretched micropatterned VSMCs ([16\)](#page-9-11), so for all deformations, we assumed $\lambda_z = (\lambda_x \lambda_y)^{-1}$.
The cell was treated as a distribution of discrete contractile acts

The cell was treated as a distribution of discrete contractile actomyosin fibers within an isotropic matrix. The fiber contraction was modeled by altering the fiber zero-stress configuration, as shown in Fig. S3. We let the passive (stress-free) cell (B) be disassembled into the bulk matrix (B_m) and individual fibers (B_f) , each of which is stress free. The fibers are treated as one dimensional, so that when they contract, they shorten along the fiber axis. In this disassembled state, the shortening is stressfree and given by the active stretch ratio λ_a . When the fibers are reassembled (b_1) , they are deformed from the zero-stress configuration back to their initial configuration, resulting in a stress before applied deformation. Finally, when the cell is deformed (F) , a fiber deforms by the fiber stretch ratio λ_f . The fiber's elastic deformation (λ^*) , or the deformation
from the zero stress configuration to the final deformation, which is used from the zero-stress configuration to the final deformation, which is used to determine the stress, is given by $\lambda^* = \lambda_f / \lambda_a$.

For a continuous distribution of fibers, the constitutive equation for the contribution of the fiber matrix was given by the following:

$$
W_f = \int_{\theta} \frac{C_f}{2} \left(\left(\frac{\lambda_f}{\lambda_a} \right)^2 - 1 \right)^2 p(\theta) d\theta, \tag{2}
$$

where C_f is a fixed stiffness parameter, and $p(\theta)$ is the fiber probability density function. The deformation of a fiber oriented with an angle θ from the x axis of the cell was given by the following:

$$
\lambda_f^2 = \lambda_x^2 \cos^2 \theta + \lambda_y^2 \sin^2 \theta. \tag{3}
$$

In this model, we use discrete fibers, rather than a distribution, so W_f for n fibers was given by the following:

$$
W_f = \frac{1}{n} \sum_{i=1}^n \frac{C_f}{2} \left(\left(\frac{\lambda_{fi}}{\lambda_{ai}} \right)^2 - 1 \right)^2, \tag{4}
$$

where λ_{fi} and λ_{di} are the fiber stretch ratio and active stretch ratio of the *i*th
fiber reconstituely and the strain energy density of a single fiber is given by fiber, respectively, and the strain energy density of a single fiber is given by the following:

$$
W_{sf} = \frac{1}{n} \frac{C_f}{2} \left(\left(\frac{\lambda_f}{\lambda_a} \right)^2 - 1 \right)^2.
$$
 (5)

The constitutive equation for the matrix was taken as neo-Hookean and given by the following:

$$
W_b = \frac{\mu}{2}(I_1 - 3), \tag{6}
$$

where μ is shear modulus, and $I_1 = \lambda_x^2 + \lambda_y^2 + \lambda_z^2$ is the first strain invariant. The total strain energy density for the cell is given by the following:

$$
W = W_b + W_f. \tag{7}
$$

For shear-free deformation of an incompressible material, the elastic PK1 stress in the *i* direction is given by $P_i^e = (\partial W/\partial \lambda_i) - (p/\lambda_i)$, where *p* is a log-value multiplier (14). Because the top surface of the cell is upcon. Lagrange multiplier ([14\)](#page-9-3). Because the top surface of the cell is unconstrained, we let $P_z = 0$, so

$$
P_i^e = \frac{\partial W}{\partial \lambda_i} - \frac{\lambda_z}{\lambda_i} \frac{\partial W}{\partial \lambda_z},
$$
 (8)

where $i = x, y$.

QLV model

We modeled cell hysteresis as viscoelastic relaxation using a Fung-type QLV model ([26\)](#page-9-12), designed for large-strain deformations and nonlinear materials. In this model, the active stretch ratio λ_a was assumed to be uniform for all fibers and constant for all times.

In the QLV model, the temporal stress was given as follows:

$$
P_i(t) = P_i^e(0)G(t) + \int_0^t G(t-\tau) \frac{\partial P^e[F(\tau)]}{\partial \tau} d\tau, \quad (9)
$$

where $G(t)$ is the reduced relaxation function. The general form for $G(t)$ is $G(t) = (\sum_i \alpha_i e^{-\beta_i t} / \sum_i \alpha_i)$. For simplicity, we used a first-order function given by the following: given by the following:

$$
G(t) = \alpha + (1 - \alpha)e^{-\beta(t)}, \qquad (10)
$$

where α and β are constants.

Hill-type active fiber model

We modeled cell hysteresis as active contraction by modeling the actomyosin fibers with the Hill equation for muscular contraction ([27](#page-9-13)). In this model, we ignore viscoelastic contributions, so that the elastic stress [\(Eq. 8](#page-2-0)) is the total stress and temporally vary λ_a in each fiber.

A standard form of the Hill equation is given by the following:

$$
V = \frac{b(F_o - F)}{F + a},\tag{11}
$$

where V is velocity of shortening of the muscle fiber, F is the constant force on the muscle, F_o is the stall force, or force at which a tetanized muscle neither shortens nor lengthens $(V = 0)$, and b and a are constants. Here, we aimed to replace the shortening velocity with the rate of change of the fiber zero-stress configuration, characterized in our framework as λ_a . The stretch ratio of the fiber (λ_f) is decomposed into λ_a and the elastic deformation λ^* (Fig. S3), such that

$$
\lambda_f = \lambda^* \lambda_a. \tag{12}
$$

The Hill equation is derived under constant force conditions (or constant PK1 stress), which in our model means that the fiber elastic deformation is constant, so we let $(\partial \lambda^*/\partial t) = 0$. Thus, the fiber shortening velocity was given by the following:

$$
V = -\frac{d\lambda_f}{dt} = -\frac{d\lambda_a}{dt}\lambda^* = -\frac{\dot{\lambda}_a}{\lambda_a}\lambda_f.
$$
 (13)

The fiber force was given by the following:

$$
F = P_f A_f = \frac{\partial W_{sf}}{\partial \lambda_f} A_f, \tag{14}
$$

where P_f is the fiber PK1 stress, and A_f is the undeformed cross-sectional area of the fiber. We assume that at the beginning of the experiment, each fiber is maintaining a homeostatic stress such that the fiber is neither contracting nor relaxing. This stress is given by P_o and defined by the following:

$$
P_o = P_f(\lambda_{ao}), \tag{15}
$$

where λ_{ao} is the active stretch ratio at which the fibers are in stress homeostasis.

Substituting [Eqs. 13,](#page-3-0) [14,](#page-3-1) and [15](#page-3-2) into [Eq. 11](#page-2-1) and letting $\gamma = a/A_f$ gives the following:

$$
\frac{\dot{\lambda}_a}{\lambda_a} = \frac{b(P_f - P_0)}{\lambda_f(P_f + \gamma)},\tag{16}
$$

where α and b are constant parameters.

Solution method

In both models, a random family of 2000 fibers, matching the measured von Mises distribution measured of an average cell, was generated. Time was discretized into 0.01-min increments over 18 min for equibiaxial stretch and 22 min for uniaxial stretch. Initially, $\lambda_x = \lambda_y = \lambda_z = \lambda_f$ 1. Parameters were fit to the equibiaxial data via least-squares fitting of the experimentally measured stresses (both P_x and P_y) and the mean model-predicted stresses during each stretch-hold period at each of the measured substrate deformations $\lambda = [1.00, 1.04, 1.08, 1.12, 1.16]$. After initially screening a large range of potential parameters to determine the most relevant range, the parameter range that was considered was $\mu = 0.5 - 4 kPa$, $C_f = 1 - 5 kPa$, $\lambda_{a0} = 0.6 - 0.75$, $\alpha = 0.8 - 0.95$, $\beta = 0.1 - 0.4$, $\gamma = .5 - 5 Pa$, and $b = 0.005 - 0.05$. After parameter optimization, uniaxial stresses for corresponding uniaxial-axial or uniaxial-transverse stretches were then computed using the fitted parameters by applying experimentally measured substrate deformations $\lambda = [1.00, 1.045, 1.09, 1.135, 1.18, 1.225]$ in the direction of stretch and $\lambda = [1.00, 0.99, 0.98, 0.97, 0.96, 0.95]$ in the off-axis direction.

Statistics

All results are expressed as means \pm SD. Differences in loading and unloading stresses for at each strain for all stretching experiments were compared using paired t-tests in SigmaPlot (Systat Software, San Jose, CA). A value of $p < 0.05$ was considered to indicate statistical significance.

RESULTS

VSMCs with in-vivo-like geometry display anisotropic hysteresis

We used C μ BS microscopy [\(23](#page-9-8)) to apply dynamic physiological deformations (up to 25% applied strain) to individual adherent VSMCs and concurrently measure the resulting stresses ([Fig. 1](#page-1-0)). Briefly, VSMCs were micropatterned with an in-vivo-like elongated geometry (4:1 AR4) on a polyacrylamide gel adhered to an elastomer membrane. Using a custom-designed microscope-mounted biaxial stretcher ([Fig. 1](#page-1-0), A–C; Fig. S1 A), we applied planar strains in increments of \sim 4% strain up to a maximum of 16–22%, then incrementally returned to 0% strain (Fig. S1, B and C). A representative equibiaxial stretch (stretched equally in both x and y directions) can be found in [Fig. 1](#page-1-0) D. Traction stress on the substrate surface was measured using the substrate displacement during stretching and well-established traction force microscopy methods ([Fig. 1](#page-1-0) D). The midcell stress parallel to the long axis of the cell, or axial stress (P_x) , and parallel to the short axis of the cell, or transverse stress (P_v) , were calculated from surface tractions and the cellular architecture, which was deter-mined from confocal microscopy [\(23](#page-9-8)) (Fig. S2 C). Within a single cycle, stresses were dissimilar during loading and unloading, resulting in a stress-strain hysteresis loop ([Fig. 1,](#page-1-0) E and F).

Under equibiaxial loading, both P_x and P_y increased when loaded and decreased when unloaded ([Fig. 2,](#page-4-0) A–D). Axial stresses were an order of magnitude higher than transverse stresses ([Fig. 2](#page-4-0), C and D), consistent with previous findings ([23\)](#page-9-8). Within the cycle, loading stresses were higher than the subsequent unloading [\(Fig. 2,](#page-4-0) C and D). These data are consistent with hysteresis loops traditionally associated with viscous energy loss. Individually, normalized cell stress plots demonstrate that this trend was consistent cell to cell ([Fig. 2](#page-4-0), E and F). Next, the cells were treated with HA-1077, a Rho-kinase inhibitor, to block actomyosin contractility. After treatment, the stresses decreased by >10 -fold [\(Fig. 2,](#page-4-0) G and H), and the cell-to-cell hysteresis decreased [\(Fig. 2](#page-4-0), I and J).

Next, we applied uniaxial deformation, where the membrane was stretched parallel to one axis and held fixed parallel to the other. Notably, because the PDMS ring is adhered to the membrane to constrain the culture media (see [Fig. 1](#page-1-0), A and B), the deformation is neither strip biaxial nor purely uniaxial. Instead, uniaxial stretching yielded some compression in the transverse direction (e.g., [Fig. 3](#page-4-0), A and B) but less compression than would be expected for uniaxial deformation of an incompressible material. When the cell was stretched parallel to its long axis (uniaxial-axial) [\(Fig. 3,](#page-4-0) A and B), both the stress in the direction of extension (P_x) and the stress in the off-axis direction (P_v) increased with strain ([Fig. 3](#page-4-0), $C-F$), and unloading stresses were lower than loading stresses for each increment of strain, suggesting energy loss,

similar to our equibiaxial stretch experiments. Rho-kinase inhibition decreased all stresses by nearly 10-fold [\(Fig. 3,](#page-4-0) G and H) and decreased the degree of hysteresis [\(Fig. 3](#page-4-0) and J, I). For stretching perpendicular to the cell's long axis (uni-axial-transverse) ([Fig. 4,](#page-5-0) A and B), the stress in the direction of extension (P_v) , increased during loading and decreased with unloading [\(Fig. 4](#page-5-0), D and F). But surprisingly, unloading stresses were greater than loading stresses, creating a hysteresis loop that was opposite to the standard loop associated with energy dissipation, instead suggesting energy gain. Stresses perpendicular to the direction of stretch (P_x) were

nearly unchanged during loading but then increased during unloading ([Fig. 4](#page-5-0), C and E). When contraction was inhibited, passive stresses were markedly lower than contractile stresses [\(Fig. 4](#page-5-0), G and H), but we observed significant differences in loading and unloading stresses for both P_x and P_y ([Fig. 4,](#page-5-0) I and J). Notably, the hysteresis in P_x was reversed in the passive state, compared to the active, with unloading stresses lower than loading stresses [\(Fig. 4,](#page-5-0) I and J). Taken together, these data suggest that in highly structured cells, like VSMCs in arteries, hysteresis depends on the orientation

of the load with respect to cell orientation and that cytoskeletal tension is an important factor in the hysteresis magnitude.

An active fiber model describes single-cell anisotropic hysteresis

To better understand the dynamics of the observed anisotropic hysteresis, we aimed to develop a theoretical model of temporal stress in the cell during stretching. We first used a QLV model ([26\)](#page-9-12). QLV was used because we applied large strains to the cells, and the QLV model is designed for viscoelastic materials with nonlinear constitutive behavior undergoing large strains. The elastic strain energy density function was based on our previously published study ([23\)](#page-9-8), and the viscous behavior was characterized with a reduced relaxation function with an exponential decay. The parameters were fit to the equibiaxial stretching data (Fig. S4, A and B; Table S1), and the model was then applied to the uniaxial-axial and uniaxial-transverse stretch cases. For uniaxial-axial stretching, the model (Fig. S4, C and D) captured the experimental hysteresis, where unloading stresses were lower than loading stresses for each point of strain for P_x and P_y . But for uniaxial-transverse stretching, the model failed to predict the observed reverse hysteresis, instead predicting unloading stresses lower than loading stresses for P_x and P_y (Fig. S4, E and F).

The Hill equation relates muscle force generation and contraction rate (27) (27) and has been used for decades to describe smooth muscle contraction in blood vessels ([28\)](#page-9-14). More recently, the Hill relationship has been used to describe discreet actomyosin fibers within cells to model cytoskeletal dynamics during cell migration [\(29–31](#page-9-15)). We modified our model to include active contraction via a Hill relationship between actomyosin fiber stress and contraction velocity. This model did not include passive viscoelasticity. Equibiaxial experimental data were used to optimize the pa-rameters [\(Fig. 5,](#page-6-0) A and B ; [Table 1\)](#page-6-1) and the model was then applied to uniaxial-axial and uniaxial-transverse stretch. For uniaxial-axial stretch, the model hysteresis (Fig. 5 , C and D) was consistent with the experimentally observed behavior. Additionally, for uniaxial-transverse stretch, the model predicted reverse hysteresis, where unloading stresses are higher than loading stresses [\(Fig. 5](#page-6-0), E and F), as seen exper-imentally (see [Fig. 4,](#page-5-0) C and D). This result suggests that active contraction and relaxation, not passive energy dissipation, was the primary source of hysteresis in our experiments. Given this finding, our subsequent work focused on our Hill-type active fiber model.

Actomyosin fiber orientation influences hysteresis anisotropy

To better understand why the Hill-type model replicated the experimentally measured hysteresis, we examined the model-predicted individual fiber active stretch ratios (λ_a) , which evolve temporally as a function of fiber stress (see [Eq. 16](#page-3-3)). In equibiaxial loading, initial applied deformation caused all fibers to be uniformly stretched such that $P_f > P_o$. So, λ_a increased uniformly, regardless of fiber orientation (Fig. $S5$ A). When individual fibers (Fig. $S5$ B) were examined at the same strain during loading and unloading (Fig. S5 C), the model predicted that λ_a was greater during unloading than during loading in all fibers, resulting

FIGURE 5 Anisotropic hysteresis is captured by a Hill-type active fiber model. (A and B) A Hill-type active fiber model for equibiaxial stretch, fitted to experimental data. in stresses that were higher in loading than in unloading and yielding the observed hysteresis loop. For uniaxial loading, λ_a varied with fiber orientation (Fig. S5, D and G). In uniaxial-axial loading, for fibers aligned with the long axis of the cell, λ_a increased with stretch, whereas in fibers transverse to the cell's axis, λ_a decreased. But because the fibers in

our micropatterned cells were primarily aligned with the long axis (Fig. S5 E), λ_a for individual fibers were qualitatively similar to the equibiaxial case (Fig. $S5$ F), resulting in lowered stresses during unloading, compared to loading. For uniaxial-transverse loading, the λ_a pattern is reverse that of the axial case (Fig. $S5$ G), because stretch was transverse to the cell's long axis. But because the fibers were primarily axially aligned (Fig. S5 H), λ_a for all fibers decreased (Fig. S5 I), and the model predicted increased stress in unloading compared to loading. Thus, the compression and subsequent contraction of the fibers primarily aligned with the cell's long axis was the source of the reverse hysteresis during uniaxial-transverse stretching in the model.

In vivo, VSMCs normally have a highly aligned actomyosin cytoskeleton. However, in vessels with complex geometries ([32,33](#page-9-16)) and in aneurysms [\(34](#page-9-17)), they can lose their characteristic spindle shape and, as a result, their cytoskeletal alignment. Using our Hill-type active fiber model, we tested how cytoskeletal architecture could alter the dynamic mechanics of the cells. We assumed that actomyosin fiber alignment could be described by a von Mises distribution, and we performed a parameter study for the fiber concentration factor (k) over a range of k values from isotropic $(k = 0)$ to highly anisotropic ($\kappa = 50$). For uniaxial-axial stretch, increasing fiber alignment (increasing κ), the model predicted higher stresses in the direction of stretch (P_x) with increased degree of hysteresis (i.e., larger loops) ([Fig. 6](#page-7-0) A), whereas stresses transverse to cell alignment (P_y) decreased ([Fig. 6](#page-7-0) B) because of decreasing fiber alignment in that direction. For uniaxial-transverse stretch, increasing anisotropy led to lower stresses in the stretch direction (P_v) [\(Fig. 6](#page-7-0) D). Interestingly, for κ < 4, the model predicts a standard hysteresis loop for dissipative viscoelastic behavior, but for $\kappa > 4$, the model predicted reverse hysteresis similar to what we observed experimentally. A similar trend was predicted in the direction of cell alignment (Fig. $6 \text{ } C$). However, for values of κ > 0.05, the reverse hysteresis behavior was observed in the axial stresses during transverse stretch (Fig. $6 \text{ } C$). Taken together, the model data suggest that cytoskeletal anisotropy is an important factor in the anisotropic temporal dynamics of VSMC mechanical properties.

Finally, cells were micropatterned with 2:1 and 1:1 ARs (AR2, AR1) but identical spread areas ([Fig. 7](#page-7-0) A), which has been previously shown to result in more isotropic cytoskeletal alignment ([23\)](#page-9-8). F-actin fiber distributions were measured from confocal imaging and characterized by von Mises distributions (Fig. $7 B$). When stretched using uniax-ial-axial [\(Fig. 7](#page-7-0) C) and uniaxial-transverse (Fig. 7 F) protocols, the stress-strain behavior and stress magnitudes closely matched those predicted by the model. AR2 cells were similar to AR4 cells with dissipative hysteresis for uniax-ial-axial stretch [\(Fig. 7](#page-7-0), D and E) and reverse hysteresis for uniaxial transverse stretch [\(Fig. 7,](#page-7-0) G and H). Uniaxial stretching performed on the nearly isotropic AR1 cell ([Fig. 7](#page-7-0) I) showed normal dissipative hysteresis, independent

FIGURE 6 Hill-type active fiber model predicts the effect actomyosin fiber orientation has on hysteresis. (A and B) Uniaxial-axial stretch model predictions for fiber concentration factor values $\kappa = 0, 0.5, 2, 10, 30, 50$. (A) Axial stresses (P_x) due to applied axial strain (λ_x) . (B) Transverse stresses (P_y) due to off-axis strain (λ_y). Solid lines represent loading stresses. Dashed lines represent unloading stresses. of stretch direction, consistent with model predictions ([Fig. 7,](#page-7-0) J and K). These data demonstrate that hysteresis anisotropy is cell-architecture dependent.

DISCUSSION

It is increasingly clear that mechanical forces play an important role in the regulation of cellular function. Thus, it is important to understand how cell stresses relate to cell deformations, particularly in mechanically dynamic tissues like arteries. Here, using $C\mu BS$ microscopy ([23](#page-9-8)), we investigated loading and unloading dynamics of individual VSMCs exposed to large-strain biaxial stretching. Previous studies found that a cell's time-dependent mechanical properties are dependent on both strain magnitude [\(17](#page-9-5)) and strain rate ([35\)](#page-9-18). Our study found that VSMCs with in-vivo-like architecture have markedly different hysteresis behavior under different loading regimes. Most notably, when stretched transverse to primary fiber alignment, VSMCs exhibited reverse hysteresis, with unloading stresses greater than loading stresses, suggestive of energy gain. To our knowledge, this reverse hysteresis has not been measured or characterized previously. We also found that this phenomenon was particular to anisotropic cells. The reverse hysteresis

was not captured by a standard QLV model but was well described by a Hill-type active fiber model, suggesting that viscoelastic models are insufficient for modeling highly structured cells, like muscle cells, under complex loading and that contractile behavior is important for describing the constitutive behavior of cells.

The source of the observed reverse hysteresis can be inferred from the Hill-type active fiber model. In the model, we assume that all fibers are at a homeostatic stress (P_0) , or stall force, before stretch. When a fiber is stretched, its stress rises above P_0 , and the fiber relaxes by altering its zero-stress configuration. Conversely, when a fiber is compressed, it contracts, raising the fiber's tension. In highly anisotropic cells, even the fibers that provide tension in the cell's short axis are primarily aligned with the cell's long axis. Thus, when the cell is stretched transversely and shortens somewhat axially, these fibers contract, increasing the cell stress in both directions. In smooth muscle, contraction and relaxation are slow ([28\)](#page-9-14), so the fiber tension does not reestablish homeostasis in the time over which the experiment was performed, thus the fiber tension remains elevated and the unloading stress is greater than the loading stress. These results demonstrate that simple isotropic models of cell properties can miss subtle but physiologically important phenomena.

There are several limitations in our measurement of viscoelastic properties. In vivo strain rates for arteries occur on the scale of 0.25–3%/s [\(36,37\)](#page-9-19), whereas in the experiment, because of temporal limitations during imaging, we perform a slower stretch, taking into account stretching and imaging time, of $\langle 0.1\% / s \rangle$ (0.5%/s during actual stretch). In addition, tissues in vivo are often exposed to continuous cyclic stretch, and in vitro studies have shown tissue properties are influenced by mechanical conditioning ([38–40\)](#page-9-20). Cell function can also be significantly altered by cyclic stretch ([41,42](#page-9-21)). We perform two conditioning stretches before the measured stretches and previously showed VSMCs do not exhibit a change in traction forces after four cycles of axial stretch [\(23](#page-9-8)) but did not investigate the ability of the cells to adapt to cyclic stretch or further conditioning stretches. In the model, we treat the cell as a bulk neo-Hookean matrix with discrete actomyosin fibers oriented with a defined distribution, but we neglect other cellular components such as the nucleus and other cytoskeletal filaments like microtubules and intermediate filaments ([43–46\)](#page-9-22). Although these other structures undoubtedly contribute to the cell's mechanical properties, the HA-1077 studies inhibiting actomyosin contractility eliminate nearly all tension in the cell, so we believe assuming actin fibers are the primary cytoskeletal filament is a reasonable first approximation.

Several other investigators have used Hill-type fiber contraction in models aiming to explain cytoskeletal self-organization, cell spreading, and durotaxis [\(29–31,47–49\)](#page-9-15). These models include both focal adhesion and cytoskeletal kinetics. Here, because our experiments take place over a relatively short time period, we have ignored both. Cytoskeletal remodeling acts in concert with contraction to modulate the stress fiber mechanics and could contribute to the temporal changes in cell stress that we observed. It is possible that these more sophisticated models can better describe the dynamics of the cell and provide more detailed insight into the mechanisms of our experimentally observed hysteresis behavior.

Finally, the large-strain mechanics of whole arteries are well characterized [\(50,51](#page-10-0)), but modern biomechanical models such as constrained mixture models ([52,53](#page-10-1)) require a firm understanding of the mechanical properties of each component of tissues, including the cells. Mechanics of individual cells have been studied using a variety of tools including but not limited to micropipette aspiration, microrheology, magnetic bead twisting, atomic force microscopy, optical tweezers, and microfluidics [\(54–56](#page-10-2)). These measurements normally yield parameters for isotropic linear materials. Our results suggest linear isotropic properties and simple viscoelastic models are insufficient for describing cells under complex loads. Moreover, it is well known that cell function is influenced by applied loading ([41,42,57,58](#page-9-21)). Our results suggest that the relationship between applied deformation and mechano-adaptation is more complex in highly structured cells in tissues than isotropic descriptions of cells might suggest. These findings are particularly notable in the development of mixture models of vascular mechano-adaptation, which have potential clinical applications predicting, for example, aneurysm growth and rupture [\(59,60\)](#page-10-3). Cells in bifurcations or in aneurysms are necessarily exposed to complex loads ([60,61](#page-10-4)), and models that can capture the anisotropic time-dependent and architecture-dependent material behavior of the cells will be more accurate.
