Abstract

Neonatal sleep is a crucial state that involves endogenous driven brain activity, important for neuronal survival and guidance of brain networks. Sequential EEG-sleep analysis in preterm infants provides insights into functional brain integrity and can document deviations of the biologically pre-programmed process of sleep ontogenesis during the neonatal period.

Visual assessment of neonatal sleep-EEG, with integration of both cerebral and non-cerebral measures to better define neonatal state, is still considered the gold standard. Electrographic

patterns evolve over time and are gradually time locked with behavioural characteristics which allow classification of quiet sleep and active sleep periods during the last 10 weeks of gestation. Near term age, the neonate expresses a short ultradian sleep cycle, with two distinct active and quiet sleep, as well as brief periods of transitional or indeterminate sleep. Qualitative assessment of neonatal sleep is however challenged by biological and environmental variables that influence the expression of EEG-sleep patterns and sleep organization. Developing normative EEG-sleep data with the aid of automated analytic methods, can further improve our understanding of extra-uterine brain development and state organization under stressful or pathological conditions. Based on those developmental biomarkers of normal and abnormal brain function, research can be conducted to support and optimise sleep in the NICU, with the ultimate goal to improve therapeutic interventions and neurodevelopmental outcome.

Keywords

Brain maturation; Sleep ontogenesis; Preterm neonate; EEG-monitoring; Sleep-wake cycle

1 Introduction

Intensive monitoring of the vulnerable preterm and critically ill term neonate, has been increasingly complemented with bed-side neuromonitoring to achieve optimal insight into neurological well-being [1–3]. Serial electro-encephalography (EEG) monitoring over time can document actual normal or altered brain function and provides insight into the progress of brain maturation during this period of intensive neonatal care [1,4,5], with the ultimate goal to improve therapeutic interventions and long-term neurodevelopmental outcome.

Neonates spend most of their time resting in the sleeping state. Previous research has highlighted the important role of neonatal sleep as a state that involves endogenous driven brain activity, crucial for neuronal survival and guidance of brain networks [6–9] and relate the impact of sleep on cognitive, psychomotor and behavioural development in both animal [10,11] as well as human studies [12–16]. Moreover, sleep ontogenesis is a specific, pre-programmed process of the maturing brain that manifests itself within a certain time window that begins in utero with rapid and major changes during the neonatal periods and infancy, and more subtle changes throughout childhood [11,17]. It's a complex and highly regulated neurologic function requiring the integration of different brain networks, influenced by the interplay between genetic endowment and environmental inputs, which allows for manifestations of neuroplasticity [6,8].

Qualitative assessment of neonatal sleep is therefore an essential and valuable measure of functional brain integrity [11,18], and recognition of sleep-wake states can be useful in the day-to-day monitoring, for assessing optimal periods for feeding and neonatal care, to support and optimise sleep in the NICU [19], as well as give insight in the sleep architecture of infants with sleep related problems (e.g. increased risk of sudden infant death syndrome, sleep apnoea).

This review discusses sleep in the preterm and term neonate and its relationship to brain development, measured with video-EEG polysomnography. We preface this with a short

overview of monitoring tools and focus on the maturation of electrographic patterns. To summarize, we assess what is currently known regarding qualitative and quantitative sleep-EEG assessment in the neonatal period.

2 Sleep monitoring

2.1 Monitoring techniques

Conventional video-EEG-polysomnography studies are using a combination of behavioural and EEG characteristics for visual sleep-wake scoring to differentiate recognizable sleep EEG patterns in the preterm and full-term neonate, since neither of these characteristics alone are considered as gold standard [17,20,21]. To yield high quality EEG-polysomnography recordings and document specific temporal and regional electrographic changes in brain activity, a reduced 10–20 position with 9 electrodes is preferred (e.g. 2 frontal Fp1–Fp2 or F3–F4, 3 central C3–C4–Cz, 2 temporal T3–T4, 2 occipital O1–O2, reference and ground electrode). Non-cerebral physiological behaviours essential for sleep analysis are motility patterns, cardiorespiration and eye movements. Transcutaneous pO₂/CO₂ measurements are in general not applied, although major fluctuations can affect brain activity and can be considered in specific conditions [17,22]. The length of recording should cover at least a complete sleep cycle, with preferably a minimum of 3–4 h to take into account the ultradian cycle, however which remain still too restricted to accurately document the periodicity and stability of the developing circadian rhythm [23].

However, this might be too intrusive for the critical, sick extreme preterm infant. In this context, there is an increasing interest to distract sleep activity unobtrusively based on a variety of related techniques such as trend analysis of limited channel amplitude-EEG (aEEG) and heart rate variability [24–27].

2.2 Visual sleep scoring

Electrographic patterns are known to evolve over time, thereby reflecting the development of the brain cortex. It is well known that there are important differences in the development of the cerebral cortex if one compares the foetal and preterm brain [28]. Therefore, it is difficult to talk about a ‘normal’ *ex utero* brain development. However, assessment of serial multichannel EEG of preterm infants without major brain lesions who develop normally, is generally accepted as the closest approximation of normal functional brain maturation [29,30]. The postmenstrual age (PMA = gestational age at birth plus the weeks postpartum) should be known to assess functional brain maturity and the actual developmental age of the brain, which can be estimated within two weeks of the actual age for the preterm infant (e.g. < 37 weeks) and within one week for the full-term and post-term infant (respectively 37–44 weeks of PMA, and 44–48 weeks PMA). Larger deviations, are considered abnormal or ‘dysmature’ and if permanent, associated with increased risk of abnormal neurodevelopmental outcome [31–34].

Recently, the American Academy of Sleep Medicine renewed their recommendations for neonatal EEG sleep scoring in infants zero to two months of age [35]. In contrast to what has been reported by other experts in the field [11,17,29,30], they recommend only to score the

EEG pattern as discontinuous or continuous rather than identifying EEG patterns according to different sleep states, due to the complexity of the EEG patterns and high variability in scoring among raters.

Studies which assess inter-rater agreement of visual EEG-sleep scoring in preterm and term neonates are scarce. Stefanski et al. [36] found an overall agreement of 87% for scoring EEG sleep patterns, whereas the agreement was 10% lower for coding behavioural patterns, and decreased with lower GA. In our own cohort of preterm infants (PMA 27–41 weeks), we found a Cohen's Kappa of 0.93 (95% CI: 0.90–0.95) for QS versus non-QS classified epochs, with the lowest Kappa value for 27–31 weeks PMA [37]. Nevertheless, scoring all different sleep states will be more challenging and induce higher disagreement when characterizing immature sleep patterns, since strict criteria for scoring sleep in preterm infants are lacking [38].

3 Development of neonatal sleep

3.1 Sleep EEG patterns according to age (Figs. 1–8)

The development of different behavioural states in humans is species-specific and can be divided in quiet sleep (QS or non-REM sleep (NREM)), active sleep (AS or Rapid-Eye Movement (REM)), and wakefulness. These behavioural states are usually defined by a combination of behavioural, cardiorespiratory and EEG state specific criteria which emerge coherently over time, concurrent with the process of rapid brain maturation during foetal and early life [39].

Ultrasound observations have documented a rest-activity pattern in foetuses as young as 20–28 weeks' gestation [39], in line with Scher et al. and Vecchierini et al. who described rudimentary sleep states in the stabilized, extremely premature infant, as early as 24 weeks [40,41] (Fig. 1a & b). A more significant organization of sleep occurs from 28 to 29 weeks PMA [6,11]. Deeper brain nuclei modulate the first reflections of two distinct sleep stages in the cortical activity and the differentiation between 'active' and 'quiet sleep' based on different grades of EEG discontinuity, can be made. However, these differences in EEG characteristics are only subtle and in preterm infants < 30 weeks, there is still the greatest uncertainty in classifying sleep. Indeed, when both behavioural and EEG criteria are required for state definition, more immature infants will have increased 'Indeterminate Sleep' (IS). These segments are sleeping periods (eyes are closed) but in which behavioural and clinical EEG features do not correspond to a definite AS or QS segment, indicating the immaturity of the organization of each parameter to represent distinct sleep states in the very premature infant [11,42], resulting in an augmentation of IS and lower levels of AS or QS. Transitional sleep (TS) is seen as a temporary presentation of IS, usually during transitions between AS and QS, when typical criteria for a specific behavioural state are vague.

From 30 to 31 weeks onwards, physical parameters of rapid eye movement, body movement and respiration are gradually integrated and time-locked with more specific recognizable EEG patterns for QS and AS [11,17,29,43], with increasing concordance over age [20,44]. This give rise to a less chaotic and more predictable stable sleep wake organization, modulated by the developing afferent connections from the deeper brain nuclei (e.g.

thalamo-cortical connections, hypothalamus, hippocampus) [11,43,45]. Rapid eye movements are the main characteristic features associated with AS and a (semi)-continuous background EEG pattern of mainly synchronous occipital delta activity, together with increased facial and head movements and irregular heart rate and respiration (Fig. 2a). The EEG background pattern during QS is highly discontinuous with bursts of high amplitude ≥ 3 s and periods of hypoactivity or electrographic quiescence (= interburst intervals or IBIs) 15–20s, associated with a more regular cardiorespiratory pattern and less body movements (Fig. 2b). From 32 weeks onwards, AS is defined as periods of continuous tracing with no discontinuity for ≥ 60 s and < 30 s of micro-arousal (Fig. 3a) and QS is defined as discontinuous tracing with bursts of activity ≥ 3 s, and periods IBIs of ≥ 15 s in all EEG channels [19,29], with specific spatial and temporal organization of EEG features (Fig. 3b). A further decrease in amplitude during AS (Fig. 4a) and decrease in IBI during QS is seen from 34 weeks (Fig. 4b) [4]. QS periods are defined as still discontinuous or semi-continuous in infants of 35–36 weeks GA and can be differentiated of AS with continuous tracing, episodes of REM and specific age-related transients. A detailed overview with a summary of cerebral and non-cerebral features for EEG sleep state scoring in preterm infants is presented in Table 1.

As more complex sleep stages follow the growth of major cortical afferent connections, the organization of the four neonatal sleep stages (two AS and two QS periods) and wakefulness are established after 36 weeks [17,46]. The background pattern during AS or REM is continuous with mixed (M) frequency activity as sleep onset AS 1 (Fig. 5), and a low voltage irregular (LVI) pattern AS 2 (Fig. 6) following QS [29,30,35]. Delta brushes are predominantly occipital in AS 1 whereas AS 2 contains more rapid, lower amplitude theta and alpha activity. From 37 to 38 weeks, a new sleep developmental trajectory during QS is expressed, with the emerging of ‘Tracé Alternant’ (TA) (Fig. 7), with the length of bursts equal to the length of IBIs, initiated by a brief ‘High Voltage Slow Wave’ (HVS, continuous diffuse high voltage delta with occipital and central predominance) QS pattern (Fig. 8). This leads to a globally more continuous EEG and the relative change in discontinuity between QS and non-QS states is only minor [37,47]. A regular respiratory rate and no REMs are the most consistent non-cerebral features associated with QS. Chin EMG activity, tonic between QS and low between AS, can be present however this parameter might be absent or unreliable to observe until 48–50 weeks GA [35]. Table 2 summarizes the EEG and non-cerebral features used in literature to score sleep in (near) term neonates [17,29–31,48].

Significant re-organization of sleep state occurs after 48 weeks GA, with transition from neonatal to infant sleep and change in terminology from AS to REM and QS to NREM [35]. The TA pattern will disappear and will be replaced completely by HVS and midline central sleep spindle activity will appear during NREM. Sleep onset will be more likely in NREM [17,35].

EEG arousals, lasting for 3 s to 1 min, are characterized by a desynchronization or change in the EEG pattern, and are usually associated with muscle activity, body activity, alterations in the respiratory pattern, and/or eye opening. Longer events (> 1 min) are scored as ‘awakening’. Neonates are considered ‘asleep’ when eyes remain closed ≥ 3 min [19,35], however others define a behavioural state to be present when features are observed for > 1

min [30]. During wakefulness (W), eyes are open, with general body movements and high muscle tone, heart rate and respiratory pattern are irregular and a low voltage, irregular or mixed EEG pattern (LVI or M) with frequent movement artefacts is presented on EEG monitoring.

4 Qualitative assessment of neonatal sleep

4.1 Sleep state and sleep wake cycling across early brain development

A rough, rudimentary sleep wake cycle, based on alternating periods with and without eye movements related to EEG discontinuity, have been described in preterm infants of 24–30 weeks of GA (Table 1) [40,41]. In our own cohort with PMA between 27 and 31 weeks, we found a slightly shorter cycle duration between two successive QS periods based on quantitative analysis (for detailed description of this study group see [37]). This is comparable to results of visual EEG-assessment of Curzi Dascalava et al., and coherent with the observation of a shorter cycle duration reported by Vecchierini et al. [44]. Nevertheless, there is still a notable wide range in cycle duration. Methodological differences in study conditions, impede exact comparison, however the presence of ‘alternating vigilance states’ in clinically stable preterms, is evident [49] and can also be captured in a time-compressed presentation with aEEG [24,25]. Although the fluctuation in aEEG trend is considered a surrogate marker for normal brain function and a delayed appearance of sleep cycles is also associated with developmental impairment [26,50,51], qualitative sleep state interpretation with aEEG in preterm infants < 30 weeks is more complicated due to higher amounts of IS [36,43]. For a more qualitative assessment of preterm sleep, the integration of both cerebral and noncerebral measures is required which can be observed in more detail with video-PSG monitoring.

Studies investigating sleep in utero and low risk premature infants found that the amount of AS predominates in the last 10 weeks of gestation [6,43,52,53]. Endogenous neuronal activation, occurring during AS, provides the growth of neural networks (e.g. neurosensory systems) in preterm and term infants that have limited waking experiences. Mirmiran et al. [11] investigated sleep behaviour in 96 low risk preterm infants < 30 weeks GA with sequential polygraphic and behavioural measurements and found a significant age effect for both the amount of QS and IS. There was a significant decrease in time spent in IS from 50% at 30–31 weeks to 20% at term age. This was accompanied by an increase of QS during this period of brain maturation when those brain areas are prepared for environmental stimuli. Percentages of QS and wakefulness will further rise up to 3 months of age, accompanied by a further decline of the time in AS (Table 3) [11,17,54]. In line with those findings, we found an increase in cycle length and mean QS time from 33 weeks PMA to term age in a group of 26 premature infants with GA < 32 weeks and normal neurodevelopmental outcome at 24 months who had sequential 4 h-EEG recordings over time (Table 1) [37]). At 33–34 weeks PMA, mean QS time was 15.1 ± 3 min (range 9–32 min), at 35–36 weeks PMA mean QS time was 19 ± 3.6 min (range 4–34 min), at 37–38 weeks PMA mean QS time was 18.8 ± 3.6 min (range 5–33 min) and at 38–40 weeks PMA mean QS time was 20.3 ± 3.3 min (range 7–37 min) which is comparable with the findings of Mirmiran et al. [11].

Near term age, the neonate expresses a clear ultradian sleep cycle across the day of 50–60 min (range 30–70 min), alternating with waking episodes in a 3–4 h cycle [17,35]. In contrast to older infants, sleep onset in neonates is predominantly with an AS segment (AS 1). An overview of the full-term sleep cycle is presented in Table 4. Only a small amount, 10–15% (10 min) of the total sleep time, is TS or IS in the healthy term infant [17,35] and this will be considered abnormal if abundant in the term neonate [30,42,55].

4.2 Sleep quality

Interpretation of sleep states remains a significant methodological challenge depending on the selected variables, maturity of the infants (biological variability), severity of illness of the infant and different environmental conditions (e.g. kangaroo care, light and sound stimulus, prone position, length of recording), which can all influence the quality of sleep expression, and the time variation of the SWC [19,54,56–59].

Several studies have focused on AS and its role in early brain development, nevertheless the importance of QS and conservation of a qualitative sleep-wake cycle cannot be overstated. Sleep has a vital function and AS provides crucial input for the development of long-term circuitry, proper sleep cycles and QS/NREM sleep are essential for the preservation of brain plasticity and the consolidation of those processes [6,11]: the progression from QS to AS is important for memory processing, and hippocampal processing of external stimuli occurs during QS [60].

Moreover, it has been hypothesized that mainly QS may be more responsive to stress factors (e.g. environmental stress related to longer extrauterine life) compared to other states and that the brain adapts to those conditions with an altered expression of state organization [61]. Scher et al. have reported changes in sleep architecture with longer sleep cycles and more sustained QS periods in preterm infants compared to matched full-terms at the same PMA, suggesting an acceleration in their development [57,61,62]. Some diurnal differences in the expressions of EEG sleep-wake patterns, triggered by the developing circadian rhythm [63] and environmental influences were also documented by Biagioni et al. and others [11,64]. Few awakenings during the morning hours and more QS patterns during the day-time were found in the preterms whereas QS patterns were equally distributed in day and night-time near term age.

Skin-to-skin-care (SSC) is associated with less arousals and an increased percentage of QS in preterm infants when also exposed to low ambient light levels, which may indicate better sleep conditions [19,65]. Welch et al. found that frontal brain activity (EEG power) increased both during QS and AS when preterm infants had SSC [66,67]. The beneficial effect of all those adaptations regarding better and more stable state organization looks promising and favours the major improvements that have been made in the developmental care interventions of those infants [68,69], but the prolonged benefits on long-term neurodevelopmental outcome, still needs to be confirmed.

In the neurologically compromised neonate, physiological parameters as well as the EEG background will undergo noticeable alterations (e.g. hypoxic ischemic encephalopathy, intraventricular haemorrhage, seizures and sedative medication). The EEG-defined sleep

states may no longer meet the criteria previously defined [11,42,55] and different grades of background depression with alterations over the whole full-term sleep cycle can be observed. In maximal depression of brain function in neonates, sleep cycles completely disappear and state differentiation is no longer possible in the acute stage. The background pattern is severely suppressed with extreme low voltage activity or with no discernible cerebral activity. Heart rate variability is decreased. In marked depression, there is a burst-suppression pattern (an invariant and unreactive pattern of bursts of paroxysmal activity alternating with periods of marked voltage attenuation), and sleep cycles are also abolished. In moderate depression, the background is depressed with low voltage and discontinuous activity, and the state-EEG relation and sleep cycles are grossly disturbed. A discontinuous pattern can be seen in both QS and AS, although less so in the latter. HVS and M patterns are no longer seen [55].

In neonates with mild depression of brain function, sleep cycles and state-EEG relation are mildly disturbed but still can be identified. QS will be replaced by IS or a discontinuous pattern and HVS will disappear and AS will have more LVI patterns as mixed frequency. In minimal depression, some EEG background abnormalities will only be apparent in QS, making the EEG more discontinuous and markedly asynchronous, whereas sleep cycles and sleep state are maintained, making QS an intriguing clinical marker for assessing more subtle alterations in brain function [11,55,70]. Not only the severity of background suppression and related to this, the quality of sleep states and cycles, but also the timing of 're-appearance' and 'stability' of sleep wake cycles have been correlated with long-term outcomes [31,42,55,71].

5 Automated sleep-EEG analysis

Automated detection of sleep periods and quantification of sleep may document alterations in cortical function during extra-uterine brain development and accelerate the more subjective visual assessment.

Detection of sleep is, however, challenging during this period of rapid brain maturation, because of the biological and technical variability in EEG background patterns. Moreover, multiple sleep-EEG studies indicate that newborn state recognition is more comprehensively assessed when integrating both cerebral and non-cerebral measures. Previous attempts were either based on single channel EEG in very preterm infants < 32 weeks [49,72,73] or focused on the neonatal, term EEG [62,74–76] or mainly determined quantitative features based on visual pre-selection of sleep states [5,70,77–80]. Quantitative EEG-features that are most related with brain maturation and applied to sleep in previous studies, are spectral analysis (which decomposes the EEG signal into its constituent frequency components) [23,79,81] and methods to define EEG discontinuity [4,49,82,83]. Recently, more interest is directed to the analysis of functional brain connectivity and non-linear methods using complexity analysis, since those methods can document physiological behaviours as a measure of the state of a dynamical process [65]. Koolen et al. showed that the synchrony between cortical activations in QS periods, based on the 'Activation Synchrony Index' (ASI), significantly increased between 30 and 40 weeks PMA [5,79]. Tokariev et al. provided a benchmarking study that functional brain connectivity develops rapidly and is

related to vigilance states in human term neonates [84]. All together, these studies provide important developmental features of functional brain maturation related to sleep states, however, current procedures for automated sleep detection, which allow subsequent quantification, are limited. To bridge this gap, our group developed an automated QS detection algorithm that performs robustly over a wide PMA range [37]. Using this automated approach, quantification of the electrocortical activity during QS was performed, as a gateway to assess the quality of brain maturation in preterm infants in future studies and allow for further exploration of the relationship between cerebral activity, brain development, and neurodevelopmental outcome. In line with this, Koolen et al. [85] used a combination of EEG features to classify EEG epochs as AS and QS across preterm brain development and provided a sleep probability trend.

6 Future directions

Studies of qualitative and quantitative assessment of preterm sleep have not been widely reported and improvements in neonatal medicine (Kangaroo Care, Newborn Individualized Developmental Care and Assessment Program (NIDCAP), non-invasive ventilation [86]) over the last decade have changed the sleeping conditions of those vulnerable preterm infants and ask for a more recent and updated assessment of preterm and neonatal sleep to complement those data. Further attempts to fully automate EEG sleep wake classification, may not only improve the analytic accuracy to develop normative data across different centres, of interest to compare subgroup populations at high risk for impaired brain function, but may also be useful in the day to day monitoring. A bedside tool, minimal invasive, which facilitate the recognition of sleep states, can guide and improve developmental clinical care.

7 Conclusion

Sequential EEG-sleep analysis during the neonatal period provides crucial insights into functional brain integrity and documents deviations of the biologically pre-programmed process of sleep ontogenesis. Visual assessment of neonatal sleep-EEG, with integration of both cerebral and non-cerebral measures to better define neonatal state, is considered the gold standard, however future studies on inter-rater agreement are definitely needed to improve its validity.

Developing qualitative and normative data with the aid of automated signal processing approaches, can further improve our understanding of extra-uterine brain development under stressful or pathological conditions and the impact of neonatal sleep on later neurocognitive function.

Fig. 1. Preterm neonate (25 2/7 weeks GA), recorded at 25 3/7 PMA

a. Rudimentary state differentiation with more continuous and discontinuous EEG. High voltage central (red arrow) and temporal delta activity during more continuous EEG, lasting 20 s.

b. Period of high discontinuity, with long IBIs alternated with high amplitude burst activity. Fluctuation of rudimentary state can also be observed in the aEEG trends (red arrow). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 2. Preterm neonate (26 3/7 weeks GA), recorded at 30 2/7 weeks PMA.

a. Continuous EEG activity associated with REM (red arrow).

b. Discontinuous EEG (*tracé discontinu*) during QS, no REM and more regular breathing (red arrow). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 3. Preterm neonate (30 4/7 weeks GA), recorded at 32 3/7 weeks PMA.

a. Continuous tracing during AS. Delta waves with superimposed fast rhythms (delta brushes) in both temporal and occipital brain regions. Irregular breathing pattern. Sleep state organization is now clearly visible in the aEEG trend.

b. Preterm neonate (30 4/7 weeks GA), recorded at 32 3/7 weeks PMA. Discontinuous tracing during QS, with IBI's \approx 15 s. More regular breathing pattern. Temporal theta activity mainly during QS and occipital delta brushes.

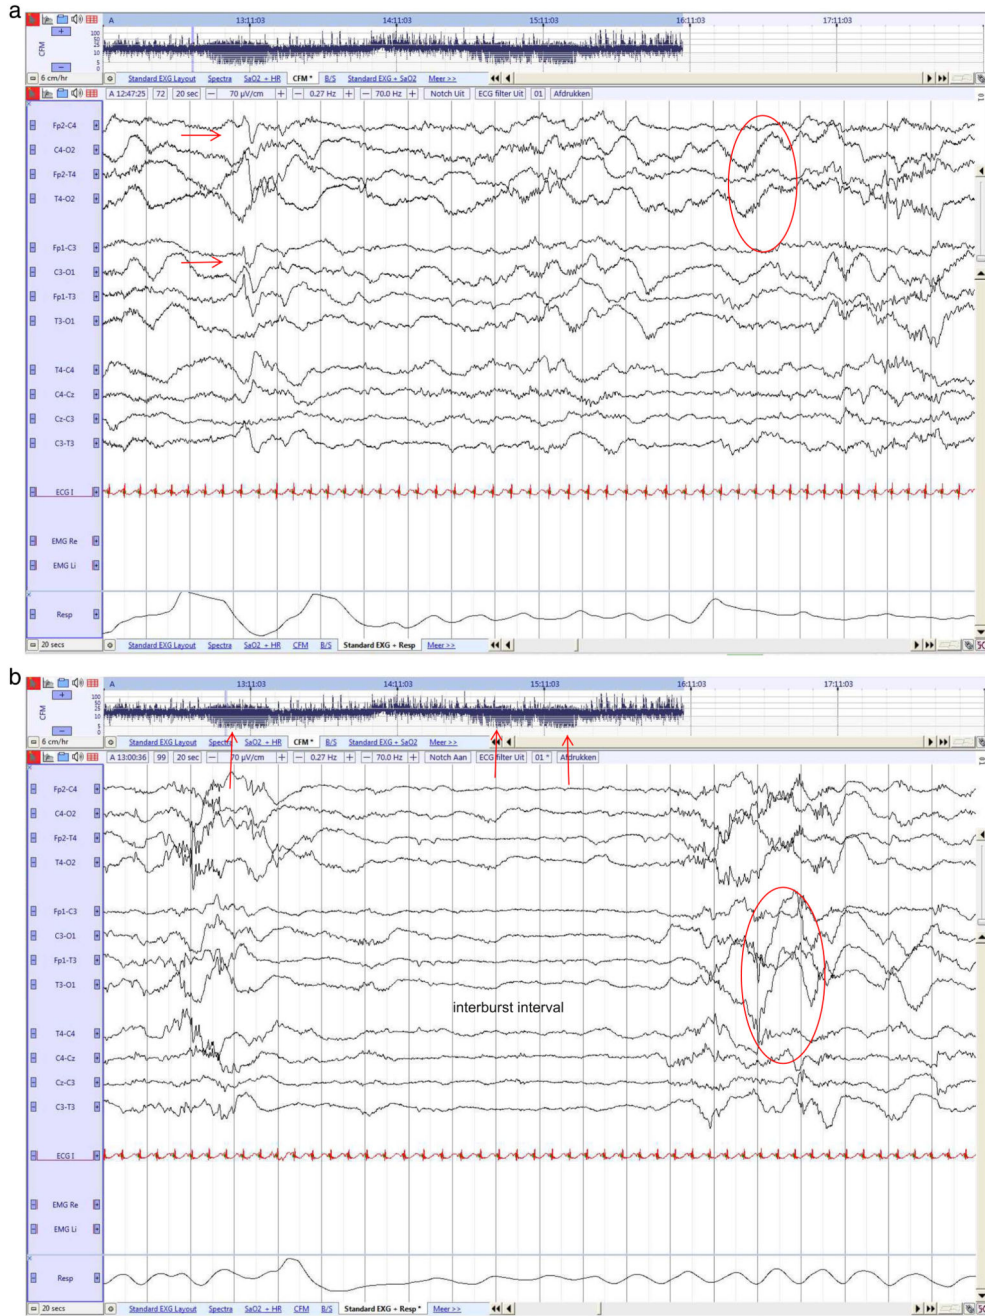

Fig. 4. Preterm neonate (29 4/7 weeks GA), recorded at 34 4/7 weeks PMA.
 a. Continuous tracing during AS. Clear decrease in amplitude. Delta waves with superimposed fast rhythms (delta brushes) in the occipital brain regions (red circle). Immature frontal transient (symmetrical) (red arrow). Irregular breathing pattern.
 b. *Tracé discontinu* during QS, with IBI's ~ 10s. More regular breathing pattern. Temporal theta decreased during QS and occipital delta brushes (red circle). Three periods of *tracé discontinu* can be observed in the aEEG trend. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 5. Late term neonate (36 weeks GA), recorded at 38 6/7 weeks PMA.

Continuous activity with mixed frequencies during AS1 associated with REM, with higher amplitude and lower frequencies than during AS2. Frontal transients (red arrow) and slow anterior dysrhythmia in frontal regions (red line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 6. Preterm neonate (29 4/7 weeks GA), recorded at 36 3/7 weeks PMA. Continuous tracing with low voltage irregular pattern during AS2 and REM (red arrow). EMG was omitted from this figure due to technical artefact. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 7. Late term neonate (36 weeks GA), recorded at 38 6/7 weeks PMA.

Tracé alternant activity during QS. Length bursts = length IBIs, IBI amplitude $25 \mu\text{V}$ (red line). Delta brushes only in QS (red circle) and rolandic theta (red line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 8. Term neonate (41 2/7 weeks GA), recorded at 42 3/7 weeks PMA.
High voltage slow wave sleep at QS onset.

Table 1
Summary of cerebral and non-cerebral features for sleep state scoring and sleep organization in preterm infants.

GA in weeks	24–26	27–28	29–30	31–32	33–34	35–36
Organization of behavioural state /	Rudimentary state with REM ² and No REM periods		AW: mainly artefacts AS with REM QS IS	AW: mainly artefacts AS with REM QS IS	AW: mainly artefacts AS with REM QS IS	AW: mainly artefacts AS with REM QS IS
EEG background activity during sleep states	Inconsistently: Eye movements: less discontinuous, higher amplitude No eye movements: discontinuous, IBIs up to 30s, lower amplitude		AS with REM: discontinuous or semi-continuous, QS –without REM: bursts of activity 3 s, IBIs < 20–30s	AS with REM: (semi) continuous QS –without REM: bursts 3 s, IBIs 15–20s	QW: continuous AS with REM: continuous QS – No REM: bursts 3 s, IBIs 10–15 s	QW: continuous AS1 with REM: higher amplitude, continuous AS2 with REM: lower amplitude, faster frequency continuous activity QS-TD – without REM: (semi) discontinuous IBIs < 10s & amplitude 15-25 μV
State specific temporal and spatial organization	No state specific organization Monorhythmic alpha and theta activity in occipital regions	=STOP ⁴ rhythm	Temporal theta in QS ↑ Synchronous delta numerous in AS Amplitude ↓	Delta brushes occipital and temporal Delta waves with theta numerous in AS Temporal theta (sawtooth) AS/QS	Delta brushes occipital, ↓ in amplitude Temporal theta (sawtooth) mainly in QS and ↓ Immature frontal transients in AS	Diffuse theta waves AS2 > AS1 Diffuse delta waves in QS, occipital and numerous in AS1 > AS2 Immature frontal transients in AS1 Onset of QS: asynchrony
Non-cerebral features	AS: ± QS: – AS: irregular QS: irregular or more regular Not discriminant AS ~ face and body, segmental myoclonus or generalized myoclonic, tonic posturing /	AS: + QS: –		AS: + QS: – AS: variability CR rate QS: ↓ variability CR rate AS: + +, ↑ head & facial movements QS: ↓ small and large body movements AS: – QS:±(not consistent, absent in ~20% of QS)	AS: + QS: – AS: variability CR rate QS: ↓ variability CR rate AS: + + +, ↑ head & facial movements QS: ↓ small and large body movements AS: – QS:±(not consistent, absent in ~20% of QS)	AS: + + QS: – AS: variability CR rate QS: ↓ variability CR rate AS: + + +, ↑ head & facial movements QS: ↓ smaller, segmental body movements AS: – QS:±(not consistent, absent in ~20% of QS)
Cycle length (min)						
Range (mean ± SD)						
[43]		> 27 weeks	10–59.6 (39.7 ± 18.6)	5–84.6 (30.0 ± 27.6) 9.3–71.3 (35.0 ± 17.2)		
[41]	9–55	10–59	4–43			
[40]	> 25 weeks	37–100 (68 ± 19-)	< 30 weeks			
[37]		> 27 weeks	1 0.6–90.2 (32 ± 18)	5.8–83 (31.6 ± 10.6)	5.9–83.9 (39.5 ± 14.8)	6.3–109 (50.9 ± 19.2)

GA in weeks	24–26	27–28	29–30	31–32	33–34	35–36
Provoked EEG reactivity	No reactivity on EEG during gentle tactile stimulation Inconsistently and variable in expression		→ →	AS: transient decrease in EEG amplitude QS: transient continuous EEG		AS: transient decrease in activity QS: appearance of continuous high amplitude slow wave activity

¹ State coded by the concordance of cerebral and non-cerebral features according to the gestational age. Adapted from: [29,9,41,17,30,35].

² Abbreviations: AW= Active Wake, AS= Active Sleep, QS = Quiet Sleep, QW: Quiet Wake, IS: Indeterminate sleep, TST= Total Sleep Time, QS-TD: Quiet Sleep, Tracé Discontinu, IBI= Interburst Interval, CR: cardiorespiratory rate.

³ ↑: increase, ↓: decrease, >: more.

⁴ STOP rhythm: spontaneous theta activity in the occipital regions in the premature neonate.

Table 2
Summary of cerebral and non-cerebral features for sleep state scoring and sleep organization in term neonates.

GA in weeks	37–38	39–40	41–44	43–48
Organization of behavioural state ¹	AW, QW, AS1, AS2, QS-HVS, QS-TA, IS, TS ²			
Proportion of time spent in any state according to age based on average cycle length of 50–60 min	AS: 50–60% QS: 30–40% IS: 10–15%	AS1: 25–35% QS-HVS: 3–5% QS-TA: 30% AS2: 15–25% IS: 10–15%	AS1: 25–35% QS-HVS: 15–20% QS-TA: 15–20% AS2: 15–25% IS: 10–15%	AS1: 25–35% QS-HVS ~ NREM: 45% AS2: 10–15% IS: 10–15%
EEG background activity during sleep states	AW/QW/AS2 low voltage irregular pattern AS1 mixed frequencies, higher amplitude QS-TA: length IBI = length bursts ~6 s, IBI amplitude 25 µV	AW/QW/AS2 low voltage irregular pattern AS1 mixed frequencies, higher amplitude QS-HVS: high voltage, slow waves, occipital predominance QS-TA: length IBI = length bursts ~6 s, IBI amplitude > 25 µV	AW/QW/AS2 low voltage irregular pattern AS1 mixed frequencies, higher amplitude QS-HVS: high voltage, slow waves, occipital predominance ↑ QS-TA: ↓	AW/QW/AS2 low voltage irregular pattern AS1 mixed frequencies, higher amplitude QS-HVS: High voltage, slow waves
State specific temporal and spatial organization	Rolandic theta waves in AS2 > AS1 Delta brushes occipital in AS & QS Diffuse delta waves QS Frontal transient, slow anterior dysrhythmia AS 1, transition QS AS: synchronous Onset of QS: asynchrony	Sharp rolandic alpha & heta bursts in QS Delta brushes occipital ↓, only in QS Frontal transient, slow anterior dysrhythmia AS 1, transition QS AS: synchronous QS: synchronous	Sharp rolandic alpha & heta bursts in QS Delta brushes disappeared in all states Frontal transient, slow anterior dysrhythmia AS 1, transition QS AS: synchronous QS: synchronous	QS-HVS: sporadic spindle like activity
Non-cerebral features	AS: +++ QS: – AS: variability CR rate QS: ↓ variability CR rate AS: + + +, ↓ head & facial movements QS: ↓ smaller, segmental body movements (10% of QS) AS: – QS: ± (absent in ~20% of QS)		AS: +++ QS: – AS: variability CR rate QS: ↓ variability CR rate AS: + + +, ↓ head & facial movements QS: ↓ smaller, segmental body movements (3% of QS) AS: – QS: ± (absent in ~20% of QS)	AS: ++ QS: – AS: variability CR rate QS: ↓ variability CR rate AS: + + +, ↓ head & facial movements QS: ↓ smaller, segmental body movements (3% of QS) AS: – QS: ± (absent in ~20% of QS) ↓

¹State coded by the concordance of cerebral and non-cerebral features according to the gestational age. Adapted from: [35,9,17,29,30].

²Abbreviations: AW =Active Wake, AS= Active Sleep, QS =Quiet Sleep, QW: Quiet Wake, IS: Indeterminate Sleep, TS: Transitional sleep HVS: High voltage slow wave sleep, TA: Tracé Alternant, REM =Rapid Eye Movements, IBI= Interburst Interval, CR: cardiorespiratory rate.

Table 3
Development of sleep states according to the gestational age in preterm and full-term neonates.

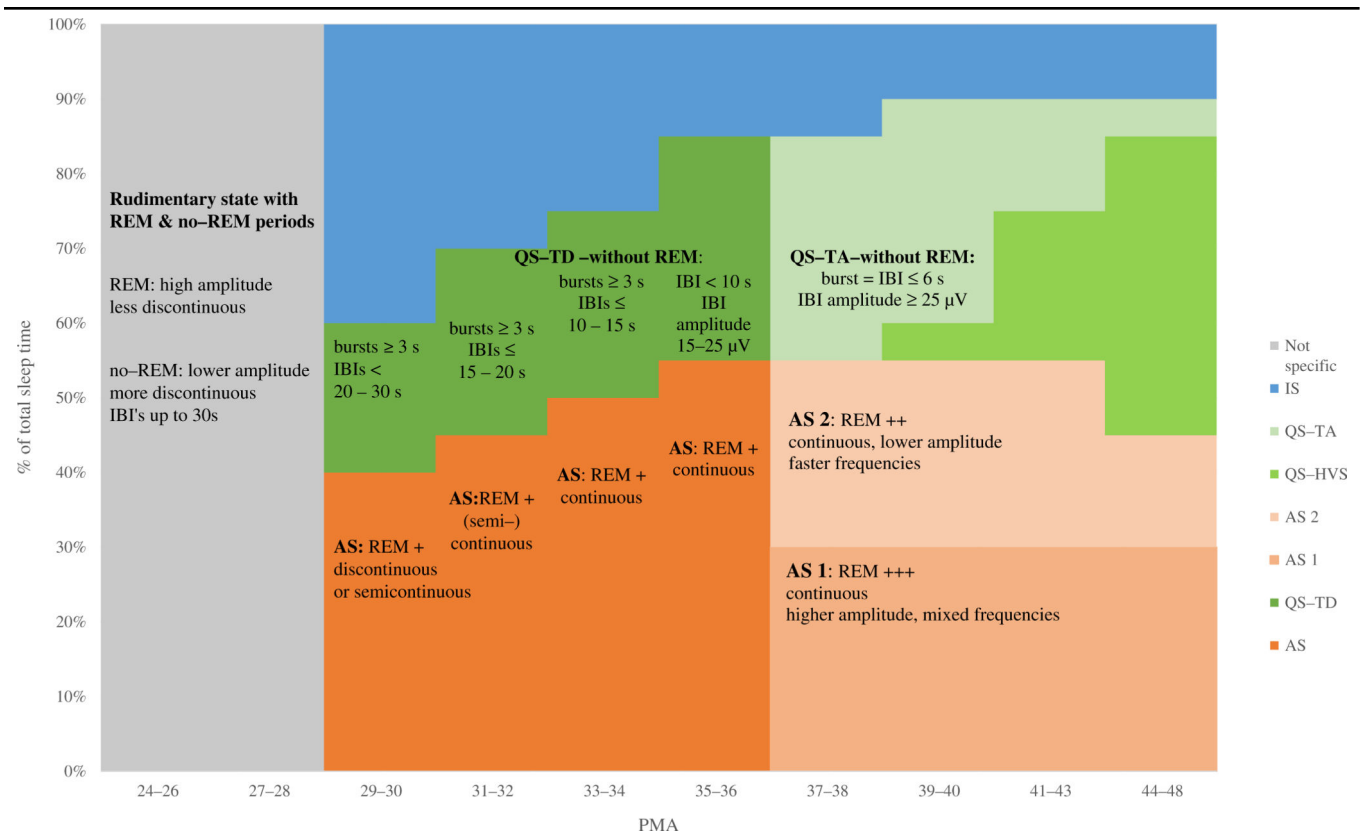

Table 4
Full-term sleep cycle average \pm 50–60 min.
