Background: No systematic investigations have been conducted to assess the lung burden imposed by the chronic inhalation of silver nanoparticles (AgNPs) emitted by spray products.

Objective: The objective of this study was to formulate a study framework that integrates a probabilistic risk assessment scheme with a mechanistic lung burden model for the estimation of health risks associated with the long-term inhalation of AgNP-containing spray products.

Materials and methods: A compartmentalized physiologically based alveolar deposition (PBAD) model was used to estimate AgNP lung burden. Dose–response relationships were established using nanotoxicity data sets obtained from rats (as a model organism). Weibull model-based thresholds of AgNP lung burden based on neutrophil-elevated inflammation biomarkers were estimated from Hill-based exposure–response relationships. Finally, the risks of lung disease posed by various AgNP-containing spray products were assessed.

Results: Conservative thresholds for the prevention of pulmonary disease were estimated as follows (mean \pm SE): 34 nm AgNPs (0.32 \pm 0.22 mg) and 60 nm AgNPs (1.08 \pm 0.64 mg). Our results indicate that the risk probability was \sim 0.5 that the hazard quotient (HQ) estimates of deodorant with a count median diameter (CMD) \approx 30 nm exceeded 1. The primary risk posed by AgNPs is transferred from the interstitial region to lymph nodes. Under the condition of 50% risk probability, the 97.5 percentile of HQ for the spray products were as follows: CMD \approx 30 nm (\sim 3.4) and CMD \approx 60 nm (\sim 1.1).

Conclusion: Our application of the proposed risk assessment scheme to the results obtained in an in vivo animal model proved highly effective in elucidating the relationship between the characteristics of metallic NP-containing spray products and their corresponding toxicity. The integration of the proposed PBAD model with a risk assessment framework enables the rapid assessment of risk posed by spray products containing metallic NPs over various time scales.

Keywords: silver nanoparticles, spray product, risk assessment, lung burdens, nanotoxicity

Introduction

Silver nanoparticles (AgNPs) are widely used for their antimicrobial effects; however, antimicrobial spray products (eg, deodorants [DO] and disinfectants [DI]) present an exposure risk via inhalation and dermal routes. It has been estimated that \sim 14% of products containing AgNPs could potentially release airborne AgNPs into the air via dry powder dispersion.¹ Dermal exposure has not been shown to cause DNA damage and/or inflammation in primary skin cells; however, the toxicity of inhaled AgNPs is yet to be fully elucidated.² Hagendorfer et al³ reported that exposure to NPs via the respiratory tract poses the greatest risk, due to the direct exposure pathway and the large surface area of human lungs.

Numerous studies have investigated the toxicity of inhaled AgNPs in vivo and in vitro. In vivo systems can be used to simulate exposure to AgNPs at higher frequencies and over longer durations. Foldbjerg et al⁴ reported DNA damage induced by reactive oxidative species (ROS) in a human alveolar cell line after acute exposure (24 hours) to AgNPs. Hyun et al⁵ reported the production of neutral mucin in lung tissue and foamy macrophages in alveolar tissue in rats exposed to AgNP aerosols for 6 h day⁻¹ over a period of 28 days. Sung et al⁶ reported dose-dependent chronic alveolar inflammation in rats exposed to airborne AgNPs for 6 h day⁻¹ over a period of 13 weeks.

Seiffert et al⁷ reported that AgNPs induced pulmonary eosinophilic and neutrophilic inflammation and bronchial hyper-responsiveness in rats. Minimal inflammation responses in lungs were also observed in mice repeatedly exposed to airborne AgNPs (3.3 mg m⁻³) for 4 h day⁻¹ over a period of 10 days.⁸ Wijnhoven et al⁹ reported that the brain could be potentially exposed to airborne AgNPs due to AgNPs coming into contact with olfactory nerves during respiration.

The pulmonary toxicity of AgNPs has generally been explored using murine models; however, there is a dearth of information pertaining to the risk of humans inhaling AgNP-containing spray products over extended time scales. In this study, we sought to overcome the limitations of in vitro and in vivo experiments in assessing the toxicity of airborne AgNPs under exposure durations comparable to the application scenarios typically encountered by humans. Most of the standard guidelines for nano-aerosols deal with workplace atmosphere, instrument setup, and measurement methods.¹⁰ Guidelines established by the Occupational Safety and Health Administration (OSHA) and National Institute for Occupational Safety and Health (NIOSH) deal exclusively with the occupational risks of exposure to airborne AgNPs.^{11,12}

At present, there is a lack of rigorous air quality standards pertaining to AgNP aerosols and AgNP content in spray products. The only regulations on the use of antibacterial sprays were established by the Federal Insecticide, Fungicide Rodenticide Act in the USA¹³ and Biocide in the EU.¹⁴

In this study, we incorporated mechanistic modeling within a comprehensive risk assessment framework to derive appropriate threshold levels for AgNPs in spray products. Our objectives in this study were fivefold: 1) to predict the total lung burden posed by long-term exposure to AgNP-containing spray products; 2) to construct a dose–response profile for humans via extrapolation from exposure experiments on rats; 3) to derive AgNP lung burden threshold levels based on inflammation-related

biomarker responses; 4) to evaluate the exceedance risks (ER) and risk quotients of lung burden imposed by AgNPs in the human body; and 5) to formulate an administrative strategy to minimize the risks associated with the long-term inhalation of AgNPs through the regulation of NP content in consumer spray products.

Materials and methods

Characterization of AgNP spray products

Figure 1 presents the overall study framework, including the following: 1) problem identification (Figure 1A), 2) exposure analysis (Figure 1B), 3) effect analysis and threshold estimation (Figure 1C and D), and 4) risk characterization (Figure 1E).

In this study, we employed experimental data obtained by Hsu¹⁵ for the characterization of size-specific mass concentrations, AgNP content, and emissions of three commercial spray products. The spray products included one DI and two DO with AgNPs of different sizes. The DO with smaller NPs (27.9–33.4 nm) was designated as DO_s, whereas the DO with larger NPs (57.3–61.5 nm) was designated as DO_L. These measurements refer to the count median diameters (CMDs) of the AgNPs. The DI product employed a pump system, whereas the DO products employed a propellant.¹⁵ The AgNP aerosols were investigated using an electrical low pressure impactor (ELPI + TM, VeReference-1.2; Dekati Corp., Tempere, Finland) and a micro-orifice uniform deposit impactor.

The morphological features of the AgNPs were analyzed using a transmission electron microscope (TEM) equipped with a personal nanoparticle sampler developed by Hsu.¹⁵ Airflow into the sampling system for TEM analysis was controlled to 100 L min⁻¹. The aerosol mass per press was as follows: DI (0.13 g press⁻¹), DO_s (1.5 g press⁻¹), and DO_L (1.3 g press⁻¹). During measurements, we set the number of presses per use (PPU) higher for DO than for DO_s and DO_L to compensate for the lower aerosol mass per press.

Spray product usage was simulated under two scenarios: nonintensive and intensive. The number of PPU under nonintensive applications was as follows: DI (30), DO_s (10), and DO_L (10). The number of PPU under intensive applications was as follows: DI (200), DO_s (40), and DO_L (40). The sampling duration under each scenario was 40 minutes.¹⁵

Physiochemical characterization of AgNPs

The size distribution of AgNPs from the three spray products was not measured; however, the aggregation of AgNPs from DO_s and DO_L was observed in TEM images.¹⁵ The dynamic behavior of the AgNPs from the three spray

Abbreviation: BALF, bronchoalveolar lavage fluid.

products was elucidated by recompiling the number concentrations released by the spray products and the Ag contents within various size ranges (Figure S1; Table S1).¹⁵ Most of the AgNPs in the three spray products were transported in aerosols exceeding 100 nm (Table S1).¹⁵ To further elucidate the contents of the aerosols from the three spray products, we also compiled the results of the energy dispersive X-ray (EDX) analyses by selecting representative TEM images of aerosols (Table S2).¹⁵

Alveolar deposition model

We employed the compartmentalized physiologically based alveolar deposition (PBAD) model developed by Kuempel et al^{16,17,19} and Tran et al¹⁸ to mechanistically estimate the human lung burden imposed by AgNPs. The PBAD model can be used to predict the long-term burden by considering clearance processes in the pulmonary region and mechanisms of particle distribution mediated by alveolar macrophages. In the PBAD model, the human lung was divided into four

Figure 2 Schematic showing the compartmentalized PBAD model.

Abbreviations: PBAD, physiologically based alveolar deposition; A, alveolar region; M, alveolar macrophage region; I, interstitial region; L, lymph node region; X_1 , AgNPs in alveolar region; X_2 , AgNPs in alveolar macrophage; X_3 , AgNPs in interstitial region; X_4 , AgNPs in lymph node region; k_p , transfer rate of AgNPs from alveolar region to interstitial region; k_c , transferred rate of AgNPs from interstitial region to lymph node; k_p , phagocytosis rate of macrophage; k_a , apoptosis rate of macrophage; k_c , physical clearance rate of AgNPs; AgNP, silver nanoparticle.

regions: alveolar surface, alveolar macrophage, interstitium, and lymph nodes (Figure 2). A first-order four-compartment PBAD model was used to simulate the input and output conditions, which largely determine the accumulation of AgNPs in human lungs. The results were derived as dynamic lung burden and biokinetic reaction rates in various compartments. This made it possible to mechanistically explore biodynamic interactions among the various compartments using a set of ordinary differential equations (Table 1).

When aerosols are inhaled (ie, access the respiratory tract), AgNPs are deposited in the alveolar region at a specific deposition fraction (Eqs. (T1) and (T2); Table 1) where C refers to the mass concentration of AgNP-containing aerosols ($\mu\text{g m}^{-3}$), DF (–) is the deposition fraction dependent on particle size (nm), ED is the exposure duration based on previous surveys of AgNP spray products (140 minutes),^{20,21} and BR is the typical breathing rate in Taiwan ($0.38 \pm 0.07 \text{ m}^3 \text{ h}^{-1}$).²²

Note that AgNPs could be transformed into other chemical forms (eg, Ag ions or Ag oxides) during the course of exposure. Nonetheless, most of the Ag particles that access alveolar regions (regardless of chemical makeup) would be at the nanoscale, due to the fact that the CMDs of all three spray products are below 100 nm (Table 1). Thus, the Ag particle content in the PBAD model simulations is expressed as AgNP lung burden.

AgNPs deposited in the alveolar region are either translocated into interstitial areas or phagocytosed by macrophages.

These processes are expressed using Eq. (T3) (Table 1), where t refers to the duration of exposure (days), $X_1(t)$ and $X_2(t)$, respectively, refer to the time-dependent AgNP dose in alveolar and macrophage regions (measured in mg), k_p is the rate of phagocytosis by macrophage (day^{-1}), k_i is the rate of AgNP transfer from alveolar to interstitial regions (day^{-1}), and k_a is the rate of macrophage apoptosis (day^{-1}). During the transfer from alveolar to macrophage regions, many AgNPs are eliminated from the lungs. This is expressed using Eq. (T4) (Table 1), where k_c refers to the physical clearance rate of AgNPs (day^{-1}).

The dynamic deposition of AgNPs in interstitial regions is expressed using Eq. (T5), where $X_3(t)$ refers to the time-dependent dose of AgNPs in the interstitial region, and k_l is the rate at which AgNPs are transferred from interstitial to lymph node regions (day^{-1}) (Table 1). Total AgNP deposition was estimated by summing the doses of AgNPs in the alveolar, macrophage, and interstitial regions using Eq. (T6) (Table 1). The deposition of AgNPs in the lymph node region was described using Eq. (T7), where $X_4(t)$ refers to the time-dependent dose of AgNPs in the lymph node region (mg) (Table 1). Table 1 lists the range of values applied to each rate parameter (k_p , k_c , k_a , k_i , and k_l) in implementing the PBAD model.

Dose–response model

We sought to match as closely as possible the size ranges of AgNPs in the spray products in this study by using AgNPs of 34 and 60 nm for the construction of a dose–response model to characterize the lung burden imposed by AgNPs in the human body vs the increase in the number of neutrophils. This was achieved by fitting the three-parameter Hill model²³ to published datasets.²⁴ We adopted the number of neutrophils isolated from bronchoalveolar lavage fluid (BALF) exposed to aerosolized AgNPs as the biomarker presenting the highest sensitivity to inflammation in male Fischer rats (F344/DuCrI).²⁴

The dose–response profile illustrating the relationship between AgNP lung burden and neutrophil increment can be written as follows:

$$E(C) = \frac{E_{\max}}{1 + \left(\frac{EC50}{C}\right)^n} \quad (1)$$

where C refers to the lung burden imposed by AgNPs (mg), E_{\max} is the maximum increase in the number of neutrophils (-fold), $EC50$ is the dose with an effect equal to 50% E_{\max} (mg), and n is the fitted Hill coefficient, such that $n=1$

Table 1 Equations for compartmentalized PBAD model along with used values of rate parameters

Interpretation	Equations ^a	
Mass-based dosimetric exposure model	$D = C \times DF \times ED \times BR$	(T1)
Silver deposition fraction in alveolar–interstitial region	$DF = \left(\frac{0.0155}{d_p} \right) \left[\exp(-0.416(\ln d_p + 2.84)^2) + 19.1 \exp(-0.482(\ln d_p - 1.362)^2) \right]$	(T2)
AgNPs dose (mg) in alveolar region A: X_1	$\frac{dX_1(t)}{dt} = D - k_p X_1(t) - k_i X_1(t) + k_a X_2(t)$	(T3)
AgNPs dose in alveolar macrophage region M: X_2	$\frac{dX_2(t)}{dt} = k_p X_1(t) - k_c X_2(t) - k_a X_2(t)$	(T4)

Abbreviations: PBAD, physiologically based alveolar deposition; A, alveolar region; BR, breathing rate; DF, AgNPs deposition fraction in alveolar–interstitial region; ED, exposure duration; I, interstitial region; L, lymph node region; M, alveolar macrophage region; k_p , apoptosis rate of macrophage; k_c , physical clearance rate of nanoparticle; k_i , transferred rate of AgNPs from alveolar region to interstitial region; k_l , transferred rate of AgNPs from interstitial region to lymph node; k_a , phagocytosis rate of macrophage; C, mass concentration of AgNPs aerosols ($\mu\text{g m}^{-3}$); AgNP, silver nanoparticle.

indicates a linear response (according to the Michaelis–Menten model) and $n > 1$ indicates that the biomarker is ultra-sensitive to the toxicant. To identify the AgNP lung burden that induces an inflammatory response, we also estimated the EC10, EC5, and EC1 resulting in 10%, 5%, and 1% E_{max} .

Predictive risk threshold

A three-parameter Weibull threshold model was used to obtain the best fit for EC10, EC5, and EC1 toxicity data in estimating the threshold lung burden of AgNPs for the prevention of pulmonary disease. EC10, EC5, and EC1 toxicity data were adopted from the estimated EC10, EC5, and EC1 cumulative distribution functions (CDFs) obtained using the Hill-based dose–response model in Eq. (1) for the probabilistic fitting of experimental data.²⁴

The Weibull threshold model can be expressed as follows:

$$F(C) = 1 - \exp \left[- \left(\frac{C - \gamma}{\alpha} \right)^\beta \right], C > \gamma > 0, \alpha > 0, \beta > 0 \quad (2)$$

where $F(C)$ represents the EC10, EC5, and EC1 CDF data corresponding to specific AgNP lung burden values in the

human body, α is the scale parameter affecting distribution of $F(C)$ as a change in the abscissa scale, β is the shape parameter representing the slope of the line in the CDF data, and γ is the fitted threshold dose (mg), also denoted as predicted no-effect concentration.

The Weibull threshold model was used to obtain the best fit for the 2.5, 5, 50, 95, and 97.5 percentiles in CDF data extracted from EC10, EC5, and EC1, resulting in the following threshold burdens: γ_{10} , γ_5 , and γ_1 .

Probabilistic risk model

Our underlying objective in this study was to protect users of AgNP-containing sprays from the effects of pulmonary disease resulting from exposure to aerosolized AgNPs. Threshold level γ_1 was selected as a conservative criterion for the characterization of risk with the aim of preventing pulmonary disease. We developed a probabilistic risk assessment model linking the PBAD model with the Hill-based dose–response model to characterize the dose–response relationship between AgNP-derived lung burden and the incremental increase in neutrophil count following exposure to aerosolized AgNPs.

In accordance with Bayesian inference, the cumulative risk of neutrophil increases under a given AgNP lung burden

(R(E)) (ie, posterior probability) is the product of a prior probability P(C) and a conditional probability function (ie, likelihood) P(E|C), which can be expressed as follows:

$$R(E) = P(C) \times P(E|C) \quad (3)$$

where

$$P(E|C) = \Phi \left(\frac{E_{\max}}{1 + \left(\frac{EC50}{C} \right)^n} \right) \quad (4)$$

It is then possible to derive exceedance profiles as $1-R(E)$, otherwise known as the ER.

To assess the potential risk to human health, we characterized the increase in the number of neutrophils as an effect of inflammation induced by AgNPs using the hazard quotient (HQ) model, as follows:

$$HQ = \frac{C}{\gamma_1} \quad (5)$$

where C and γ_1 are estimated probabilistically. $HQ > 1$ implies that AgNP-induced lung burden poses a potential risk to human health based on neutrophil expression, whereas $HQ < 1$ indicates that AgNP-induced lung burden poses no risk to human health. To perform a reasonable assessment of risk from the three products in this study, we estimated the risks associated with the inhalation of spray DO_s and DO_L only, because the shape of the AgNPs in DI was inconsistent with the shape of AgNPs in dose–response analysis.²⁴ We also estimated threshold exposure durations of DO_s and DO_L based on the threshold dose estimates obtained under the condition that $HQ = 1$.

Uncertainty and data analysis

Simulations of the PBAD model were conducted using Berkeley Madonna 8.0.1, which was developed by Robert Macey and George Oster at the University of California, Berkeley. TableCurve 2D (Version 5.01; AISN Software, Mapleton, OR, USA) was used for mathematical model fittings. Monte Carlo (MC) analysis was used to obtain 2.5 and 97.5 percentiles as 95% CIs for all assessments of uncertainty. We also performed sensitivity analysis to identify the PBAD model parameters with the most pronounced effect on AgNP lung burden in the human body.

We performed parameterization and sensitivity analysis of variables using 10,000 MC simulations, implemented on Crystal Ball software (Version 2000.2; Decisioneering, Denver, CO, USA).

Results

Estimating size distribution and mass concentration of aerosols

Figure 3 presents the size distribution and estimated mass concentrations of aerosols from three AgNP-containing spray products under non-intensive and intensive applications. The size distributions of the aerosols from each of the products were well fitted to the lognormal (LN) function ($r^2=0.67-0.99$ with $P<0.01$), regardless of whether applied intensively or non-intensively. Under non-intensive applications, the estimated mass geometric mean diameters (GMDs) and geometric standard deviations (GSDs) were as follows: DI ($1.78 \mu\text{m} \pm 1.34$), DO_s ($1.94 \mu\text{m} \pm 3.82$), and DO_L ($0.48 \mu\text{m} \pm 3.90$) (Figure 3A, C, and E).

Under non-intensive applications, the estimated mass GMDs and GSDs were as follows: DI ($1.87 \mu\text{m} \pm 1.34$), DO_s ($2.09 \mu\text{m} \pm 5.88$), and DO_L ($0.34 \mu\text{m} \pm 5.15$) (Figure 3B, D, and F). The estimated mass concentrations of aerosols in non-intensive applications were as follows: DI ($43.96 \mu\text{g m}^{-3}$ [95% CI: 36.96–50.96]), DO_s ($118.80 \mu\text{g m}^{-3}$ [100.87–136.74]), and DO_L ($139.99 \mu\text{g m}^{-3}$ [138.24–141.74]) (Figure 3A, C, and E).

The estimated mass concentration of aerosols in intensive applications were as follows: DI ($611.04 \mu\text{g m}^{-3}$), DO_s ($1,504.74 \mu\text{g m}^{-3}$), and DO_L ($4,051.50 \mu\text{g m}^{-3}$) (Figure 3B, D, and F). The measured AgNP contents in aerosols in intensive applications were as follows: DI (4.59%), DO_s (0.60%), and DO_L (0.37%), which indicated the following mean AgNP mass concentrations: DI ($2.02 \mu\text{g m}^{-3}$), DO_s ($0.71 \mu\text{g m}^{-3}$), and DO_L ($0.52 \mu\text{g m}^{-3}$) (Figure 3A, C, and E). The measured AgNP contents in aerosols in intensive applications were as follows: DI (4.64%), DO_s (0.58%), and DO_L (0.57%), which indicated the following mean AgNP mass concentrations: DI ($28.35 \mu\text{g m}^{-3}$), DO_s ($8.73 \mu\text{g m}^{-3}$), and DO_L ($23.09 \mu\text{g m}^{-3}$) (Figure 3B, D, and F).

On the other hand, size distributions as function of number concentrations of AgNP-containing aerosols from three spray products were also re-analyzed (Figure S1).¹⁵ The LN function well fitted to the size distributions of aerosols ($r^2=0.99$ with $P<0.01$). The GMDs were 0.016, 0.002, and 0.003 with GSDs of 1.90, 1.29, and 2.37 in spray DI, DO_s , and DO_L , respectively (Figure S1).

Figure 3 Estimated mass concentrations of aerosols based on size distributions of droplets in spray (**A, B**) DI, (**C, D**) DO_s, and (**E, F**) DO_L in non-intensive or intensive application. **Abbreviations:** DI, disinfectant; DO_s, deodorant of AgNPs in smaller scales; DO_L, deodorant of AgNPs in larger scales; LN, lognormal; AUC, area under the curve; AgNP, silver nanoparticle.

Lung deposition analysis

In exploring the long-term risks associated with the inhalation of AgNP-containing spray products, we made predictions pertaining to the accumulation of AgNPs in the alveolar, macrophage, interstitial, and lymph node regions under chronic exposure (non-intensive and intensive) over

a period of 2 years (Figures 4 and S2). Overall, the total AgNP-induced lung burden and accumulation of AgNPs reached the point of saturation in the alveolar, macrophage, and interstitial regions under non-intensive as well as intensive applications (Figures 4 and S2). After 2-year exposure, the non-intensive application of DI would result

Figure 4 (A, B) Total AgNP lung burden and **(C, D)** accumulation rates after long-term exposure of aerosolized AgNPs released by AgNP-containing spray products in non-intensive and intensive using condition.

Abbreviations: AgNP, silver nanoparticle; DO_s , deodorant of AgNPs in smaller scales; DO_L , deodorant of AgNPs in larger scales; DI, disinfectant.

in the highest AgNP-induced lung burden (0.063 mg), followed by DO_s (0.022 mg) and DO_L (0.010 mg) (Figure 4A). Within a period of 2 years, the annual accumulation of sprays DI, DO_s , and DO_L were 0.031, 0.011, and 0.005 mg, respectively (Figure 4C).

After 2-year exposure, the intensive application of the sprays DI, DO_s , and DO_L would result in the following AgNP-induced lung burden: DI (0.870 mg), DO_s (0.257 mg), and DO_L (0.359 mg) (Figure 4B). The annual accumulation of sprays DI, DO_s , and DO_L were 0.435, 0.180, and 0.132 mg, respectively (Figure 4D).

Dose–response analysis

The Hill-based model provided an effective tool to convert data on AgNP-induced lung burden in humans from published data on rats (as a model organism), based on weight ratio and the effects of inflammation due to an increase in neutrophil expression under exposure to AgNPs of two sizes: 34 nm ($r^2=0.79$, $P<0.001$) and 60 nm ($r^2=0.92$, $P<0.001$)

(Figure 5). The quantities of 34 nm AgNPs required to induce 1%, 5%, 10%, and 50% of the maximum increase in neutrophil expression were 1.69, 3.05, 3.98, and 8.73 mg, respectively. The quantities of 60 nm AgNPs required to induce 1%, 5%, 10%, and 50% of the maximum increase in neutrophil expression were 5.52, 8.25, 9.89, and 16.88 mg, respectively (Table S3). The fitted Hill coefficients n were as follows: 34 nm NPs (2.80) and 60 nm NPs (4.11) (Figure 5; Table S3).

Threshold estimation

The Weibull threshold model provided the best fit to the CDFs of EC1, EC5, and EC10 ($r^2=0.99$, $P<0.001$) derived from the profiles indicating the dose-dependent relationship between lung burden and neutrophil expression induced by the inhalation of 34 nm or 60 nm AgNPs (Figure S3; Table S4). The fitted threshold estimates (mean \pm SE) were as follows: γ_1 (0.32 \pm 0.22 mg), γ_5 (0.84 \pm 0.30), and γ_{10} (1.26 \pm 0.30 mg) under exposure to 34 nm AgNPs, and γ_1 (1.08 \pm 0.64 mg),

Figure 5 Dose–response describing relationship between lung burdens of (A) 34 nm and (B) 60 nm AgNPs and increase of neutrophils in BALF-based on the Hill model. **Abbreviations:** AgNP, silver nanoparticle; BALF, bronchoalveolar lavage fluid.

γ_5 (1.95 ± 0.98 mg), and γ_{10} (3.23 ± 0.67 mg) under exposure to 60 nm AgNPs (Figure S3; Table S4).

Risk estimates

The long-term risks associated with the inhalation of AgNP-containing spray products were characterized under non-intensive and intensive applications using γ_1 as a conservative threshold criterion (Figure 6A and B). Based on the threshold level of γ_1 (exposure to 34 or 60 nm AgNPs and the HQ equaling 1), the threshold exposure durations of sprays DO_S and DO_L following 2 years of exposure were predicted to be 2.29 hours (95% CI: 0.83–6.36) and 5.91 hours (95% CI: 2.21–15.67) per day (Table S5). Overall, the HQs of DO_S and DO_L were higher under intensive applications than under non-intensive applications (Figure 6A; Table S5). In non-intensive applications, HQ estimates in all percentiles of DO_S and DO_L were <1 . In intensive applications, HQ estimates in all percentiles were >1 , as follows: DO_S (0.29–3.38) (95% CI) and DO_L (0.14–1.12) (Figure 6A; Table S6). There was a probability of 0.495 that HQ estimates of DO_S exceeded 1 (Figure 6B).

We also estimated the ERs corresponding to specific HQ estimates of DO_S and DO_L under non-intensive and intensive applications (Figure 6C–F; Table S7). Overall, the ERs of DO_S and DO_L were higher in intensive applications than in non-intensive applications (Figure 6C–F; Table S7). DO_S presented higher ERs than did DO_L in non-intensive as well as intensive applications (Figure 6C–F; Table S7). Under 50% risk probability (ER = 0.5), the HQ estimates in non-intensive applications were as follows: DO_S (0.024–0.284) (95% CI) and DO_L (0.004–0.032), and the HQ estimates in non-intensive applications were as

follows: DO_S (0.288–3.392) (95% CI) and DO_L (0.136–1.123) (Figure 6C–F; Table S7).

Sensitivity analysis

Sensitivity analysis was performed on total AgNP-induced lung burden following 2-year exposure to DI under intensive application. Our objective was to identify the most influential parameters of the PBAD model (Figure 7). The results revealed that except for the phagocytosis rate of macrophage (k_p), all of the increments in k_p , k_c , k_a , k_i , and k_l led to a decrease in AgNP accumulation in the lungs (Figure 7). Moreover, the rate at which AgNPs were transferred from interstitial to lymph node regions (k_l) was the parameter with the greatest sensitivity to alternations in total AgNP-derived lung burden. This is a clear indication of the high degree to which k_l influences the risks associated with the inhalation of AgN-containing spray products (Figure 7).

Proposed conceptual model

Our results were used as the basis for the construction of a conceptual model describing the toxicity pathway and mechanisms underlying inflammation resulting from exposure to AgNP-containing aerosols in conjunction with the PBAD model (Figure 8). As shown in Figure 8, it is possible that AgNPs interact with alveolar epithelial cells through diffusion or endocytosis pathways. Following uptake, AgNPs could translocate to the macrophage region via phagocytosis, followed by the recruitment of neutrophils. Macrophage cells either leave the alveolar-macrophage region in so doing clean out the AgNPs, or undergo apoptosis and in so doing release AgNPs in alveolar regions.

We predict that most of the AgNPs are transferred from alveolar cells into interstitial regions and lymph nodes. When the quantity of accumulated AgNPs exceeds the estimated

threshold level, this can cause mitochondrial dysfunction and ROS generation associated with oxidative stress, followed by the recruitment of inflammation-related cytokines and chemokines leading to macrophage activation. Furthermore,

chronic inflammation of the lungs due to the inhalation of AgNPs for prolonged periods could plausibly lead to genotoxicity, the formation of tumor cells, and/or damage to nucleic acids (Figure 8).

Discussion

AgNP spray products: exposure scenarios

It is crucial that experiments be conducted in scenarios that replicate (as closely as possible) those encountered in the real world. Nonetheless, formulating realistic exposure scenarios involving antibacterial sprays can be hindered by variations in duration, intensity, and frequency of application.²⁵

The mass concentrations of the three spray products were measured over a period of 40 minutes,¹⁵ which is close to the values obtained in previous surveys (44.8–143.8 minutes).^{20,21} The air flow rate in our experiments was $0.0067 \text{ m}^3 \text{ s}^{-1}$, which is close to the air flow adjacent to desks in an air-conditioned office (0.01 – $0.047 \text{ m}^3 \text{ s}^{-1}$).²⁶ This is a clear indication that the duration and flow rate measured in this experiment were representative of real-world scenarios.¹⁵ Non-intensive applications were simulated by pressing the nozzles of the sprays multiple times, as follows: DI (30 times), DO_s (10 times), and DO_L (10 times).¹⁵ We sought to match the daily spray usage behaviors described in previous studies on a household device cleaner, air conditioner deodorizer, and air freshener (5.55 g day^{-1}),^{20,21} by spraying the samples a set number of times: DI (40), DO_s (4), and DO_L (4). These spray frequencies are close to the experimental settings adopted in a previous study (10–30 times).¹⁵

The airflow adopted in the experiment was 100 L min^{-1} ($24 \text{ m}^3 \text{ h}^{-1}$),¹⁵ Sundell et al²⁷ claimed that the air exchange rate should exceed 0.5 h^{-1} to reduce the risk of allergic manifestations among children in a Nordic climate. This translates into air flow of $24 \text{ m}^3 \text{ h}^{-1}$ for a 48 m^3 room to meet

the recommended standards.^{15,28} It has been estimated that the average short-term air exchange rate in the US is 0.65 h^{-1} , reaching 2–3 h^{-1} in rooms with open windows. This means that in several realistic scenarios, the AgNP concentrations from AgNP-containing sprays could be below the measurements reported by Hsu,¹⁵ particularly in cases of higher air exchange rates ($>0.5 \text{ h}^{-1}$).²⁸

Modeling of aerosol deposition in alveolar region

The alveolar deposition (PBAD) model when implemented within a risk assessment framework proved highly effective in predicting the total and regional lung burden of AgNPs from aerosol emissions. For decades, researchers have been developing models to describe the deposition of airborne toxicants in the respiratory system. Mathematical modeling can be used to overcome the limitations of in vitro and in vivo models in assessing dynamic and long-term aerosol deposition. This approach examines particle deposition and clearance from a mechanistic viewpoint. In the biomathematical model developed by Kuempel et al,^{16,17} the kinetic processes of airborne particles are first formulated within the context of compartments (alveolar, interstitial, and hilar lymph nodes). That three-compartment model proved highly effective in predicting the long-term dust-derived lung burden among coal miners as well as the distribution of inhaled silica in specific lung regions.^{16–19}

Computational fluid dynamics and multiple path particle deposition models have also been used to estimate the deposition of diesel exhaust particles, hygroscopic particulate matters, and other ultrafine aerosols in human lungs.^{29–31} Lung models with various compartments have also been constructed to obtain estimates of NP burdens in the human respiratory tract.^{32–34} The International Commission on Radiological Protection revised the respiratory tract dosimetry model as a five-compartment model by including the alveolar–interstitial region.^{35,36}

In another study, a physiological lung model was used to predict the burden associated with titanium dioxide NPs in alveolar surface areas among workers in the manufacturing industry.³⁷ Liao et al³⁸ used the PBAD model to assess the silica threshold levels among workers facing long-term exposures in ceramic manufacturing facilities.

Toxicity of inhaled AgNP-containing aerosols

It has been widely reported that inhalable NPs penetrate the lung alveoli more deeply than larger particles. The alveoli

Figure 8 A A conceptual model showing mechanisms of inflammation response exposed to aerosolized AgNPs via inhalation.

Abbreviations: AgNP, silver nanoparticle; PBAD, physiologically based alveolar deposition.

consists only of surfactant with a small number of cells separating the gaseous phase from the blood. In this environment, it is very easy for inhaled NPs to be transported into the bloodstream.^{39–41} Takenaka et al⁴² reported on the translocation of AgNPs (14.6±1.0 nm) from the lungs into the heart, liver, kidney, and brain in rats following exposure via inhalation and instillation. Kwon et al⁴³ measured Ag distributions in various organs in mice. They also observed mild pulmonary toxicity associated with the activation of mitogen-activated protein kinase signaling.

Numerous researchers have investigated the biological effects of inhaled AgNP-containing aerosols in murine systems. Under acute exposure scenarios, Sung et al⁴⁴ observed no significant difference in terms of body weight or lung function in Sprague Dawley rats exposed to aerosolized AgNPs (average diameter of 18–20 nm at concentration reaching 750 mg m⁻³) over an observation period of 2 weeks. Roberts et al⁴⁵ also reported that the short-term inhalation of 100 µg m⁻³ AgNPs in commercial antimicrobial products had no acute toxic effects in Sprague Dawley rats.

However, other studies on acute exposure reported several biological responses at specific endpoints or at the molecular level. Hyun et al⁵ reported increases in the size and number of goblet cells containing neutral mucins in Sprague Dawley rat lungs exposed to aerosolized AgNPs for a period of 28 days. Campagnolo et al⁴⁶ detected AgNPs in maternal tissues, placentas, and fetuses of pregnant mice after exposure to 640 $\mu\text{g m}^{-3}$ aerosolized AgNPs for 15 days. They also reported an increase in cytokine-related inflammation. Lee et al⁴⁷ observed gene expression in brains associated with neurodegenerative diseases, motor neuron disorders, and immune cell functions following sub-chronic exposure to 22 nm AgNPs via inhalation over a period of 14 days.

Under subchronic exposure scenarios, researchers have reported a decrease in lung tidal volume as well as inflammation of the alveolar and liver and abnormal bile duct hyperplasia in Sprague Dawley rats exposed to airborne AgNPs for 90 days.^{5,6,48} Clearly, the effects of long-term exposure to airborne AgNPs cannot be disregarded. Further research on the risks of inhalation using long-term experimental data is required.

The physiochemical properties of NPs, such as particle size and surface characteristics, also play a vital role on respiratory toxicity. Braakhuis et al⁴⁹ investigated the size-dependent effects of AgNPs of different sizes but similar mass concentrations in a short-term inhalation experiment. They found that 15 nm AgNPs had moderate pulmonary effects on Fischer rats, whereas the 410 nm particles had no observable effects at all. In another study, it was shown that 20 nm AgNPs had a more pronounced effect on inflammation via intratracheal installation compared to 110 nm AgNPs, as evidenced by neutrophil influx.⁷

Mechanisms underlying AgNP-induced inflammation in human lungs

Previous *in vivo* and *in vitro* studies have also noted the importance of ROS in dictating toxic responses to AgNPs. McShan et al⁵⁰ and Cheng et al⁵¹ suggested that in mammalian cells, AgNPs disrupt fibroblast membranes, thereby allowing the influx of calcium, which leads to intracellular calcium overload and the subsequent overproduction of ROS. Kruszewski et al⁵² observed the production of ROS in human lung carcinoma (A549) exposed to AgNPs (20 or 200 nm) at concentrations of 10, 50, or 100 mg mL^{-1} over periods of 2–24 hours.

In concert with the proposed inflammation pathway, Braakhuis et al²⁴ reported an increase in pro-inflammatory cytokines, interleukin-1 β (IL-1 β), tumor necrosis factor- α , monocyte chemoattractant protein (MCP-1), and regulated on

activation, normal T cell expressed and secreted (RANTES) in the bronchoalveolar lavage fluid (BALF) of Fischer rats exposed to 40–1,100 $\mu\text{g m}^{-3}$ AgNPs via inhalation over a period of 4 days. Several studies also demonstrated that ROS production exceeding the neutralizing capacity of antioxidants leads to the activation of inflammatory responses, such as IKK/NF- κB pathways and the release of chemokines or cytokines (eg, IL-1 β) aimed at recruiting inflammatory cells (eg, neutrophils and macrophages) to remove invasive NPs.^{53–55}

Numerous studies have investigated genotoxicity or DNA damage associated with oxidative stress following exposure to AgNPs. AshaRani et al⁵⁶ suggested that a disruption of the mitochondrial respiratory chain by AgNPs could increase ROS production, interrupt ATP synthesis, and cause DNA damage. Hackenberg et al⁵⁷ reported that AgNPs induce genotoxic effects in human mesenchymal stem cells. Strong pro-inflammatory responses and DNA damage have also been observed in transformed human alveolar epithelial type-1-like cells.⁵⁸ Several studies have linked comet tail length and apoptosis in cell cultures to DNA damage.^{59,60} Nallanthighal et al⁶¹ reported that humans with genetic polymorphisms are more susceptible to AgNP-mediated DNA damage.

There is a growing body of evidence suggesting that NPs-exposed inflammatory cells (eg, neutrophils and macrophages) induce inflammation through ROS production and generated oxidative DNA damage.^{50,51,62–64} Rahban et al⁶⁵ reported that AgNPs affect calf thymus, resulting in DNA that is tightly bound with altered conformation. AshaRani et al⁶⁶ reported corona induction and DNA damage-related gene expressions in cytosolic proteins. They also found evidence of DNA double-strand breakage manifesting as an increase in ataxia telangiectasia mutated (ATM) and ATM-related levels in normal lung fibroblast cells (U251).⁶⁶

Administrative strategies to reduce the risk of long-term inhalation

There are at present no regulations pertaining to airborne/aerosolized AgNPs in commercial spray products. The permissible exposure limit established by the OSHA for airborne Ag particles (metallic or soluble forms) is 0.01 mg m^{-3} .⁶⁷ The American Conference of Governmental Industrial Hygienists (ACGIH) also established the threshold limit of 0.1 mg m^{-3} for metallic Ag dust.⁶⁸ However, it should be noted that the toxic effects of airborne AgNPs differ fundamentally from that of other Ag compounds due to differences in particle size and chemical forms makeup. It is very likely that standards will have to be established specifically for AgNP-containing spray products.

Sung et al⁴⁸ reported that the threshold level of no observable chronic alveolar inflammation was 0.1 mg m^{-3}

in Sprague Dawley rats following the inhalation of AgNPs of ~20 nm. This is consistent with the threshold limit established by the ACGIH.⁶⁸ However, it should be noted that the threshold level is based on a no-observed-adverse-effect-level in a murine system that underwent sub-chronic exposure for a period of 13 weeks. In this study, we sought to establish a representative threshold value for human lungs exposed to AgNPs under long-term exposure scenarios by formulating a risk assessment scheme that incorporates tools for extrapolation (from rats to human) with mathematical modeling.

Protective measures have been established for workers in several fields; however, the development of strategies for the prevention of AgNP exposure is lagging. The International Organization for Standardization (ISO) has introduced the control banding approach to limit exposure to NPs, such as Ag oxides from fume hoods and local exhaust ventilation for engineered nanomaterials.^{69,70} Respiratory protection devices, such as respirators, have also been certified by the NIOSH for various occupations in the US.⁷¹ However, none of these measures address the issue of exposures to NPs by consumers. Further regulations pertaining to the management of AgNP aerosols released from commercial spray products should be strengthened for the protection of consumers.

The European Commission and ISO are currently regulating the labeling of nano-objects in cosmetics and other consumer products.⁷²⁻⁷⁴ However, the standards used in the labeling of NPs in spray products remains unclear. Regulations pertaining to AgNP content in commercial spray products are of paramount concern, due to the direct exposure to pulmonary regions and potential risks associated with human inhalation over extended periods.

Adopting the threshold exposure durations of each product would be a more practical approach to reducing the risks of inhalation. Park et al²⁰ reported that using sprays in well-ventilated areas and remaining at a distance from the spray source after spraying could reduce the amount of particles that are inhaled. Thus, the predicted threshold exposure durations were 2.29 hours per day for DO_s and 5.91 hours per day for DO_L , in accordance with the requirement the usage of these sprays does not result in a HQ exceeding 1 within a period of 2 years.

The risks associated with inhaling the two spray products in this study could be mediated by labeling the spray products with a recommended threshold exposure duration. Workers, such as cleaners, should definitely wear respirators or use ventilation systems when using these or similar products.⁷⁵

The type of nozzle also plays an important role in persistence and the dispersion distance of aerosols. We found

that the long-term use of propellant-type bottles leads to a higher mass concentrations of AgNPs in the lungs, compared to the use of pump-type spray bottles. Pump sprays generate larger droplets, which settle more rapidly. It is reasonable therefore to surmise that the application of pump nozzles in spray products could reduce the resulting lung burden of toxicants in the human body.²⁰

Control equipment with high NP-collection efficiency could also be used to reduce the volume of aerosolized AgNPs in the ambient environment during the production of AgNPs.¹ It is also necessary to enforce risk assessments when dealing with other manufactured NPs that are frequently added to commercial spray products (eg, titanium dioxide, copper oxide, and siloxane-modified alumina).⁷⁶ Our proposed risk assessment framework in conjunction with the PBAD model could be applied to assess the hazards imposed by any NPs on the human respiratory system.

Limitations and implications

In this study, we assessed the risks posed by exposure to AgNP-containing spray products using a well-established risk assessment scheme in conjunction with mathematical modeling and experimental data. However, it should be noted that the exposure scenarios in laboratory experiments (ie, NPs of homogeneous purity and purified air streams) do not necessarily reflect the conditions encountered in the real-world.⁷⁷ Even minor factors such as spatial-temporal dispersion (applied distance, frequency of use), nozzle and solvent types, indoor ventilation, and air flow rate could lead to considerable variation in the concentrations of AgNPs inhaled from aerosols.^{20,78}

The agglomeration and aggregation of NPs in the presence of water and organic solvents in consumer spray products could affect the morphology, size distribution, and surface area of NPs.¹⁸ EDX technology can be incorporated with TEM analysis to identify the elements in NPs in aerosols from spray products. EDX could be also used to explore bioaccumulations and distributions of AgNPs in human lungs. Finally, EDX could be implemented in conjunction with a mechanistic in cases where specimens of BALF are available.^{79,80}

Most of the NP-containing aerosol particles enter the human respiratory tract; however, Bressan et al⁶² reported the accumulation of AgNPs outside mitochondria in human dermal fibroblasts, suggesting the potential toxicity of AgNPs via the dermal route.⁸¹ Further research will be required to verify those findings and explore the implications for human health.

Conclusion

This paper presents a novel approach to risk assessment based on mechanistic modeling (using empirical nanotoxicity data obtained in a rat model) to estimate the risks associated with the chronic inhalation of AgNPs from spray products. The PBAD model-based risk assessment framework is meant to overcome the limitations of assessing risks of spray products over extended time scales in an experimental setting. This powerful tool can be used to derive the long-term AgNP-derived lung burden and obtain risk estimates of NP-containing aerosols. The proposed risk assessment scheme provides considerable insight into the relationship between the characteristics of metallic NP-containing spray products and the corresponding toxicities over various time scales.

International Journal of Nanomedicine

Dovepress

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <http://www.dovepress.com/international-journal-of-nanomedicine-journal>
