Abstract

Introduction Increased visceral adipose tissue (VAT) has been shown to be associated with the development of insulin resistance, type 2 diabetes, stroke, and ischemic heart disease. It remains unknown whether fat distribution impacts on coagulation markers and/or the risk of venous thrombosis. This study evaluates markers of hypercoagulability in class III obesity (body mass index [BMI] >40 kg/m²) compared with nonobese controls. We further investigated whether hypercoagulability was influenced by VAT, metabolic syndrome, and metabolic markers, including adiponectin.

Patients and Methods Ninety patients were recruited from the obesity clinic at King's College Hospital from November 2009 to December 2011. The inclusion criteria were class III obesity (BMI ≥40 kg/m²) and age 18 to 65 years. A control group (healthy ambulatory participants, with a BMI < 30 kg/m²) was recruited from volunteers responding to advertisement. Abdominal VAT and subcutaneous adipose tissue surface areas were determined by evaluation of a single-slice CT at spinal vertebra L4.

Results Thrombin generation revealed a significantly increased peak and endogenous thrombin potential in patients compared with controls. Lag time and time to peak (ttP) were also significantly prolonged in patients. VAT was found to have the strongest association with thrombin generation parameters: lag time ($\beta = 0.378$; $p < 0.001$), peak thrombin (0.378 ; $p = 0.04$), and ttP ($\beta = 0.373$; $p = 0.001$). BMI was found to be a predictor for lag time only ($\beta = 0.313$; $p = 0.003$). SAT was not associated with any of the thrombin generation parameters (data not shown). VAT was found to be an independent determinant of peak thrombin, lag time, and ttP. The study suggests not only fat mass but also fat distribution, particularly visceral adiposity, mediates hypercoagulability in obesity.

Introduction and Background

Obesity is recognized as a growing global concern with a worldwide prevalence for overweight and obesity approach-

ing 40% in adults.¹ Morbid obesity (body mass index [BMI] >40 kg/m²) has been described in 3.9% of women and 1.6% of men in the United Kingdom.² There is a significantly increased risk of cardiovascular disease, type 2 diabetes,

hypertension, and venous thromboembolism in obesity, particularly when severe.³

Several mechanisms have been proposed to explain the increased risk of venous and arterial thromboembolism, including increased procoagulant activity (factor [F] VII, FVIII, von Willebrand factor, and fibrinogen), impaired fibrinolysis (increased plasminogen activator inhibitor [PAI]), increased inflammation, endothelial dysfunction, and altered lipid and glucose metabolism in metabolic syndrome.⁴ Inflammation and insulin resistance are at least in part mediated by adipocytokines,^{4,5} with those released by visceral rather than subcutaneous tissue directly associated with metabolic abnormalities.⁶

Increased visceral adipose tissue (VAT) has been shown to be associated with the development of insulin resistance, type 2 diabetes, stroke, and ischemic heart disease.⁷⁻⁹ BMI and other conventional anthropometric measures, such as waist circumference, are insensitive to fat distribution pattern^{10,11} and do not reflect recognized age, gender, and ethnic-specific differences in fat distribution.¹²⁻¹⁴ It remains unknown whether fat distribution impacts on coagulation markers and/or the risk of venous thrombosis.

Adipose tissue is known to produce several cytokines including leptin and adiponectin, tumor necrosis factor- α , and PAI-1.¹⁵ Leptin is predominantly but not specifically produced and secreted by adipose tissue.⁴ Adiponectin, in contrast, is exclusively produced by adipose tissue. Adiponectin levels correlate negatively with obesity and recent work has shown adiponectin release to be reduced from the VAT of obese subjects (with no change in release from subcutaneous fat).^{6,16} There are no studies examining the relationship of these adipocytokines and risk of VTE in morbidly obese patients.

Global coagulation assays, such as thrombin generation, can provide an indirect measure of overall "coagulability" and have been demonstrated to be sensitive to the prothrombotic state associated with increased age, hormone use, and pregnancy. Recent studies have reported increased thrombin generation in morbid obesity with a reduction following weight loss, suggesting adiposity mediates the hypercoagulable state.^{17,18} This study aims to evaluate markers of hypercoagulability in grade III obesity (BMI >40 kg/m²) compared with nonobese controls. We further sought to determine whether hypercoagulability was influenced by VAT, metabolic syndrome, and metabolic markers, including adiponectin.

Patients and Methods

Study Participants

Ninety patients were recruited from the obesity clinic at King's College Hospital NHS Foundation Trust from November 2009 to December 2011. The inclusion criteria were class III obesity (BMI \geq 40 kg/m²) and age 18 to 65 years. A control group (healthy ambulatory participants, with a BMI < 30 kg/m²) was recruited from volunteers responding to advertisement. The control participants were matched to cases for age and sex. Exclusion criteria for all participants were personal history of VTE, known active cancer, previous history of myocardial infarction, cerebrovascular accident or peripheral vascular disease, current use of hormone replacement therapy (HRT),

oral contraceptives or anticoagulants, previous bariatric surgery, and current pregnancy.

Body weight and height were measured to enable calculation of BMI. Blood pressure (BP) was recorded using the OxiMax Nellcor spot signs device (Nellcor OxiMax, New York, United States); this was measured in the right arm with the subject in a sitting position. Participants had their BP measured after a 15-minute rest period. Data regarding participant's self-reported ethnicity, medical history, and smoking status were also collected. Fasting blood samples were collected from all participants at their convenience following a \geq 10-hour fasting period. Visceral adiposity was evaluated by computed tomography scan as detailed below.

The study was approved by King's College Research Ethics Committee (REC: 09/H0808/64) and the Research and Development Committee. All participants gave written informed consent prior to participation.

Blood Collection

Venous blood was drawn from an antecubital vein using a plastic syringe connected to a 21 g butterfly system (Hospira Venisystems, Illinois, United States). Blood was immediately dispensed into 0.109 mol/L sodium citrate tubes (Vacutainer BD, Plymouth, UK) following an initial 10 mL blood drawn, which was subsequently dispensed into 0.369 EDTA (Vacutainer BD, Plymouth), SST II (Vacutainer BD, Plymouth), and sodium fluoride tube (Vacutainer BD, Plymouth).

Sample Preparation

Platelet poor plasma (PPP) for standard coagulation assays was prepared within an hour of sample collection by double centrifugation (7 minutes) at 1,700 g (Hettich 38R Rotina centrifuge; Hettich-Zentrifugen, Tuttlingen, Germany). Prothrombin time (PT), activated partial thromboplastin time (APTT), Clauss fibrinogen (CFIB), and D-dimer (DD) were measured in fresh unfrozen plasma within 4 hours of sample collection. Aliquots (2 mL) were immediately frozen at -40° C and only thawed by incubating in a water bath at 37° C immediately before testing. Metabolic markers were measured using serum separated by centrifugation of fresh blood collected in SST II tubes for 7 minutes at 1,700 g (38R Rotina centrifuge [Hettich-Zentrifugen]). All patient and control samples were assayed by the same experienced biomedical scientists.

PPP for thrombin generation was prepared by double centrifugation at 4,754 g for 10 minutes (420R Rotina centrifuge [Hettich-Zentrifugen]). After the first spin, the top three-quarter volume of supernatant was transferred into a polypropylene tube before second spin. PPP was then frozen at -40° C within 45 minutes of sample collection. Samples were thawed at 37° C immediately before analysis. All samples were analyzed within 2 months of collection.

Laboratory Measurements

Metabolic Analysis

Total cholesterol, triglycerides, and high-density lipoprotein (HDL) were determined using Siemens kits (Chol-c, Trig and

D-HDL kits [Siemens Diagnostics, Illinois, United States]), respectively, on the ADVIA2400 (Siemens Diagnostics). Manufacturer protocols were employed in all testing.

Fasting insulin was measured using a solid phase chemiluminescent assay on the Siemens Immulite 2000 analyzer (Siemens Healthcare Diagnostics). The original homeostasis model assessment index (HOMA-IR: $\text{HOMA-IR} = [\text{fasting glucose (mmol/L)} \times \text{fasting insulin (mIU/L)}] / 22.5$) was used to estimate insulin resistance among the patients. Patients with $\text{HOMA-IR} > 2.4$ were classified as having insulin resistance.¹⁹

Metabolic syndrome was defined using the International Diabetes Federation (IDF) guidelines:²⁰ presence of central obesity (assumed for patients with $\text{BMI} \geq 30 \text{ kg/m}^2$) plus any two of the following four conditions—hypertriglyceridemia, $\geq 1.7 \text{ mmol/L}$; low HDL cholesterol, $< 1.03 \text{ mmol/L}$ (men) and < 1.29 (women); high BP, $\geq 130 \text{ mm Hg}$ systolic pressure or $\geq 85 \text{ mm Hg}$ diastolic pressure; or fasting glucose, $> 5.6 \text{ mmol/L}$. Previously diagnosed or patients on treatment for hypertension, diabetes, or hyperlipidemia were considered to satisfy the criterion.

Serum levels of adiponectin were measured using an ELISA kit (total human Adiponectin/Acrp 30 Quantikine ELISA; R&D Systems, Minneapolis, Minnesota, United States).

Coagulation Tests

PT, APTT, and CFIB were measured using STA Neoplastine C1 plus, STA Cephascreen, and STA fibrinogen in clot-based assays, respectively. Antithrombin (AT), protein C (PC), free protein S (FPS), and DD were assayed using STA-Stachrom ATIII, STA-Stachrom protein C, Liatest Free Protein S, and STA Liatest D-Di. Colorimetric technique was employed for AT and PC, while latex immunoassay technology was employed for DD and FPS. FVII and FVIII were assayed using STA deficient VII/VIII immunodepleted plasma in coagulation-based assays. All reagents were purchased from Diagnostica Stago (Asniers, France) with assays performed on STA-R Evolution analyzer (Diagnostica Stago) according to manufacturer protocols and as previously described.²¹

Free tissue factor pathway inhibitor (TFPI) was measured using an ELISA (Asserachrom Free TFPI, Diagnostica Stago). PAI was also measured with ELISA (Human Serpin E1/PAI-1 Quantikine ELISA kit (DSE100), R&D Systems).

Thrombin Generation Assay

Thrombin generation was measured using the calibrated automated thrombography method as described in detail by Hemker et al.^{21,22} PPP reagent (5 pM; Thromboscope BV, Maastricht, the Netherlands) and the thrombin calibrator were reconstituted in 1 mL of distilled water. The calibrator is made of a thrombin-like substance that is able to cleave the fluorescent substrate (Z-Gly-Gly-Arg-AMC; Bachem, Bubendorf, Switzerland). Eighty microliters of PPP, prewarmed to 37°C, was added to 20 μL of either PPP reagent (5pM; Thromboscope BV) or calibrator (Thrombin Calibrator, Thromboscope BV) at room temperature in a 96-well microtiter plate (Immulon 2HB; Thermo Electron Corporation, Vantaa, Finland) to give a final concentration of 5 pM tissue factor and 4 μM phospholipids. Both calibrator and test wells were processed

in triplicate. Thrombin generation was then initiated by adding 20 μL of the fluorogenic substrate (FluCa, Thromboscope BV) containing 100 mM calcium chloride. A Fluoroskan Ascent plate reader (Thermo Labsystems, Helsinki, Finland); excitation filter of 390 nm and emission filter of 460 nm, and Thromboscope software (Thromboscope BV) were used for the assay following manufacturer's instructions. The continuous production of thrombin was determined by measuring fluorescence every 20 seconds for a period of 1 hour. The assay yields four thrombin generation parameters: lag time, ttP, peak thrombin, and endogenous thrombin potential (ETP; area under the curve, nM/min) (Thromboscope software version 3.1.0.55; Synapse BV, Maastricht, the Netherlands). Furthermore, Velocity Index = $\text{Peak} / (\text{ttP} - \text{Lag Time})$, indicating the average net rate of prothrombin activation during the propagation phase, was calculated. Control plasma (Normal Human Control Plasma, Technoclone, Vienna, Austria) was utilized in each thrombin generation assay and this was utilized to evaluate interassay variability across all tests. Intra-assay variability was $< 5\%$ and interassay variability was $< 10\%$ for all parameters.

Fat Distribution Analysis

Computed Tomographic Scans

A Somatom Sensation 16 CT scanner (Siemens, Forchheim, Germany) was used to take a noncontrast single-slice CT scan at the midpoint of the L4 vertebral body. The patients were examined in supine position with their arms extended above their heads. The CT protocol used was as follows: slice thickness, 10 mm; scan parameters, 120 kv, 120 mA; field of view, 499 mm with a 512×512 matrix; window level, 300; center, 40. The images were transferred onto CDs in DICOM (Digital Imaging and Communications in Medicine) format to allow for analysis.

Image Analysis

Semiautomated assessment of VAT and SAT compartments was performed using a dedicated software package, Analyze direct 10 (AnalyzeDirect, Kansas, United States). The measurement of adipose tissue area was determined by setting a Hounsfield unit (HU) range between -190 and -30 .²³ SAT was defined as fat that is superficial to abdominal wall musculature, whereas VAT was defined as adipose tissue inside the muscular wall and included the mesenteric, subperitoneal, and intraperitoneal components. All the images were analyzed by only one observer and the intraobserver variability for one image examined 10 times on the same day was $< 5\%$ for VAT areas (**► Fig. 1**).

Statistical Analysis

Normality on continuous variables was evaluated with the Shapiro–Wilk test and normality Q-Q plots. Continuous variables are given as mean and standard deviation or median and interquartile ranges for normal and nonnormal variables, respectively. Nonnormal variables were logarithmically transformed to normalize where possible. The means of continuous variables were compared using the independent Student's *t*-test. Fisher's exact test was used to assess the differences between nominal variables for potential

Fig. 1 Measurement of visceral and subcutaneous adipose tissue. (A) Screen capture from the region of interest module before segmenting. (B) Screen capture after segmenting VAT (green area) and SAT (yellow area).

confounders on thrombin generation. Correlations between continuous variables were evaluated with Pearson's correlation for normal data and Spearman's correlation for non-normal data. Simple and multiple linear regression analyses were performed to assess the association of obesity markers, metabolic markers, and thrombin generation parameters within the morbidly obese group. The dependent variable was always the thrombin generation parameter. Statistical significance was given a p -value of < 0.05 . All statistical analyses were performed using SPSS version 19 software (IBM SPSS, Chicago, Illinois, United States).

Results

Study Population

Ninety subjects were recruited, of which one did not attend for blood tests and was thus excluded, along with 77 age- and sex-matched controls. Baseline anthropometric parameters of morbidly obese cases and controls are shown in **Table 1**. There was no significant difference in age, gender, and smoking status between the two groups. Subjects had higher mean systolic and diastolic blood pressure as shown in **Table 1**. The mean fasting insulin, mean glucose, median triglycerides, and median HOMA-IR were significantly increased in subjects with significantly depressed mean levels of HDL and adiponectin. Twenty-one (24%) subjects were taking antihypertensive medication 16 (18%) hypoglycemic agents, and 6 (7%) statin therapy. Fifty-three (60%) subjects met the criteria for metabolic syndrome.

Hemostatic Markers

There were significant differences in the activity of coagulation factors and natural anticoagulant as shown in **Table 2**, with FVII, FVIII, PC, FPS, and TFPI significantly increased in morbid obesity and AT significantly reduced. Markers of fibrinolysis, PAI, and DD were found to be significantly enhanced in morbid obesity as shown in **Table 2**.

Thrombin generation revealed a significantly increased peak and ETP in subjects compared with controls as shown in **Fig. 2**. Lag time was significantly prolonged in subjects (**Fig. 2**).

Fat Distribution Markers as Determinants of Hypercoagulability Markers in Morbid Obesity

VAT was significantly increased in the morbidly obese (**Table 1**). Within the obese cohort, there were positive correlations between VAT, FVIII, fibrinogen, free protein S, and TFPI and a negative correlation with AT (**Table 3**). VAT also positively correlated with thrombin generation, lag time, and peak thrombin as shown in **Table 4**. BMI was significantly correlated with FVIII, fibrinogen, TFPI, DD, and lag time. There were no correlations between SAT and any of the hemostatic markers (data not shown). There was no significant difference in the velocity index between the patient group and control group (data not shown). Within the patient group, velocity index was positively correlated with FVIII (0.219, $p = 0.04$) and negatively with FVII (-0.213 , $p = 0.04$).

Multiple stepwise regression analysis (adjusted for age, smoking status, gender, and ethnicity) was used to assess the strength of the relationships between the fat distribution markers and thrombin generation parameters. VAT was found to have the strongest association with thrombin generation parameters: lag time ($\beta = 0.378$; $p < 0.001$), peak thrombin (0.378; $p = 0.04$), and ($\beta = 0.373$; $p = 0.001$). BMI was found to be a predictor for lag time only ($\beta = 0.313$; $p = 0.003$). SAT was not associated with any of the thrombin generation parameters (data not shown).

Metabolic Syndrome, Its Components, and Hypercoagulability Markers

Of the 89 participants, 50 (56%) had metabolic syndrome. There were no significant differences in gender, ethnicity, BMI, or smoking status between those with and without metabolic syndrome (data not shown). Individuals with the metabolic syndrome were older (47 ± 11 vs. 42 ± 11 years, $p = 0.038$) and had higher VAT (265 ± 95 cm² vs. 215 ± 75 cm², $p = 0.01$) compared with those without metabolic syndrome. On comparing hemostatic markers, TFPI and PC were the only hemostatic markers that were significantly raised in those with metabolic syndrome compared to those without (12.7 ± 4.1 vs. 15.2 ± 5.3 , $p = 0.012$ and 111 ± 18 vs. 119 ± 20 , $p = 0.05$, respectively). There were no differences in thrombin generation parameters seen (data not shown). There was a positive correlation

Table 1 Anthropometric and metabolic parameters for the study population

| Parameter | Cases (N = 89) | Controls (N = 77) |
|--|---------------------|------------------------|

Abbreviations: AT, antithrombin activity; DD, D-dimer; Fib, Clauss fibrinogen; FPS, free protein S; N, number; PAI-1, plasminogen activator inhibitor 1; PC, protein C activity; PLT, platelet count; TFPI, tissue factor pathway inhibitor.

Notes: Normally distributed data are presented as mean ± SD (standard deviation) and the *p*-values are based on independent Student's *t*-test. Nonnormally distributed data are presented as median (interquartile range) and *p*-values are based on test. Significant differences are indicated as follows: ***p* < 0.001; *0.05 < *p* ≤ 0.001.

between glucose and ETP ($r = 0.259$, $p = 0.003$), and between triglycerides and ttP ($r = 0.230$, $p = 0.031$). There were no correlations seen between thrombin generation parameters and other metabolic markers (insulin, HOMA-IR, HDL) or adiponectin (data not shown). There was no significant difference in adiponectin between those with and without metabolic syndrome and no correlation with VAT (data not shown). VAT remained a significant independent determinant of peak thrombin, lag time, and after adjusting for metabolic markers as shown in ►Table 5.

Discussion

We have demonstrated an altered thrombin generation profile in morbid obesity, with prolonged lag time, time to peak, and increased peak thrombin and ETP. Additionally, FVII, FVIII, fibrinogen, DD, PC, FPS, PAI, and TFPI were increased in the morbidly obese with reduced AT compared with nonobese individuals in keeping with previous reports.^{24,25} Our findings confirm those reported by two other groups during the course of our study, which demonstrated increased thrombin generation in the morbidly obese.^{17,18} Weight loss following bariatric surgery was additionally associated with a significant reduction in the hypercoagulable markers of thrombin generation.¹⁷

We observed an unexpected prolongation of thrombin generation, lag time, and time to peak in the morbidly obese, in contrast to the findings of Campello and colleagues,¹⁷ who reported a shortened lag time. Of note, Ay et al¹⁶ did not compare with a control group and lag times reported in the

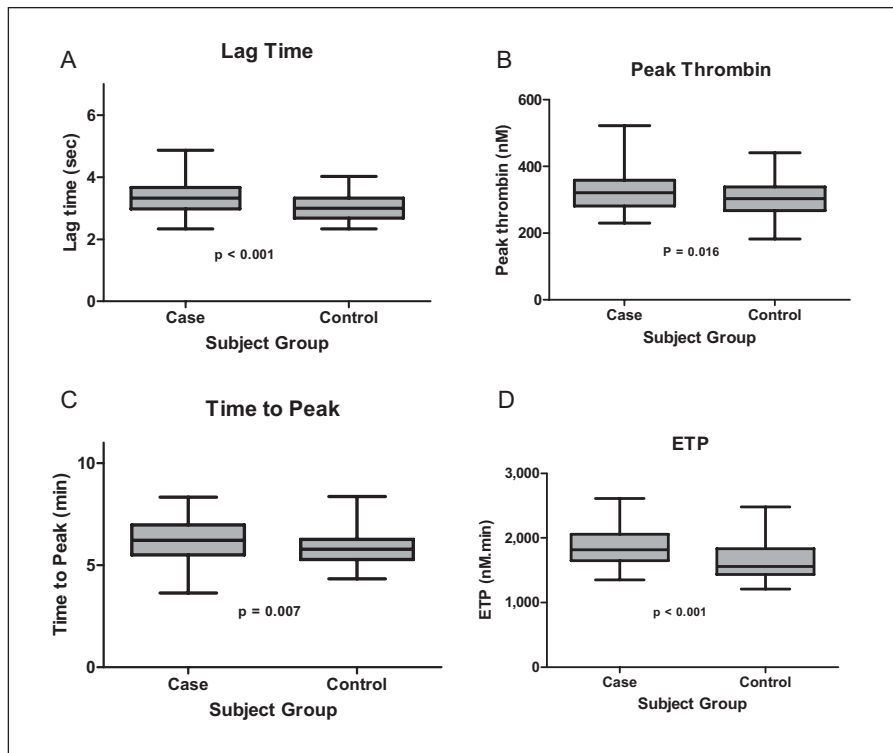

Fig. 2 Comparison of thrombin generation parameters in cases and controls. (A) Mean lag time in cases was significantly higher than in the control group: 3.33 ± 0.56 versus 3.0 ± 0.41 , $p < 0.001$. (B) Mean peak thrombin was higher in the cases compared with the control group: 322 ± 54 versus 304 ± 55 , $p = 0.016$. (C) Mean time to peak was higher in cases than in the control group: 6.20 ± 0.99 versus 5.77 ± 0.81 , $p = 0.007$. (D) Cases had a significantly higher mean ETP compared with the control group: $1,854 \pm 287$ versus 1660 ± 282 , $p < 0.001$.

subject group prior to bariatric surgery were increased compared with those seen in our study (this may be, in part, due to different thrombin generation methodology). This group reported a reduction in lag time following weight loss.¹⁷ Fibrinogen, FVII, FPS, and free TFPI have previously been reported as independent determinants of lag time in healthy subjects measured at high tissue factor concentrations.²⁶ We observed significantly increased levels of these parameters in the morbidly obese group compared with controls, with positive correlations between these parameters and VAT. We propose that the increase in these parameters is responsible for an in vitro effect of prolonged lag time. This is supported by the findings of Brodin and colleagues²⁶ that increasing concentrations of TFPI increase lag time with no effect on ETP or peak thrombin. The same group reported that removal of native TFPI shortens the lag time with no change on ETP and peak thrombin. TFPI acts on

activated FX (a) and VIIa-TF-Xa to regulate the initiation phase of thrombin generation. FPS inhibits thrombin generation independent of activated protein C by potentiating TFPI's activity.²⁸ Increased DDs have also been reported to have an in vitro effect of prolonging lag time in patients with acute myocardial infarction.²⁹ DDs were higher in our morbidly obese group and this may be additional contributor to the prolonged lag time observed. Of note, this is an in vitro effect; increased DD, FPS, and TFPI are not associated with bleeding in healthy individuals. Ttp is determined by initiation of coagulation (lag time) and rate of thrombin generation (velocity index); as there was no difference in velocity index between morbidly obese and controls, the prolonged ttp is a consequence of the initial prolongation in lag time.

Our study additionally investigated how morbid obesity and fat distribution patterns influence known markers of hypercoagulability. We observed positive correlations between FVII,

Table 3 Correlation between fat distribution markers and general hemostatic markers in the morbidly obese

| Variables | F VII | F VIII _{log} | FIB | AT | PC | PAI _{log} | TFPI | FPS | D-dimer _{log} |
|-----------|-------|-----------------------|--------|---------|--------|--------------------|---------|--------|------------------------|
| BMI | 0.017 | 0.281* | 0.323* | -0.131 | -0.047 | -0.071 | 0.246* | 0.096 | 0.202* |
| VAT | 0.111 | 0.253* | 0.263* | -0.275* | -0.009 | 0.043 | 0.341** | 0.337* | -0.003 |

Abbreviations: AT, antithrombin; BMI, body mass index; FIB, fibrinogen; FPS, free protein S; FVII, factor VII; FVIII, factor VIII; PAI, plasminogen activator inhibitor; PC, protein C activity; TFPI, tissue factor pathway inhibitor; VAT, visceral adipose tissue area.

Notes: Data are Pearson's correlation coefficients (R). Variables (FVIII, D-dimer, and PAI) were not normally distributed and logarithmic transformation (log) was performed. Significant coefficients are indicated as follows: ** $p < 0.001$; * $0.05 < p \leq 0.001$.

Table 4 Correlation between fat distribution markers and thrombin generation parameters in morbid obesity

| Variable | Lag time | ETP | Peak | ttP |
|----------|----------|--------|--------|--------|
| BMI | 0.313* | 0.097 | -0.058 | 0.127 |
| VAT | 0.411** | -0.039 | 0.257* | 0.360* |

Abbreviations: BMI, body mass index; ETP, endogenous thrombin potential; ttP, time to peak; VAT, visceral adipose tissue area. Notes: Data are Pearson's correlations (R). Significant correlation coefficients are indicated as follows: ** $p < 0.001$; * $0.05 < p \leq 0.001$.

FVIII, fibrinogen, and FPS; both BMI and VAT; and a negative correlation with antithrombin, in keeping with previous reports.²⁶ Correlations were slightly stronger with BMI compared with VAT. Given both procoagulant factors and natural anticoagulants were increased in the morbidly obese cohort, it is difficult to evaluate how each of these individual factors influence overall thrombotic risk. This is overcome by measuring thrombin generation which provides an overall view of "coagulability" as described earlier.³⁰ VAT was found to be an independent determinant of peak thrombin, lag time, and ttP. Although prolongation of the lag time might suggest hypocoagulability, previous studies evaluating thrombotic risk suggest ETP and peak thrombin provide the most consistent results and are associated with both first and recurrent VTE.^{22,31-35} This suggests that fat distribution and, specifically, VAT may therefore modulate the risk of venous thrombosis, similar to previous reports of increased cardiovascular morbidity and mortality associated with increased VAT.⁷⁻⁹

VAT is known to have endocrine function and to mediate adipocytokine expression associated with metabolic abnormalities in obesity.³⁶ We measured adiponectin, which is inversely related to body fat mass and insulin resistance. Low circulating levels are strongly associated with metabolic syndrome.⁵ Adiponectin has been shown to directly modulate endothelial function by reducing the inflammatory response to vascular injury with low levels reported as

Table 5 Multiple regression models of anthropometric, biochemical markers as determinants of thrombin generation

| | ETP | Lag time | ttP | Peak |
|---------------|--------|----------|--------|--------|
| VAT | ns | 0.341* | 0.212* | 0.204* |
| Systolic BP | 0.266* | ns | ns | 0.247* |
| Diastolic BP | ns | ns | ns | 0.236* |
| Glucose | 0.259* | ns | ns | ns |
| Triglycerides | ns | ns | 0.244* | ns |
| HDL | ns | ns | ns | ns |
| Cholesterol | 0.264* | 0.234* | 0.275* | ns |

Abbreviations: BP, blood pressure; ETP, endogenous thrombin potential; HDL, high-density lipoprotein; ns, nonsignificant; ttP, time to peak; VAT, visceral adipose tissue area.

Notes: For regression multivariate model, age, gender, ethnicity, and smoking status were included as independent variables. Significant results are indicated as follows: ** $p < 0.001$; * $0.05 < p \leq 0.001$.

associated with increased risk of coronary artery disease.³⁷ Adiponectin was significantly lower in the morbidly obese patients compared with controls. However, there was no significant difference between those with or without metabolic syndrome and adiponectin levels did not correlate with VAT in our study. It is perhaps unsurprising that we did not therefore observe any correlation between adiponectin and thrombin generation parameters.

We did not identify any direct association between the presence of metabolic syndrome and thrombin generation parameters. This supports findings of Campello et al,¹⁷ who found no association between metabolic syndrome and thrombin generation but a close relationship with BMI and waist circumference (but not other components of the metabolic syndrome) leading them to conclude that hypercoagulability is closely related to fat mass.¹⁸ In contrast, we found no relationship between BMI and metabolic syndrome, but identified significantly increased VAT in those with metabolic syndrome. Our study suggests not only fat mass but also fat distribution mediates hypercoagulability in obesity. Of note, this finding may have been influenced by the unselected inclusion of participants with morbid obesity; while none had undergone bariatric surgery, many were already on treatment for comorbidities associated with obesity such as hypertension, diabetes, or hyperlipidemia. However, upon examining individual components of the metabolic syndrome, we observed the hypertension criterion as an independent determinant of both peak thrombin and ETP, with fasting glucose also significantly contributing to ETP, and triglycerides to ttP. There is increasing evidence to suggest hyperglycemia constitutes a prothrombotic state.³⁷ To our knowledge, thrombin generation has not been specifically studied in hypertension, hypertriglyceridemia, or hyperglycemia.

Limitations

Due to the cohort size, and as we did not measure all coagulation factors, we were unable to evaluate independent determinants of thrombin generation parameters in the morbidly obese. However, our aim was to establish whether morbid obesity is associated with hypercoagulability and the role of individual coagulation markers in evaluating this is dubious. While there was no significant difference in age or sex between groups, there was a greater proportion of males in the control group. Healthy females have lower FPS concentrations compared with men.²⁶ However, as FPS was lower in the control group, which had the smaller proportion of females, this does not explain the difference detected between groups.

We used a high concentration, 5 pM of tissue factor for thrombin generation and did not use thrombomodulin/Protac to evaluate the protein C pathway. At the time of study, lower concentrations of tissue factor (≤ 1 pM) were thought to be associated with contact activation and collection of samples with corn trypsin inhibitor (CTI) was considered necessary. We selected a higher concentration of tissue factor to avoid the need for CTI and potentially improve the reproducibility of the study. Similarly, the use of Protac/thrombomodulin was not standardized and we did not evaluate TG in its presence, we are therefore not able to comment on the significance of the

protein C pathway. The additional use of these thrombin generation assays may have enabled further elucidation of the effects of increased FPS and TFPI observed in the morbidly obese. We did not measure other adipocytokines or inflammatory markers and are therefore unable to comment further on the mechanism by which VAT mediates hypercoagulability. Adiponectin, the cytokine produced most specifically by VAT, was not associated with thrombin generation parameters. Other studies have reported positive correlations between tumor necrosis factor- α , leptin, CRP and ETP.¹⁸

Conclusion

Morbid obesity is associated with an altered thrombin generation profile suggestive of hypercoagulability with increased peak thrombin. Hypercoagulability appears to be mediated by visceral adiposity, with VAT being a strong determinant for peak thrombin. We suggest this relates to endocrine function of VAT; further research is required to establish the underlying mechanism.
