**Acetylation, a prevalent modification of cell-wall polymers, is a tightly controlled regulatory process that orchestrates plant growth and environmental adaptation. However, due to limited characterization of the enzymes involved, it is unclear how plants establish and dynamically regulate the acetylation pattern in response to growth requirements. In this study, we identified a rice (*Oryza sativa*) GDSL esterase that deacetylates the side chain of the major rice hemicellulose, arabinoxylan. Acetyl esterases involved in arabinoxylan modification were screened using enzymatic assays combined with mass spectrometry analysis. One candidate, DEACETYLASE ON ARABINOSYL SIDECHAIN OF XYLAN1 (DARX1), is specific for arabinosyl residues. Disruption of DARX1 via *Tos17* insertion and CRISPR/Cas9 approaches resulted in the accumulation of acetates on the xylan arabinosyl side chains. Recombinant DARX1 abolished the excess acetyl groups on arabinoxylan-derived oligosaccharides of the *darx1* mutants in vitro. Moreover, DARX1 is localized to the Golgi apparatus. Two-dimensional <sup>13</sup>C-<sup>13</sup>C correlation spectroscopy and atomic force microscopy further revealed that the abnormal acetylation pattern observed in *darx1* interrupts arabinoxylan conformation and cellulose microfibril orientation, resulting in compromised secondary wall patterning and reduced mechanical strength. This study provides insight into the mechanism controlling the acetylation pattern on arabinoxylan side chains and suggests a strategy to breed robust elite crops.**

## INTRODUCTION

Plant cells are encased in structurally diverse polymers, which are assembled into a dynamic network, forming the plant cell walls. The cell wall represents a complex structure that plays many fundamental roles in plants, including determining plant growth and development and providing structural integrity and mechanical support for the plant body (Bacic et al., 1988; Carpita and Gibeau, 1993; Somerville et al., 2004). Land plants harbor more than 40 types of cells with varied morphologies and functions (Farrokhi et al., 2006). The cell-wall compositions and organizations in these cell types are different and can change dynamically (Burton et al., 2010; Loqué et al., 2015), posing challenges to understanding the functions of cell-wall constituents. Heterogeneity in cell-wall chemistry and structure also suggests that plants have evolved regulatory mechanisms to control cell-wall composition and organization in response to internal and environmental stimuli.

Cell-wall polysaccharides are composed of at least 14 sugars that are organized into linear polymers with or without substituents through more than four linkages. Three kinds of modifications are incorporated in some of these sugars and substantially modify the physicochemical properties. Pectin esterification affects cell-wall plasticity and mechanical strength (Bosch and Hepler, 2005), while feruloylation on arabinoxylan side chains offers a way of bridging xylan and lignin (de O Buanafina, 2009). Compared with the level and position of these two modifications, which are constrained to a few epitopes, *O*-acetyl groups are widespread in most cell-wall polymers (Kiefer et al., 1989; Ishii, 1991). At least eight of 14 cell-wall-composing monosaccharides have acetylated forms; some monosaccharides can be substituted with two *O*-acetyl groups, such as the galactosyl residue on xyloglucan branches, the xylosyl residue on xylan backbone, and the galacturonosyl residue on pectic polymers (Gille and Pauly, 2012). In plants and bacteria, the acetylation pattern, which comprises acetate quantity and distribution along the cell-wall polymers, varies across developmental stages and species (Janbon et al., 2001; Teleman et al., 2002; Gille et al., 2011; Yuan et al., 2016). Compromised acetylation patterns often result in abnormalities in either plant growth or stress resistance (Xin and Browse, 1998; Vogel et al., 2004; Zhu et al., 2014; Gao et al., 2017; Zhang et al., 2017). Disrupting the characteristic acetylation profile on the *Arabidopsis* (*Arabidopsis thaliana*) xylan backbone causes xylan misfolding and interferes with the interactions with cellulose

## IN A NUTSHELL

**Background:** Plant cells are encased in structurally diverse polymers, which are assembled into a fibrous network, forming the plant cell walls. Acetylation, a common modification on cell-wall polymers, affects polymer properties and determines how these polymers interact. Increasing evidence revealed that acetylation profile on cell-wall polymers is tightly controlled, indicating a regulatory machinery to orchestrate cell-wall architecture and plant growth. Arabinoxylan is an important hemicellulosic polysaccharide modified with majority of acetyl esters. Furthermore, xylan interacts with cellulose and lignin, the other two cell-wall major polymers, via the two- and three-fold conformation that is modulated by the balance of acetylation and deacetylation according to plant-growth demands. Hence, comprehensive understanding of the mechanisms underpinning the control of xylan acetylation is crucial for elucidating cell-wall architecture and functions.

**Question:** We wanted to know how plants regulate and establish the cell-wall acetylation profile in response to growth requirements. We aimed at identifying a new xylan deacetylase that can control acetylation pattern and xylan conformation from our previously discovered new family of deacetylases.

**Findings:** We screened acetyl esterases likely involved in arabinoxylan modification by purification of the total membrane proteins extracted from rice internodes combined with enzymatic assays. Protein mass spectrometry analysis identified several GDSL esterases; DARX1 is one of them. Mutations in *DARX1* resulted in accumulation of acetates on arabinosyl side chains of xylan, which could be abolished by recombinant DARX1 in vitro. Moreover, solid-state NMR spectroscopy and atomic force microscopy revealed that the abnormal acetylation pattern in *darx1* interrupts arabinoxylan conformation and cellulose microfibril orientation, resulting in compromised secondary wall structure and reduced mechanical strength. Our finding in identifying an arabinosyl deacetylase, a new enzyme, provides insight into how the arabinoxylan acetylation pattern, as well as its conformations, are established, which suggests a strategy to breed robust elite crops.

**Next steps:** How do minor changes in xylan side chain give rise to dramatic effects on cell-wall architecture? Characterization of acetyl esterases, such as DARX1, open the door for understanding of the complicated relationship between polysaccharide acetylation profile and cell-wall structure, which is important for uncovering how functional cell walls are built.

(Busse-Wicher et al., 2014; Grantham et al., 2017). Excess acetylation of the rice (*Oryza sativa*) xylan backbone alters secondary wall patterning and plant development (Zhang et al., 2017). These data suggest that control of the cell-wall acetylation pattern offers a precise mechanism to manipulate cell-wall properties and organization, thereby modulating cell-wall biological functions.

Despite the prevalence of acetyl modifications on cell-wall polymers, the underlying mechanism for cell-wall acetylation control has remained mysterious until recent years. Mutant screens and biochemical studies have revealed that three groups of proteins, including TRICHROME BIREFRINGENCE-LIKE proteins, REDUCED WALL ACETYLATION proteins, and ALTERED XYLOGLUCAN9 are involved in acetylation of cell-wall polymers (Gille et al., 2011; Lee et al., 2011; Manabe et al., 2011; Xiong et al., 2013; Schultink et al., 2015). Furthermore, plant deacetylases, such as a CARBOHYDRATE ESTERASE13 member and a GDSL esterase/lipase protein (GELP) family member, have been demonstrated to trim acetyl groups from polysaccharides (Gou et al., 2012; Zhang et al., 2017). These findings open a door to unravel the mechanism for precise regulation of cell-wall acetylation.

After nonacetylated cellulose, arabinoxylan is the second most abundant polysaccharide in the plant cell wall and is a central polymer that is substituted with the majority of acetyl esters (Wende and Fry, 1997; Chiniquy et al., 2012; Rennie and Scheller, 2014; Smith et al., 2017). The acetate patterns on the xylan backbone and arabinosyl substituents affect the physicochemical properties of arabinoxylan and determine how xylan interacts with other cell-wall polymers (Grantham et al., 2017). However, in contrast with the heavily acetylated backbone, arabinosyl side

chains have been rarely reported to bear acetyl groups, and enzymes that catalyze acetylation and deacetylation of arabinosyl side chains have not been identified (Grantham et al., 2017).

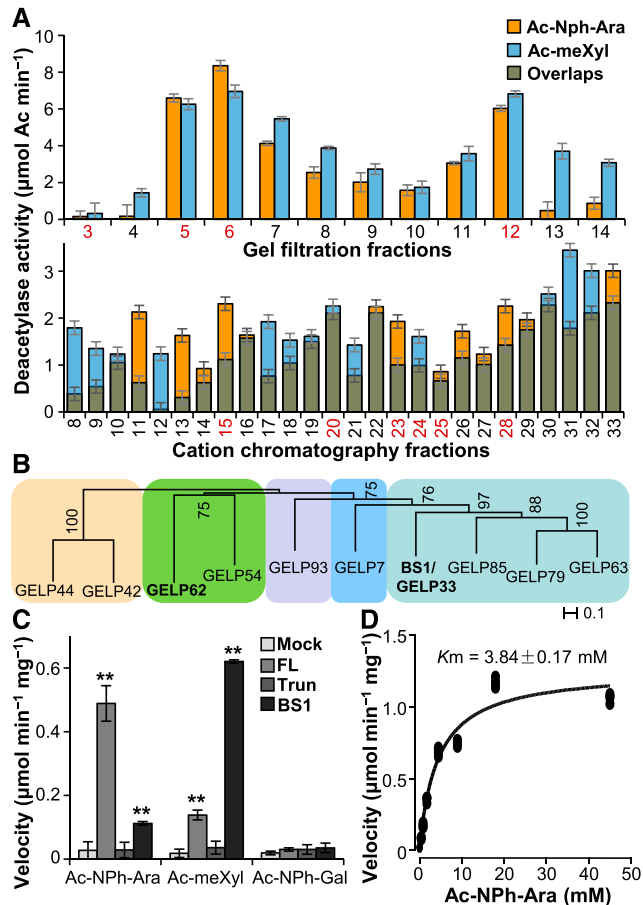

Here, we report a previously uncharacterized GELP member in rice that functions as an arabinosyl deacetylase and catalyzes the removal of acetyl residues from xylan arabinosyl side chains. Mutations in this gene alter the acetylation pattern on xylan side chains and affect arabinoxylan conformation and cellulose microfibril organization. Our study reveals a mechanism that regulates the acetylation pattern on arabinoxylan side chains. Manipulating this mechanism may improve the mechanical strength of plants and thus have applications in crop breeding.

## RESULTS

### Identification of Deacetylases Governing the Acetylation Pattern on Rice Arabinoxylan

To determine how the acetylation pattern of arabinoxylan is modulated in rice, we enzymatically screened for glycosyl acetyl esterases that remove acetyl groups from xylosyl and arabinosyl residues, which are the two major sugars in arabinoxylan, using microsomes extracted from the internodes of rice plants. Two fully acetylated glycosides, namely 2,3,4-*O*-acetyl methyl xyloside (Ac-meXyl) and 2,3,5-*O*-acetyl *p*-nitrophenyl  $\alpha$ -L-arabinofuranoside (Ac-NPh-Ara), were used as the substrates. After examining the acetyl esterase activities in the microsomes (Supplemental Figure 1A), we fractionated the solubilized microsomes using

a Superdex 200 size-exclusion column or cation and anion exchange columns. By subjecting the collected fractions to enzymatic assays, we detected deacetylase activities on either xyloside or arabinoside substrates in some fractions (Figure 1A; Supplemental Figure 1B), suggesting that these fractions may

**Figure 1.** Identification of Arabinoxylan Deacetylases.

(A) Deacetylase activity analysis of the protein fractions separated on a gel filtration Superdex 200 column (upper) and a cation-exchange chromatography HiTrap SP column (lower). The proteins present in the fractions numbered in red were separated by SDS-PAGE and digested with trypsin. The tryptic fragments were subjected to LC-MS analysis. Error bars = mean  $\pm$  SD of three replicates of assays with independent proteins. \*\* $P < 0.01$  by Welch's unpaired  $t$ -test.

(B) Phylogenetic analysis of the GELPs identified by LC-MS. Bootstrap percentages are shown at the nodes. Color blocks sequentially label the Ivd, Ix, Id, Ia, and Ib clades of the GELP family from left to right (Volokita et al., 2011; Chepyshko et al., 2012). "Ix" indicates the unclustered members of subfamily I.

(C) Quantification of deacetylase activities on acetylated sugars. One microgram of purified recombinant FL- and Trun-GELP62 (FL and Trun) and BS1 was incubated with 5 mM of Ac-meXyl, Ac-NPh-Ara, or Ac-NPh-Gal substrate. "Mock" represents the negative controls in the absence of recombinant proteins. Error bars = mean  $\pm$  SD of three replicates of assays with independent proteins. \*\* $P < 0.01$  by Welch's unpaired  $t$ -test.

(D) Determination of the  $K_m$  value of FL-GELP62 for the Ac-NPh-Ara substrate using a Michaelis-Menten plot. The  $K_m$  value represents the mean of three replicates of assays with independent proteins.

harbor deacetylases. Fractions containing BRITTLE LEAF SHEATH1 (BS1), a previously reported xylan deacetylase (Zhang et al., 2017), exhibited xylosyl deacetylase activity (Figure 1A; Supplemental Figure 1C), confirming the veracity of this experimental approach.

To identify candidate deacetylases, we subjected the fractions that exhibited relatively high activities on Ac-NPh-Ara and Ac-meXyl substrates to liquid chromatography-coupled mass spectrometry (LC-MS) analysis. The fractions from gel filtration and cation-exchange analyses (numbered in red in Figure 1A) were separated by SDS-PAGE. Proteins ranging from 15 to 130 kD were collected and digested with trypsin for LC-MS analysis. We identified 10 GELP proteins as possible candidates that may catalyze arabinoxylan deacetylation (Supplemental Table 1).

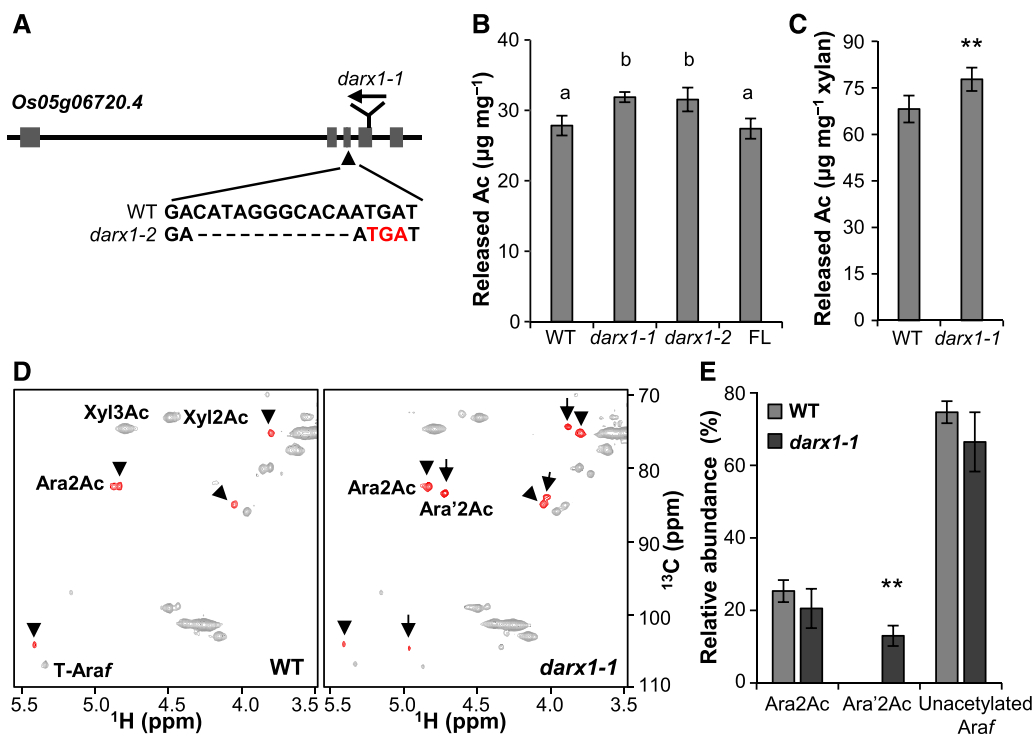

Phylogenetic analysis clustered these 10 GELP proteins into five clades. Among these candidates, *GELP62* is highly and ubiquitously expressed in rice (Supplemental Figures 1D and 1E) and belongs to a different clade than BS1 (Figure 1B; Supplemental Data Set), suggesting that *GELP62* may have distinct enzymatic specificity from BS1.

To test this hypothesis, we subjected *GELP62* to an in vitro verification of deacetylase activity. According to the annotations in the Michigan State University Rice Genome Annotation Release 7 (LOC\_Os05g06720.1) and the Rice Annotation Project Database (Os05g0159300), the hypothetical nucleotide sequence encoding *GELP62* is 636 bp. As *GELP62* is predicted to lack the conserved GDS motif (Supplemental Figure 2A), it is classified as the truncated (Trun) version. To determine the full coding sequence, we performed an RNA sequencing analysis and mapped the reads obtained from the wild-type plants onto the *GELP62* genomic region. The transcripts included an exon upstream of a 9-kb intron (Supplemental Figures 2B and 2C). Hence, the full-length (FL) version of *GELP62* is likely 1,371 bp in length (LOC\_Os05g06720.4) and encodes a 456-amino acid protein containing all four conserved domains of GELP proteins (Supplemental Figure 2A).

We then heterologously expressed FL- and Trun-GELP62 in *Pichia pastoris* and incubated the purified recombinant proteins (Supplemental Figure 1F) with Ac-meXyl, Ac-NPh-Ara, and a negative control, fully acetylated *p*-nitrophenyl galactoside (Ac-NPh-Gal). In contrast with BS1, which was most active on Ac-meXyl, FL-GELP62 exhibited major activity on Ac-NPh-Ara, whereas the Trun version was not active (Figure 1C). Taken together with the observation that the predicted FL-GELP62 three-dimensional structure contains a classic SGNH catalytic triad (Supplemental Figure 2D), the FL-GELP62 is functional. Furthermore, the esterase activity of FL-GELP62 displayed saturable kinetics with a  $K_m$  value of 3.84 mM (Figure 1D), which is comparable to that of BS1 (Zhang et al., 2017). Hence, we designated *GELP62* as a putative DEACETYLASE ON THE ARABINOSYL SIDECHAIN OF XLAN1 (*DARX1*).

### Lesions in *DARX1* Cause Excess Acetyl Modification on the Arabinosyl Side chain of Xylan

To obtain genetic evidence for *DARX1* function, a *Tos17* insertional mutant (*darx1-1*) was isolated (Figure 2A; Supplemental Figures 3A and 3B). The insertion causes undetectable levels of

**Figure 2.** Isolation and Characterization of the *darx1/gelp62* Mutants.

**(A)** Schematic of *DAX1* gene structure and the mutation sites of the indicated mutants. The boxes and lines in the diagram indicate exons and introns, respectively. The arrow indicates the insertion of the *Tos17* transposon. The arrowhead indicates a deletion mutation in *darx1-2* that results in a premature translational stop codon (red letters).

**(B)** The acetyl ester content in the cell-wall residues of mature internodes. Error bars = mean  $\pm$  SD (for three biological replicates of pooled internodes). The letters “a” and “b” indicate statistically significant differences according to the variance analysis and Tukey’s test ( $P < 0.05$ ). WT, wild type; FL, full-length *DAX1*.

**(C)** Measurement of the acetyl ester level in the acetyl-xylan extracted from the wild-type and *darx1-1* mature internodes. Error bar = mean  $\pm$  SD (for three biological replicates of pooled internodes). \*\* $P < 0.01$  by Welch’s unpaired *t* test. WT, wild type.

**(D)** Representative HSQC spectra of acetyl-xylan of wild-type and *darx1-1* plants. Signals of acetylated arabinosyl residues are in red. Arrowheads and arrows indicate Ara2Ac and Ara’2Ac, respectively. The chemical shifts of Ara2Ac, O-2 acetylated arabinosyl residues and Ara’2Ac, O-2 acetylated arabinosyl residues on the O-2 acetylated xylosyl backbone, are described in Supplemental Table 2. WT, wild type.

**(E)** Quantification of arabinosyl residues in the wild-type and mutant acetyl-xylan based on examinations of HSQC spectra. The data are expressed as the abundance relative to the total Ara signals. Error bars = mean  $\pm$  SD (for three biological replicates of pooled internodes). \*\* $P < 0.01$  by Welch’s unpaired *t* test. WT, wild type.

*DAX1* transcript as revealed by RNA gel blotting analysis (Supplemental Figure 3D). Additionally, immunoblotting analysis of total membrane proteins extracted from plants with a *DAX1* polyclonal antibody revealed a single band in the wild-type plants and no bands in the mutant plants (Supplemental Figure 3E). This result demonstrated the specificity of the *DAX1* antibody and indicated that *darx1-1* is a null mutant. Next, we generated another allele by CRISPR/Cas9 gene editing. *darx1-2*, which harbors an 11-bp deletion that introduces a premature translational stop codon, is expected to produce a truncated *DAX1* protein (Figure 2A; Supplemental Figures 3A and 3B). Total acetate content analysis revealed that both mutants have increased amounts of wall-bound acetyl esters (Figure 2B); amounts were restored to wild-type levels by expressing FL*DAX1* in the *darx1-1* mutant (Figure 2B; Supplemental Figures 3A and 3C).

To determine which polymer is the source of excessive acetate esters, we separated the wall residues of mature internodes into

pectin-containing and pectin-free fractions. The acetate content analysis revealed that excess acetates were derived from the pectin-free fraction, which contains a large amount of arabinoxylan (Supplemental Figure 4A). Examination of acetate content in the dimethyl sulfoxide (DMSO)-extracted acetyl-xylan confirmed that the excess acetates were derived from arabinoxylan (Figure 2C; Supplemental Figure 4B).

To identify which arabinoxylan sites bound to the additional acetyl groups in the *darx1* mutants, we subjected intact acetyl-xylans to nuclear magnetic resonance (NMR) analyses. Heteronuclear single quantum coherence (HSQC) analysis revealed that the xylan backbone was decorated with monoacetyl groups and that the relative abundance of acetyl groups attached to the xylan backbone at the O-2 (Xyl2Ac) or O-3 (Xyl3Ac) sites was not significantly altered in *darx1* (Figure 2D; Supplemental Figures 4C and 4D). Interestingly, although the O-2 acetylated arabinosyl residues (Ara2Ac) with the characteristic signal of the acetyl

modified carbon (4.83 ppm for  $^1\text{H}$  and 82.41 ppm for  $^{13}\text{C}$ ) were comparable in the wild type and mutants, an additional acetylated arabinosyl residue with the characteristic signal (4.71 ppm for  $^1\text{H}$  and 83.36 ppm for  $^{13}\text{C}$ ) was present in the mutants but not in the wild type (Figures 2D and 2E). We then implemented several approaches to characterize this extra residue.

Total correlation spectroscopy (TOCSY) analysis indicated that the hydrogen signals (H1 4.96 ppm, H3 3.88 ppm, H4 4.03 ppm, and H5 3.45 ppm) were associated with the characteristic hydrogen signals in this extra residue (Supplemental Table 2; Supplemental Figure 5A). Similarly, the associated carbons were assigned using two-dimensional (2D) heteronuclear multiple bond correlation (HMBC) and HSQC analysis (Figure 2D; Supplemental Figure 5C; Supplemental Table 2). Although this extra residue had adjacent chemical shifts similar to Ara2Ac on the carbon–hydrogens, it exhibited an  $\sim 0.5$ -ppm downfield shift on H1 (on Carbon 1) compared with Ara2Ac (Figure 2D). This finding suggests that its attachment position on the xylosyl backbone is different from Ara2Ac and we thus designated it as Ara'2Ac.

Moreover, based on a nuclear Overhauser effect spectroscopy (NOESY) analysis, the interglycosidic NOE connection between H1 (4.96 ppm) of Ara'2Ac and H2 (4.61 ppm) of the O-2 acetylated xylosyl backbone indicated that an Ara'2Ac substitution was present on the O-2 acetylated xylosyl backbone. The connection between methyl hydrogen on acetyl groups and H2 (on Carbon 2) of Ara'2Ac suggested that the acetyl group of Ara'2Ac resided on the hydroxyl at Carbon 2 (Supplemental Figures 5B to 5D). These correlation spectroscopy analyses support that this extra sugar, Ara'2Ac, is likely to be an O-2 acetylated arabinosyl residue. Additionally, it is likely that Ara'2Ac is substituted on the Carbon 3 of an O-2 acetylated xylosyl residue (Supplemental Figure 5E).

To determine whether mutation of *DARX1* alters the xylan side-chain profile, we analyzed the arabinoxylo-oligosaccharides generated by digesting the wild-type and mutant alkali-extracted arabinoxylan with a xylanase of Glycosyl hydrolase family 11 (GH11) using a DNA sequencer-assisted saccharide analysis in high throughput. The similar oligosaccharide profiles of wild-type and *darx1* extracts suggest that the *DARX1* mutation does not significantly alter the pattern of arabinosyl substitution on xylan (Supplemental Figure 6).

Given that Ara'2Ac is the specific defect arising from *DARX1* mutation, *DARX1* is likely an arabinosyl deacetylase of arabinoxylan with regiospecificity.

### **DARX1 Removes Acetyl Esters from Acetylated Arabinoside and Arabinoxylo-Oligosaccharide**

We next conducted a series of biochemical assays to elucidate the enzymatic activities of *DARX1*. First, we investigated how many acetyl esters can be removed by *DARX1*. Ac-NPh-Ara, which has three acetyl epitopes, was incubated with purified recombinant *DARX1* and then subjected to LC-MS analysis. Diacetylated and monoacetylated NPh-Ara were detected in the reactions (Figures 3A and 3B), indicating that one or two acetyl epitopes could be removed by *DARX1*.

To further determine the regiospecificity of *DARX1*, we shortened the reaction time to achieve partial digestion of Ac-NPh-Ara.

2,5-O-acetyl, 3,5-O-acetyl, 3-O-acetyl, and 5-O-acetyl arabinosides were recognized and quantified by proton NMR and TOCSY assays (Figure 3C; Supplemental Figure 7A). Compared with 25% and 12% of acetyl groups derived from the O-3 and O-5 sites of acetylated arabinosides,  $\sim 60\%$  were released from the O-2 position (Figure 3D). This finding suggests that *DARX1* is an arabinoside deacetylase with a preference for O-2 acetyl groups.

Considering that the native substrate of *DARX1* in plants would be arabinoxylan or oligosaccharides, we incubated recombinant *DARX1* protein with a xylan oligosaccharide mixture produced by cleaving the acetyl-xylan of *darx1* with a GH11 xylanase. The Ara'2Ac signals were completely abolished after incubation with *DARX1*, indicating that *DARX1* can release acetyl groups from Ara'2Ac (Figures 3E and 3F; Supplemental Figure 7B). Such activity corroborates the wall defects observed in the *darx1* mutants (Figure 2E; Supplemental Figure 5). Therefore, *DARX1* is an arabinoxylan deacetylase with regiospecificity.

### **DARX1 Is Localized to the Golgi**

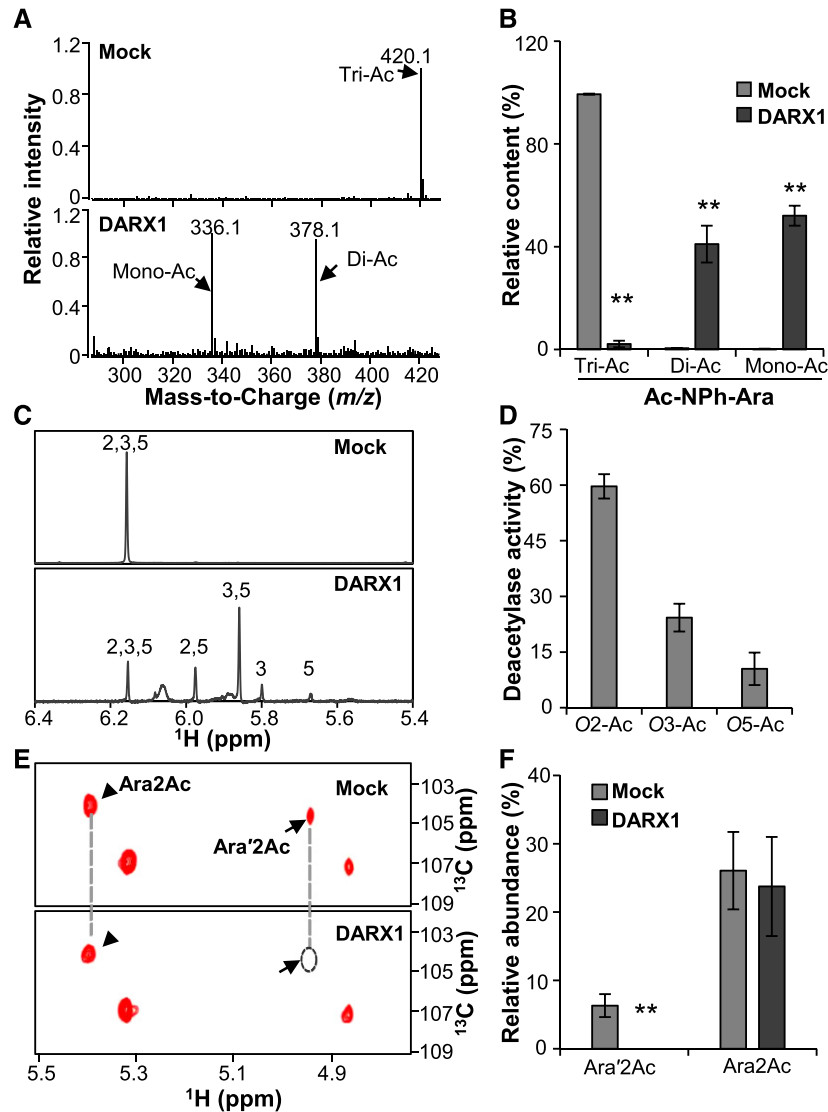

Deacetylation occurs in the Golgi apparatus and apoplast. To determine the subcellular location of *DARX1*, we fused the FL coding sequence of *DARX1* in-frame to the sequence encoding green fluorescent protein (GFP) at the 3' end and then co-transfected tobacco leaves with this construct and one for the mCherry-tagged Man49 Golgi marker. The resulting overlaid signals suggested that *DARX1* is a Golgi-localized protein (Figures 4A and 4B). To confirm this localization in planta, we examined the *DARX1*-resident profile by Suc density centrifugation using the *DARX1*-specific antibody (Supplemental Figure 3E). The distribution pattern of *DARX1* was almost identical to that of BS1, which is a Golgi-localized deacetylase (Zhang et al., 2017). However, *DARX1* distribution was distinct from that of the endoplasmic reticulum marker Binding immunoglobulin protein (BiP) and the plasma membrane-marker Plasma membrane intrinsic protein 1s (PIP1s; Figure 4C). Furthermore, immunogold labeling with *DARX1*-specific antibody verified its localization in Golgi stacks (Figures 4D and 4E). Therefore, *DARX1* is a Golgi-targeted arabinosyl deacetylase.

### ***darx1* Has Compromised Cellulose-Xylan Interactions and Microfibril Orientation**

Next, we investigated the effect of the aberrant acetylation profiles in the *darx1* mutants on arabinoxylan conformation and cell-wall architecture. 2D  $^{13}\text{C}$ – $^{13}\text{C}$  correlation INADEQUATE spectroscopy analysis was applied to probe xylan conformation in the field-harvested mature internodes of wild-type and *darx1* plants. The NMR sensitivity was boosted 20 to 21 times using the cutting-edge dynamic nuclear polarization (DNP) technique (Figure 5A), making it feasible to measure 2D correlation spectra without isotope enrichment. The wild-type sample was dominated by xylan in a flat-ribbon conformation (twofold helical screw) with negligible signals for the threefold conformer (Figure 5B). Based on previous reports, in which xylan that has a flat-ribbon conformation, twofold xylan was annotated as binding to cellulose

microfibrils (Simmons et al., 2016; Grantham et al., 2017) and threefold xylan was interpreted as forming a hydrated matrix and contacting lignin nanodomains (Kang et al., 2019). The dominating twofold xylan signals in the wild-type internodes indicated extensive interactions between xylan and cellulose microfibrils.

However, the two- and threefold signals were nearly equal in the *darx1* internodes (Figure 5C). Considering the substantial upsurge of threefold xylan in the *darx1* plants (Figure 5B), we concluded that mutation of *DARX1* alters the conformation of xylan and thereby perturbs xylan–cellulose interactions.

 (D) Immuno-gold labeling of DARX1, showing DARX1 localized in the Golgi stacks. The red arrows indicate gold particles. Scale bar = 100 nm.  
 (E) Quantification of gold particles per area of the indicated organelles. Error bars = mean  $\pm$  SE.  $n = 50$  images of ultrathin sections from three plants. Mit, mitochondria; Vac, vacuole; Cyt, cytoplasm. The letters “a” and “b” indicate significant differences according to variance analysis and Tukey’s test ( $P < 0.01$ ).

To explore whether the reduced cellulose-xylan interactions affect cellulose microfibril deposition, we used atomic force microscopy (AFM) to examine the cellulose microfibrils in metaxylem cells of the wild-type and mutant mature internodes. In contrast with the wild-type cellulose microfibrils that were oriented in an orderly manner, the mutant plants displayed microfibrils that were randomly oriented (Figures 5D and 5E). Furthermore, fewer macrofibrils were aggregated in the *darx1* mutants than in the wild type (Figure 5D), but the diameter of cellulose macrofibrils was not significantly changed (Supplemental Figure 8). Therefore, DARX1 is indispensable for cellulose microfibril orientation.

#### DARX1 Affects Secondary Wall Properties Resulting in Developmental Phenotypes

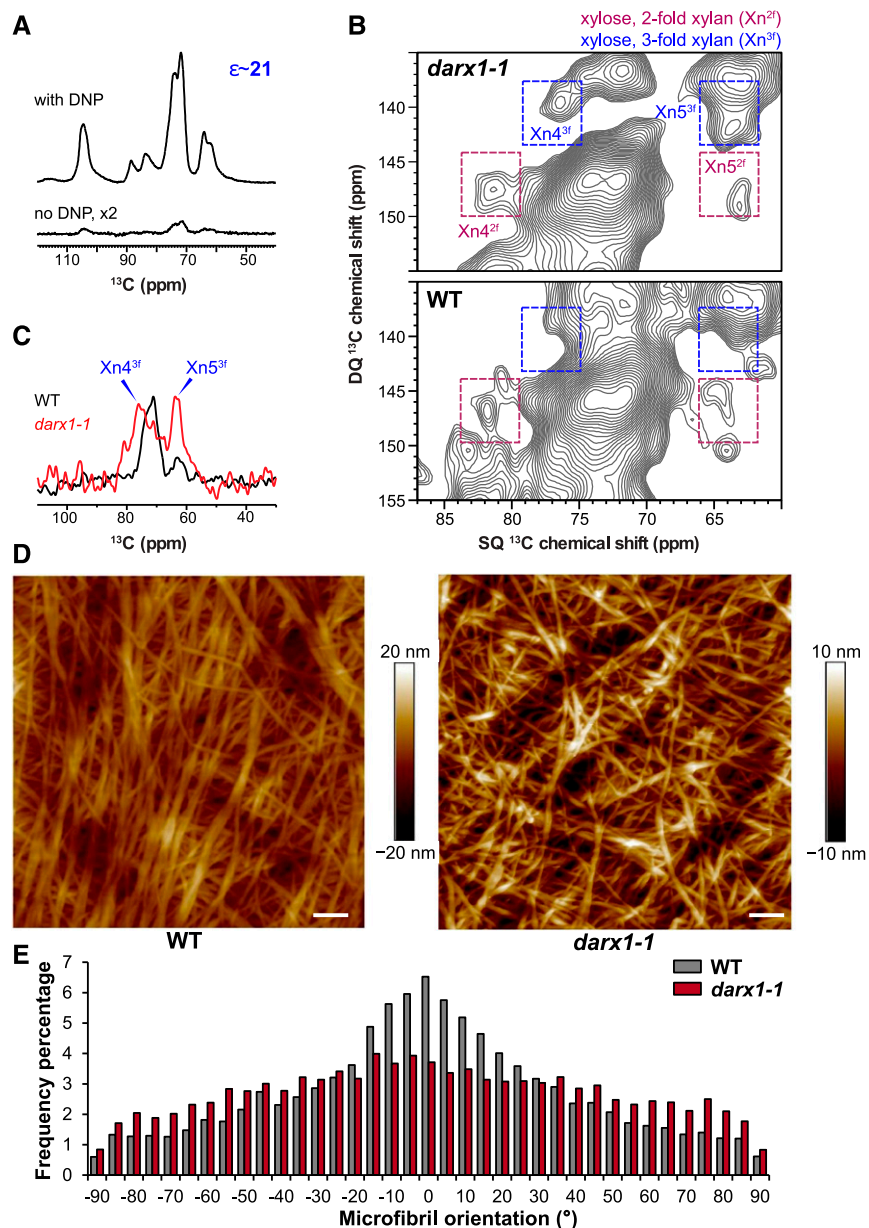

To determine the effect of the excess acetylation in the *darx1* mutants on secondary cell-wall organization, we analyzed the sclerenchyma fiber and metaxylem cells that possess secondary cell walls by scanning electron microscopy (SEM). The wall thickness of sclerenchyma fiber cells in the *darx1* mutant was significantly reduced (Figures 6A and 6B), whereas the pit size in metaxylem was increased (Figures 6C and 6D). Furthermore, the content of cellulose, another major component of secondary cell walls, was decreased in the *darx1* plants (Figure 6E). Hence, the *darx1* mutants have disrupted secondary wall formation and patterning, which results in reduced mechanical strength

manifesting through easily broken internodes (Figure 6F) and drooping leaves (Supplemental Figure 3A), and slightly decreased plant height (Figure 6G) in the *darx1* plants. Moreover, the abnormal cellulose content and morphological phenotypes were fully rescued in plants expressing FL *DARX1* (Figures 6E to 6G). These findings suggest the importance of DARX1 in secondary wall organization and plant growth.

#### DISCUSSION

Acetylation is a prevalent modification on cell-wall polymers. Due to its importance in glycan structure and function, acetylation patterns are tightly controlled by the antagonistic actions of acetyltransferases and deacetylases. Compared with tens of polysaccharide acetyltransferase candidates (Gille et al., 2011; Lee et al., 2011; Manabe et al., 2011; Xiong et al., 2013; Schultink et al., 2015; Pauly and Ramirez, 2018), few deacetylases were identified until the discovery of a xylan backbone deacetylase; this finding indicated the involvement of a large family of esterases in polysaccharide deacetylation (Zhang et al., 2017). Hence, deacetylases that regulate acetylation profiles during polysaccharide biosynthesis or turnover may have comparable substrate specificities and/or regiospecificities (Gou et al., 2012; Scheller, 2017; Zhang et al., 2017).

In this study, we identified 10 GDSE esterase candidates of unknown function using an enzymatic screen. Among these candidates, we showed that DARX1 possesses arabinosyl-

**Figure 5.** *DARX1* Is Crucial for Xylan Binding to Cellulose.

**(E)** Distribution of microfibril/microfibril orientation. The orientation of microfibril/microfibril is represented as percentage frequency of the orientation of microfibril/microfibril segments (snakes) identified using the software SOAX ( $n = 60,000$  snakes from three images of three cells of three individual plants). WT, wild type.

deacetylation activity. We further demonstrated that *DARX1* specifically releases acetyl groups from the acetylated arabinosyl substituents of xylooligosaccharides, in agreement with the altered acetate patterns in *darx1* mutants. Because such enzyme activity has not previously been reported in plants, bacteria or

fungi, *DARX1* is the first known arabinosyl deacetylase that acts on arabinoxylan.

Ara is a central monosaccharide present in arabinoxylan, pectic rhamnogalacturonan I and rhamnogalacturonan II, arabinogalactan proteins, and xyloglucan. Arabinofuranose with  $\alpha$ -(1,2) or  $\alpha$ -(1,3)-

linkage to xylan is a characteristic side chain found on monocot arabinoxylan (Wende and Fry, 1997; Burton et al., 2010; Chiniquy et al., 2012). Similar to glucuronic acids substituted at the O-2 position of Xyl residues of glucuronoxylan, the side-chain level and pattern affect the physicochemical properties and conformations of xyans (Grantham et al., 2017). However, acetates on arabinosyl residues have rarely been reported (Ishii, 1991), and the corresponding acetyltransferases and deacetylases have not been identified. It remains unclear whether the acetylated arabinosyl residue exists in plants and what functions it would mediate. A recent study revealed that excess acetylation of the xylan backbone results in a substantial amount of acetylated arabinosyl substituents (Zhang et al., 2017); this finding brought this epitope to our attention. Here, we identified *DAX1* as a deacetylase that removes acetyl groups from the arabinosyl residues of xylan. Lesions in

deacetylases, such as BS1 and *DAX1*, provide opportunities to investigate the acetylated polysaccharide intermediates that are not retained in wild-type plants. Based on our findings and recent progress in the field of acetyltransferase biology (Gille and Pauly, 2012; Xiong et al., 2013; Zhu et al., 2014; Yuan et al., 2016; Zhong et al., 2017), we propose that polysaccharide acetylation may occur at more glycosyl residues and would be catalyzed by more regio-specific acetyltransferases and deacetylases than we initially expected. The acetyl groups on the polysaccharide backbone and side chains are likely catalyzed by a series of acetyltransferases and deacetylases in multiple steps. Our study therefore highlights a complex and precise mechanism for acetylation profile control.

The complexity of polysaccharide acetylation is driven by subcellular compartmentalization of the enzymes. Acetylation occurs in the Golgi apparatus, the hub for cell-wall polymer

biosynthesis (Gille and Pauly, 2012; Zhang et al., 2017), and in the apoplast, where cell-wall remodeling takes place (Gou et al., 2012). Based on the behavior of the two Golgi-localized deacetylases DARX1 and BS1 (Zhang et al., 2017), the newly synthesized polysaccharides are probably excessively acetylated; this feature might be essential for maintaining the glycan intermediates in a soluble or other unknown status within the Golgi stacks. After processing many enzymatic reactions, the cell-wall polymers could be acetylated and deacetylated until secretion. Moreover, deacetylation likely occurs also in the postbiosynthesis stages. For example, deacetylase candidates were identified in secretome analyses (Chen et al., 2009; Cho et al., 2009); an apoplastic carbohydrate esterase was found to catalyze pectin deacetylation (Gou et al., 2012). Hence, the acetylation pattern is tightly controlled at multiple levels during cell-wall biogenesis.

The precise regulation of acetylation confers the acetylation-relevant proteins with regulatory roles in the control of the glycan properties and biological functions of the cell wall (Xin and Browse, 1998; Vogel et al., 2004; Zhu et al., 2014; Gao et al., 2017). Due to its interaction with cellulose and lignin, xylan is indispensable for secondary cell-wall organization and function (Gille and Pauly, 2012). The acetate pattern on the xylan backbone determines the folding of this polymer and its binding to cellulose (Grantham et al., 2017). However, the influence of acetylated side chains on xylan conformation remains unclear. In this study, excess acetylation on the xylan arabinosyl side chain alters the ratio of the two- and threefold conformers, which interrupts the interactions with cellulose microfibrils based on the solid-NMR analysis. Interestingly, the abnormal xylan conformation in *darx1* disrupts cellulose microfibril orientation, much like how changes in xyloglucan binding compromise cellulose microfibril orientation (Xiao et al., 2016). The possibility that the reduced cellulose content of *darx1* affects xylan conformation cannot be excluded, as the cellulose synthesis deficiency alters xylan conformation in *Arabidopsis* (Simmons et al., 2016). AFM revealed that the organization of rice secondary wall cellulose microfibrils is similar to that in maize (*Zea mays*; Ding et al., 2012). Hence, abnormalities in xylan conformation and cellulose microfibril orientation in the mutant plants result in compromised secondary wall patterning in sclerenchyma fiber and metaxylem cells, leading to reduced mechanical strength and plant height. Our study offers a mechanistic view for the control of arabinoxylan acetylation and reveals the importance of acetylated xylan side chains on secondary cell-wall architecture. These findings may suggest a strategy for developing elite crops with improved mechanical strength.

## METHODS

### Plant Materials

All rice plants (*Oryza sativa*) used in this study are in the Nipponbare cv background and were sown in the experimental fields at the Institute of Genetics and Developmental Biology in Beijing (China) and in Lingshui (Hainan Province, China) in different growing seasons. Usually, ~24 plants of each genotype were planted in the field with the same intervals for at least 2 y. While the plants matured, they were photographed and subjected to phenotypic analysis.

For generation of the *darx1* mutant by CRISPR/Cas9 approach, a coding sequence (734 to 756 bp) was chosen as a target sequence and

cloned into the binary plasmid (pYLRCRISPR/Cas9 Pubi-MH) as described in Naito et al. (2015) and Ma et al. (2016) using the primers shown in Supplemental Table 3. The transgenic plants were generated by *Agrobacterium tumefaciens* strain EHA105 infection (Zhang et al., 2017) and genotyped. The *Tos17* mutant was purchased from the Rice Genome Resource Center (National Institute of Agrobiological Sciences, Japan).

### Fractionation of Rice Total Microsomes

Twenty grams of rice internodes were ground and homogenized in a buffer (25 mM of Tris-acetate, 250 mM of Suc, 1 × protease inhibitor, 10% glycerol, and 2 mM of EDTA, pH 7.5). After centrifuging at 10,000g for 15 min, the supernatants were further ultracentrifuged at 100,000g for 2 h at 4°C to collect total microsomes. The pellets were suspended in a buffer (150 mM of NaCl, 50 mM of Tris-HCl at pH 7.4, 1 mM of EDTA, 2% Triton X-100, and 1 × protease inhibitor). After centrifugation at 10,000g for 15 min at 4°C and filtration through 0.22- $\mu$ m filters, the protein extracts were applied to a Superdex 200 10/300 GL Column (GE Healthcare) and eluted with Column Buffer (150 mM of NaCl, 50 mM of Tris, and 1 mM of EDTA at pH 7.4) at 0.5 mL/min. For ion chromatography, the solubilized membrane protein samples were loaded onto a HiTrap Q HP column (GE Healthcare) equilibrated with Q Column Buffer (20 mM of Tris-HCl at pH 7.6) and a HiTrap SP HP Column (GE Healthcare) equilibrated with SP Column Buffer (50 mM of sodium phosphate at pH 6.7; GE Healthcare). Through fractionating with a linear gradient of 0 to 1 M NaCl in the relevant column buffer using the Fast protein liquid chromatography System (ÄKTA pure; GE Healthcare), 100  $\mu$ L of each eluent fraction was subjected to enzymatic assays and SDS-PAGE. To monitor the experiments, the fractions were blotted on membranes, and the membranes were probed with anti-BS1 antibody at a 1:500 dilution (Zhang et al., 2017).

### Protein Mass Spectrometry Analysis

The fractions with obvious arabinosyl and xylosyl deacetylase activity were separated by SDS-PAGE. The proteins ranging from 15 to 130 kD were collected and subjected to an in-gel digestion with trypsin. After extraction with 60% acetonitrile, the resultant peptides were separated on a reverse-phase C18 column and detected with a Linear Ion Trap Mass Spectrometer (Thermo Finnigan). The generated mass spectrum data were analyzed with Proteome Discoverer (Thermo Fisher Scientific).

### Bioinformatics

A phylogenetic tree of the GELP members was built using neighbor-joining with a protein alignment (Supplemental Data Set) generated by Clustal W in the MEGA6 software (Tamura et al., 2013). One-thousand bootstrap replicates were used to calculate the support for the nodes in the tree. The clades were defined according to the genome-wide GELP family analysis (Volokita et al., 2011; Chepyshko et al., 2012) and shown in different color blocks. The expression profile of *DARX1* in various rice tissues was obtained from the online database RiceXPro (<http://ricexpro.dna.affrc.go.jp/>). *DARX1* and *BS1* were aligned using Clustal W (Tamura et al., 2013). The three-dimensional model of *DARX1* was generated using a hierarchical approach on the Iterative Threading Assembly Refinement server through homology modeling with default settings. The *DARX1* catalytic center was visualized using the software CHIMERA (Pettersen et al., 2004).

### Expression of *DARX1* in *Pichia*

To express *DARX1* protein in *Pichia pastoris*, the FL coding sequence without the region encoding the transmembrane domain (50 to 456 amino acids) and a Trun version (245 to 456 amino acids) were amplified and inserted in-frame into the pPICZ $\alpha$  vector and transformed into *Pichia* strain

SMD1168 by electroporation. Supernatants of the induction culture were supplemented with ammonium sulfate to a concentration of 1 M and loaded onto a HiTrap phenyl FF (HS) Column equilibrated with the Column Buffer (1 M of ammonia sulfate and 50 mM of Tris-HCl buffer, pH 7.0) using ÄKTA Pure (GE Healthcare). The trapped recombinant DARX1 proteins were eluted with a diminishing and linear gradient of 1–0 M ammonium sulfate buffer. The purified proteins were desalted with a HiTrap Desalt Column (GE Healthcare) and stored in aliquots.

### Enzyme Activity Assays

To analyze the glycosyl acetyl esterase activity, the full acetylated galactoside and arabinoside were prepared as described in Mastihubová et al. (2006). In brief, 2,3,4,6-*O*-acetyl *p*-nitrophenyl  $\beta$ -D-galactoside (Ac-NPh-Gal) and 2,3,5-*O*-acetyl *p*-nitrophenyl  $\alpha$ -L-arabinofuranoside (Ac-NPh-Ara) were generated by acetylating *p*-nitrophenyl  $\beta$ -D-galactoside and *p*-nitrophenyl  $\alpha$ -L-arabinofuranoside using acetic anhydride, respectively. Another substrate, 2,3,4-*O*-acetyl methyl  $\beta$ -D-xylopyranoside (Ac-meXyl), was purchased from Carbosynth. After purification, 5 mM of each substrate was incubated with 1  $\mu$ g of the purified recombinant proteins or 100  $\mu$ L of the above-fractionated microsomes in the reaction buffer (50 mM of Tris-HCl, pH 7.0) at 37°C for 2 h, respectively. The released acetates were examined using an Acetate Kinase Format Kit (Megazyme) according to the manufacturer's instructions. The kinetics of FL-DARX1 on Ac-NPh-Ara were determined by quantification of the quantities of acetic acids released from a gradient of substrate amounts.

To ascertain the reaction products of Ac-NPh-Ara after incubation with DARX1, the reaction products were loaded onto a 6530 Accurate-Mass Quadrupole Time-of-Flight Mass Spectrometer (Agilent Technologies) equipped with an electrospray ionization source. The data were acquired using positive electrospray ionization mode with capillary voltage 3500 V and fragmentor voltage 175 V in mass range of 50 to 600 *m/z* and analyzed using the MassHunter Qualitative Software package (version B.07.00; Agilent Technologies). To determine the regiospecificity of DARX1, 1  $\mu$ g of the purified recombinant DARX1 was incubated with 5 mM Ac-NPh-Ara in buffer (50 mM of ammonium acetate, pH 6.0) at 37°C for 3 h. After filtration with a 10-kD Ultra-Filtration Column (Omega), the products were determined by proton and TOCSY NMR spectroscopy.

To determine the DARX1 activity on native substrates, acetyl-xylan extracted from *darx1-1* was digested with xylanase M6 (Megazyme) to generate the xylooligosaccharide mixture. Approximately 50  $\mu$ g of the purified DARX1 recombinant proteins was incubated with xylooligosaccharides (1 mg mL<sup>-1</sup>) in the buffer (50 mM of Tris, pH 7.0) at 37°C for 16 h. After boiling for 15 min to inactivate the enzymes, the products were examined by HSQC NMR spectroscopy. NMR spectra were acquired at 298 K with a gradient 5-mm <sup>1</sup>H/<sup>13</sup>C/<sup>15</sup>N triple resonance cold probe as described in Zhang et al. (2017). The assays in the absence of the purified DARX1 were used as negative controls. At least three independent experiments were conducted in all these enzymatic assays.

### Transcriptome and RNA Gel Blotting

For the genome-wide gene expression analysis, the young internodes were collected from Nipponbare for mRNA isolation. Library construction and sequencing were performed by Berry Genomics. The clean pair-ended reads were aligned to the Rice Genome version 7 (<http://rice.plantbiology.msu.edu/>) using the software TopHat2 (<https://ccb.jhu.edu/software/tophat/index.shtml>). For RNA gel blotting, 20  $\mu$ g of total RNA was separated by 1% agarose gel electrophoresis and transferred onto a positively charged nylon membrane. A specific probe (913 to 1,212 bp) was amplified using primers shown in Supplemental Table 3 and labeled with [<sup>32</sup>P]-dCTP (PerkinElmer) to detect *DARX1* transcripts.

### Cell-Wall Compositional Analysis

Alcohol-insoluble cell-wall residues (AIR) were prepared by pooling the mature second internodes of ~20 mutant and wild-type plants and subject to composition analyses (Zhang et al., 2017). The crystalline cellulose content was analyzed by hydrolyzing the remains of trifluoroacetic acid treatment with Updegraff reagent (acetic acid/nitric acid/water, 8:1:2 v/v) at 100°C for 30 min and quantified by the anthrone method. To determine the content of acetyl esters, 1 mg of destarched AIRs were saponified by incubating with 100  $\mu$ L of 1 M sodium hydroxide for 1 h at 28°C and then neutralized with 100  $\mu$ L of 1 M hydrogen chloride. The released acetic acids were immediately quantified according to the instruction of Acetate Kinase Format Kit.

To extract pectin from cell-wall residues, ~6 mg destarched AIR was incubated with 2 U of endopolygalacturonase M2 (Megazyme) and 0.04 U of pectin methyl esterase (Sigma-Aldrich) in 50 mM of ammonium formate, pH 4.5 at 37°C overnight. The pectin-rich supernatants were collected by centrifugation at 3220g for 10 min and the remnants were considered as pectin-free samples. To isolate the acetyl-xylan, ~400 mg of destarched AIR was treated with 1% ammonium oxalate to remove pectin. After incubation in 11% peracetic acid solution at 85°C for 30 min, the pellets were extracted twice in DMSO at 70°C overnight. The acetyl-xylan was pelleted with 5 volumes of ethanol/methanol/water solution (7:2:1, pH 3.0) at 4°C for 3 d. After lyophilization, 1 mg of acetyl-xylan was subjected to the acetate content analysis.

To examine the arabinosyl substitution pattern in arabinoxylan, the alkali-extracted xylans from wild-type and *darx1* plants were digested with xylanase (Zhang et al., 2017) and then subjected to DNA sequencer-assisted saccharide analysis in high throughput as described in Li et al. (2013), but with minor modifications. Briefly, xylans were extracted from AIR residues with 4 M of NaOH and precipitated with 5 volumes of ethanol/methanol/water solution (7:2:1, pH 3.0). After lyophilization, 1 mg of xylan preparation was digested with 16 U xylanase M6 (Megazyme) in 200  $\mu$ L of sodium acetate buffer (pH 6.0) for 16 h. The digestion containing ~10 nmol oligosaccharides was dried and labeled with 1 mM of 9-aminopyrene-1,4,6-trisulfonic acid and 5 mM of NaCNBH<sub>3</sub> at 37°C for 6 h. The labeled oligosaccharides were diluted to ~1 pmol and detected by a model no. 3730xl96-Sample DNA Sequencer (ABI). A xylooligosaccharide ladder (Xyl to xylohexaose; Megazyme) was used as the molecular-size standard. The abundance of each oligosaccharide was quantified using peak analyzer in the software Origin 9 (OriginLab). All experiments described in this section were performed at least three times.

### NMR Analyses

The solution-state NMR spectroscopy analyses were performed on a model no. DD2 600-MHz NMR spectrometer (Agilent). The proton and 2D-NMR spectra were acquired at 298 K with a gradient 5-mm <sup>1</sup>H/<sup>13</sup>C/<sup>15</sup>N triple resonance cold probe as described in Zhang et al. (2017). For HSQC analysis, 20 mg of the isolated acetyl-xylans from wild type and mutant AIR was dissolved in 0.6 mL of deuterated DMSO-*d*<sub>6</sub> (99.9%; Sigma-Aldrich). The standard pulse sequence “gHSQCAD” was used to determine the one-bond <sup>13</sup>C-<sup>1</sup>H correlation in samples. The <sup>1</sup>H-<sup>13</sup>C HSQC spectra were collected using a spectrum width of 10 ppm in F2 (<sup>1</sup>H) dimension and 200 ppm in F1 (<sup>13</sup>C) dimension. The 2,048 × 512 (F2 × F1) complex data points were collected with receiver gain set to 30; 64 scans per FID were accumulated with an interscan delay (“d1”) of 1 s. For TOCSY analysis, the experiments were conducted using the standard pulse sequence with a 100-ms spin lock period. HMBC spectra were recorded using the standard gHMBCAD pulse sequence at 298 K temperature. NOESY spectra were recorded at mixing times of 200 ms using the standard NOESY pulse sequence. These spectra were calibrated using the DMSO solvent peak (dC 39.5 ppm and dH 2.49 ppm). All NMR data analysis was conducted with the software MestReNova 10.0.2. The NMR analyses were performed with three biological replicates of the pooled internodes.

Solid-state magic-angle spinning (MAS) NMR experiments were performed on a 600-MHz/395-GHz MAS-DNP spectrometer (Bruker; Dubroca et al., 2018) as described in Takahashi et al. (2012) and Kang et al. (2019). Briefly, ~60 mg slices from two intact and unlabeled internodes of wild-type and *darx1-1* plants were placed into 150  $\mu$ L of AMUPol solution in D<sub>2</sub>O. The samples were dried under vacuum for 10 h and combined with 5  $\mu$ L of D<sub>2</sub>O to provide moisture. They were then subjected to DNP measurements under 10-kHz MAS frequency after being packed into 3.2-mm thin-wall ZrO<sub>2</sub> rotors. The microwave irradiation power was ~12 W. A 3.2-mm MAS probe was used, and the typical radiofrequency field strengths were 100 kHz for <sup>1</sup>H decoupling, 62.5 kHz for <sup>1</sup>H and <sup>13</sup>C cross polarization, and 40 kHz for <sup>13</sup>C dipolar recoupling using the SPC5 sequence. The temperature was ~104 K when the microwave was on and ~98 K when the microwave was off. The DNP buildup time was 3.4 s and 2.2 s for the wild-type and *darx1-1* samples, respectively. The recycle delays were 1.3 times of the DNP buildup time for each sample. The sensitivity enhancement factors ( $\epsilon_{\text{on/off}}$ ) were 21 and 20 for the wild-type and *darx1-1* samples, respectively. The 2D <sup>13</sup>C-<sup>13</sup>C INADEQUATE spectra were recorded for 17~37 h with the spectral width of 60 ppm for the indirect dimension (double-quantum chemical shift) and 331 ppm for the direct dimension. The <sup>13</sup>C chemical shift was externally referenced to the adamantane CH<sub>2</sub> signal (38.48 ppm) on the Tetramethylsilane scale. All spectra were analyzed using the software Topspin (version 3.2 or 3.5; Bruker).

### Subcellular Localization

The full coding sequence for DARX1 was cloned and in-frame-fused with that for GFP in the pCambia1300 vector. The resulting construct was cotransformed into tobacco leaves with a construct for expression of the Golgi marker Man49-mCherry. The fluorescence signals were recorded with a confocal laser scanning microscope (Axio Imager Z2; Zeiss). To analyze the DARX1-resident profile in vivo, anti-DARX1 polyclonal antibodies were produced in mice. Briefly, the polypeptide encompassing amino acids 305 to 338 of DARX1 was fused with a carrier protein glutathione S-transferase and expressed in *Escherichia coli*. The column-purified recombinant protein was used as an antigen in mice. The generated serum harboring DARX1 polyclonal antibodies was used for immunoblotting and immunolabeling. One-week-old wild-type seedlings were homogenized in a buffer (250 mM of sorbitol, 50 mM of Tris-acetate at pH 7.5, 1 mM of EGTA at pH 7.5, 2 mM of dithiothreitol, 1  $\times$  protease inhibitor, 2% (w/v) polyvinylpyrrolidone, and 4 mM of EDTA). After centrifugation at 12,000g for 10 min, the supernatant was further ultracentrifuged at 100,000g for 1 h at 4°C. The pellet was suspended and fractionated in 20% to 55% Suc gradient solution. The fractionations were separated by SDS-PAGE and probed with the anti-DARX1 antibody at a 1:500 dilution and organelle marker antibodies against BS1 (using a Golgi marker from Agrisera; Zhang et al., 2017), BiP (AS09 481, an endoplasmic reticulum marker; Agrisera) and PIP1s (AS09 505, a plasma membrane marker; Agrisera) at a 1:1,000 dilution, respectively.

For immunogold labeling, 3-d-old root tips of wild-type plants were cryofixed by high-pressure freezing (HPM100; Leica) and freeze-substituted with 2% uranyl acetate in acetone at -90°C for 48 h using AFS2 (Leica). The samples were embedded in Lowicryl HM20 Resin (Electron Microscopy Sciences). The 80-nm-thick sections were cut with a microtome (EM UC6; Leica) and incubated with anti-DARX1 antibody at 1:300 dilution. Secondary antibody, 15 nm of colloidal gold-conjugated goat anti-mouse IgG (Abcam), was applied to the sections at 1:20 dilution. The images were acquired using a transmission electron microscope (model no. HT7700; Hitachi) equipped with a charge-coupled device camera (model no. 832; Gatan).

### Scanning Electron Microscopy Analysis

At least five mature second internodes from different plants were collected from wild-type and *darx1-1* plants and fixed in 4% paraformaldehyde

(Sigma-Aldrich). The samples were prepared by longitudinally cutting along the metaxylem of internodes under stereoscope and by cross sectioning the internodes. After critical-point drying and spraying with gold particles, the secondary wall patterns in metaxylem and secondary wall thickness of sclerenchyma fiber cells were observed with a scanning electron microscope (model no. S-3000N; Hitachi). The software Cell-Profiler 2.1 (Broad Institute) was used to calculate pit areas in metaxylem cells.

### Examination of the Breaking Force

The mature second internodes of at least 20 plants of wild type and *darx1-1* were cut into segments of equal length and immediately used for measurement. The crushing force to break the internodes was measured with a digital force tester (model no. 5848 Microtester; Instron).

### AFM

To probe microfibrils in cell walls, the mature second rice internodes were sliced and treated in 11% peracetic acid solution at 85°C for 3 h to remove lignin. After rinsing, the samples were imaged by a MultiMode Scanning Probe Microscope (MM-SPM; Bruker) with an advanced NanoScope V Controller (Veeco) operating in air (Xu et al., 2018). All images were scanned in 1- $\mu$ m scale at 512  $\times$  512 pixels using the ScanAsyst-Air probe (Bruker). The images were flattened to remove bow or tilt and exported in the TIFF format using the software Nanoscope Analysis (version 1.8; Bruker). At least five different metaxylem cells from one plant were scanned, and at least three different plants were used. Three representative images of three cells of three individual plants were selected for quantification. To quantify macrofibril/microfibril orientation, AFM images were analyzed using the software ImageJ (National Institutes of Health) with the plugin shape index map and then converted to "mask." The macrofibrils/microfibrils were automatically detected by the software SOAX (3.6.1; <https://omictools.com/soax-tool>) as "snakes" (segments) using a snake point spacing of 1 pixel and a minimum snake length of 20 pixels. Microfibril orientation was evaluated by calculating the orientation of 60,000 snakes after snake cuts at junctions. The data are shown as frequency percentage in a histogram.

### Accession Numbers

Sequence data from this article can be found in the GenBank/EMBL data libraries under accession numbers XM\_015782069.2 for the identified DARX1.

### Supplemental Data

**Supplemental Figure 1.** Screening arabinoxylan deacetylases in rice.

**Supplemental Figure 2.** Determining the coding sequence of *DARX1*.

**Supplemental Figure 3.** Genetic verification of *DARX1*.

**Supplemental Figure 4.** *darx1* Arabinoxylan has altered acetylation pattern.

**Supplemental Figure 5.** NMR correlation spectrum analyses of acetyl-xylan in *darx1*.

**Supplemental Figure 6.** Arabinosyl substitution pattern is unchanged in *darx1*.

**Supplemental Figure 7.** Enzymatic activity assays of *DARX1*.

**Supplemental Figure 8.** Quantification of macrofibril diameter in situ by AFM.

**Supplemental Table 1.** Detected GELP proteins in LC-MS analyses.

**Supplemental Table 2.** Chemical shifts (ppm) assignment for arabinosyl residues identified by 2D-NMR analyses.

**Supplemental Table 3.** Primers used in this study.

**Supplemental Data Set.** Text file of the alignment used for the phylogenetic analysis shown in Figure 1B.

## ACKNOWLEDGMENTS

We thank Professor Yaoguang Liu for kindly providing the gRNA expression cassettes and the binary CRISPR/Cas9 vectors, Dr. Xue-Hui Liu and Shanshan Zang for help with the solution-state NMR analyses, and Dr. Junli Xu and Prof. Suojiang Zhang for assistance with the AFM analysis. This work was supported by the National Natural Science Foundation of China (grants 31530051, 31571247, and 91735303), the Youth Innovation Promotion Association, Chinese Academy of Sciences (2016094), the U.S. National Science Foundation (grant NSF/OIA-1833040), and the State Key Laboratory of Plant Genomics. The DNP work was performed at the National High Magnetic Field Laboratory, which was supported by the U.S. National Science Foundation (grants NSF/DMR-1644779 and NSF/CHE-1229170), the State of Florida, and the U.S. National Institutes of Health (grant NIH-S10-OD018519).

## AUTHOR CONTRIBUTIONS

Y.Z., B.Z., and L.Z. designed experiments; B.Z. and L.Z. analyzed the data; L.Z. and C.G. performed biochemical and cell-wall composition analyses; T.W. and F.M.V. performed DNP analysis; L.Z. and S.C. conducted AFM analysis; L.T. and D.Z. performed protein localization experiments; S.W. conducted RNA gel blotting; Z.X. and X.L. performed plant transformation and filed experiments; Y.Z. and B.Z. wrote the article; Y.Z. supervised the project.

Received January 15, 2019; revised March 12, 2019; accepted March 18, 2019; published March 18, 2019.
