We describe a recently recognized disease entity, limbic-predominant age-related TDP-43 encephalopathy (LATE). LATE neuropathological change (LATE-NC) is defined by a stereotypical TDP-43 proteinopathy in older adults, with or without coexisting hippocampal sclerosis pathology. LATE-NC is a common TDP-43 proteinopathy, associated with an amnesic dementia syndrome that mimicked Alzheimer's-type dementia in retrospective autopsy studies. LATE is distinguished from frontotemporal lobar degeneration with TDP-43 pathology based on its epidemiology (LATE generally affects older subjects), and relatively restricted neuroanatomical distribution of TDP-43 proteinopathy. In community-based autopsy cohorts, ~25% of brains had sufficient burden of LATE-NC to be associated with discernible cognitive impairment. Many subjects with LATE-NC have comorbid brain pathologies, often including amyloid- β plaques and tauopathy. Given that the 'oldest-old' are at greatest risk for LATE-NC, and subjects of advanced age constitute a rapidly growing demographic group in many countries, LATE has an expanding but under-recognized impact on public health. For these reasons, a working group was convened to develop diagnostic criteria for LATE, aiming both to stimulate research and to promote awareness of this pathway to dementia. We report consensus-based recommendations including guidelines for diagnosis and staging of LATE-NC. For routine autopsy workup of LATE-NC, an anatomically-based preliminary staging scheme is proposed with TDP-43 immunohistochemistry on tissue from three brain areas, reflecting a hierarchical pattern of brain involvement: amygdala, hippocampus, and middle frontal gyrus. LATE-NC appears to affect the medial temporal lobe structures preferentially, but other areas also are impacted. Neuroimaging studies demonstrated that subjects with LATE-NC also had atrophy in the medial temporal lobes, frontal cortex, and other brain regions. Genetic studies have thus far indicated five genes with risk alleles for LATE-NC: *GRN*, *TMEM106B*, *ABCC9*, *KCNMB2*, and *APOE*. The discovery of these genetic risk variants indicate that LATE shares pathogenetic mechanisms with both frontotemporal lobar degeneration and Alzheimer's disease, but also suggests disease-specific underlying mechanisms. Large gaps remain in our understanding of LATE. For advances in prevention, diagnosis, and treatment, there is an urgent need for research focused on LATE, including *in vitro* and animal models. An obstacle to clinical progress is lack of diagnostic tools, such as biofluid or neuroimaging biomarkers, for ante-mortem detection of LATE. Development of a disease biomarker would augment observational studies seeking to further define the risk factors, natural history, and clinical features of LATE, as well as eventual subject recruitment for targeted therapies in clinical trials.

Abbreviations: ADNC = Alzheimer's disease neuropathological changes; ALS = amyotrophic lateral sclerosis; FTD = frontotemporal dementia (clinical syndrome); FTLN-TDP = frontotemporal lobar degeneration with TDP-43 proteinopathy; GWAS = genome wide association study; LATE-NC = limbic-predominant age-related TDP-43 encephalopathy neuropathological changes; PPA = primary progressive aphasia; SNAP = suspected non-Alzheimer (non-amyloid- β) pathophysiology (by biomarkers)

Introduction

Transactive response DNA binding protein of 43 kDa (TDP-43) proteinopathy in limbic brain structures is commonly observed in subjects past 80 years of age. This proteinopathy has been associated with substantial cognitive impairment that mimicked Alzheimer's disease clinical syndrome in retrospective studies. Despite evidence from many sources attesting to the public health impact of age-related TDP-43 proteinopathy, there is as yet no consensus-based nomenclature. To address this problem, we propose new terminology: limbic-predominant age-related TDP-43 encephalopathy (LATE). Guidelines are suggested for the autopsy evaluation and staging of LATE neuropathological change (LATE-NC). We review the medical literature pertaining to LATE, including cognitive manifestations, neuroimaging, public health impact, and genetics. The importance of LATE as a contributing factor in neurodegeneration is stressed, as are the needs for specific LATE biomarker development, TDP-43 focused drug discovery, and eventual clinical trials. We conclude by highlighting important knowledge gaps and potential future directions for research on LATE. Summary points are presented in Box 1.

Background

There is growing awareness that Alzheimer's disease neuropathological change (ADNC) is only one of multiple neuropathological substrates associated with amnesic mild cognitive impairment and the Alzheimer's clinical syndrome in the aged population (Korczyn, 2002; Zekry *et al.*, 2002; Bennett *et al.*, 2006; Jellinger and Attems, 2007; Schneider *et al.*, 2007; Crary *et al.*, 2014; Murray *et al.*, 2014; Rahimi and Kovacs, 2014; James *et al.*, 2016). Recent studies have gathered rich clinical data from large groups of subjects across a spectrum of cognitive states, correlated these clinical findings with new pathological markers at autopsy, and then analysed the data using powerful statistical methods. These studies have indicated that the diseases of aged human brains are complex: multiple comorbid pathologies are the norm, and there is substantial interindividual variation in neuropathological phenotypes (Neuropathology Group. Medical Research Council Cognitive and Aging, 2001; Brayne *et al.*, 2009; Kovacs *et al.*, 2013; Murray *et al.*, 2014; Rahimi and Kovacs, 2014; White *et al.*, 2016; Abner *et al.*, 2017; Kapasi *et al.*, 2017; Suemoto *et al.*, 2017; Tanskanen *et al.*, 2017; Robinson *et al.*, 2018b, c). While there is a strong

Box | LATE and LATE-NC summary points

- LATE-NC features
 - A sampling and staging system for routine autopsy diagnosis is proposed to characterize the anatomical distribution of TDP-43 proteinopathy
 - Stage 1: amygdala only
 - Stage 2: + hippocampus
 - Stage 3: + middle frontal gyrus
 - Hippocampal sclerosis pathology may be observed (and should be reported), but is neither necessary nor sufficient for diagnosis of LATE-NC
- LATE-NC is present in >20% (up to 50%) of individuals past age 80 years according to large community-based autopsy series
- LATE is associated with substantial disease-specific cognitive impairment, usually an amnesic dementia syndrome ('dementia of the Alzheimer's type')
- The overall public health impact of LATE is on the same order of magnitude as Alzheimer's disease neuropathological changes; the diseases are often comorbid, but which pathology is more severe varies greatly between individuals
- Genetic risk factors for LATE have some overlap with FTLD-TDP and with Alzheimer's disease
- There is no molecule-specific biomarker for LATE. This is an important area of need for use in clinical trials (including as a potential exclusion criterion for Alzheimer's disease clinical trials) and longitudinal studies of the clinical and pathological progression of LATE

association between severe ADNC and cognitive impairment in all age groups (Nelson *et al.*, 2009; Abner *et al.*, 2011), subjects who die after 80 years of age often have exhibited cognitive decline exceeding expectation given the severity of ADNC (Kawas and Corrada, 2006; Savva *et al.*, 2009; Nelson *et al.*, 2012). LATE-NC is an important contributor to this apparent clinicopathological mismatch (see below).

Historically, the first-recognized pathological manifestation of LATE was profound hippocampal neuron loss and gliosis, collectively termed hippocampal sclerosis. In a landmark study, Dickson *et al.* (1994) identified 13 elderly subjects with dementia and hippocampal sclerosis, yet who lacked substantial ADNC. Other larger autopsy series that included subjects with dementia and hippocampal sclerosis were later reported (Crystal *et al.*, 2000; Barker *et al.*, 2002; Leverenz *et al.*, 2002; White *et al.*, 2002; Zarow *et al.*, 2005; Attems and Jellinger, 2006; Brayne *et al.*, 2009). In 2006, phosphorylated TDP-43 was discovered as the disease protein in the ubiquitylated inclusions that are signatures of amyotrophic lateral sclerosis (ALS) and

most cases of frontotemporal lobar degeneration (FTLD), known as FTLD-TDP (Neumann *et al.*, 2006; Cairns *et al.*, 2007a). TDP-43 protein, encoded by the *TARDBP* gene (Ou *et al.*, 1995), is a protein that binds to RNA and DNA as well as to other proteins, and serves multiple functions in gene expression regulation at the levels of both transcription and translation (Cohen *et al.*, 2011; Guo and Shorter, 2017). Expressed in most human tissues and cell types, TDP-43 is predominantly non-phosphorylated and localized mostly within nuclei, while in disease states the protein is phosphorylated and often translocated to the cytoplasm (Neumann *et al.*, 2006).

Following the detection of TDP-43 proteinopathy in FTLD-TDP and in the large majority of ALS cases (Mackenzie *et al.*, 2007), TDP-43 proteinopathy was also discovered in the brains of subjects over age 80 years without FTLD or ALS, but often with comorbid hippocampal sclerosis and/or ADNC (Amador-Ortiz *et al.*, 2007a, b). In subjects with ADNC, LATE-NC represents a common comorbid lesion that lowers the threshold for developing dementia (Josephs *et al.*, 2014b, 2015). In retrospective studies, age-related TDP-43 proteinopathy has been associated with a progressive amnesic syndrome that mimicked the Alzheimer's clinical syndrome (Pao *et al.*, 2011; Brenowitz *et al.*, 2014). TDP-43 proteinopathy, hippocampal sclerosis pathology, and the associated amnesic dementia increases with advanced age, while the prevalence of severe ADNC decreases in extreme old age (Nelson *et al.*, 2011a, b, 2013; Brenowitz *et al.*, 2014). The presence of pathological TDP-43 in these cases suggests a novel disease mechanism in older adults. As there is currently no universally agreed upon terminology or staging system for common age-related TDP-43 proteinopathy, this condition is under-studied and not well recognized even among investigators in the field of dementia research. The promotion of research and increasing awareness of this disease are the primary motivations for developing the new term LATE, and for the recommendations that follow.

LATE neuropathological changes

LATE-NC is a TDP-43 proteinopathy of advanced age, especially in subjects older than age 80. Following the convention proposed by a working group for the neuropathological criteria of Alzheimer's disease (Montine *et al.*, 2012), we use LATE to refer to the disease, and LATE-NC as the term to indicate LATE neuropathological changes. The term LATE is intended to encompass several previously used designations related to TDP-43 proteinopathy that may be associated with cognitive impairment, including hippocampal sclerosis, hippocampal sclerosis of ageing, hippocampal sclerosis dementia, cerebral age-related TDP-43 with sclerosis, and TDP-43 pathologies in the elderly (for reviews see Kuslansky *et al.*, 2004; Lippa and Dickson, 2004; Nelson *et al.*, 2013, 2016b; Dutra *et al.*, 2015).

‘TDP-43 proteinopathy’ refers to loss of normal nuclear TDP-43 immunoreactivity, with TDP-43 protein ‘inclusion bodies’ in the neuronal cytoplasm, as well as abnormal TDP-43 accumulation (much of it phosphorylated) in nuclei and cell processes (neurites) of neurons and in oligodendroglia and astrocytes. For representative examples of TDP-43 proteinopathy, see Fig. 1. Mislocalized and phosphorylated TDP-43 is a necessary feature of LATE-NC and sometimes has characteristics similar to those seen in type A FTLTDP (Lin *et al.*, 2009; Mackenzie *et al.*, 2011; Murray *et al.*, 2014; Aoki *et al.*, 2015), but often the features do not fit cleanly into an established FTLTDP subtype. Indeed, a recent study described features of LATE-NC including both similarities and differences from type A FTLTDP (Josephs *et al.*, 2019). In addition to limbic structures, TDP-43 proteinopathy in LATE has also been described in the olfactory bulb, neocortex, basal ganglia, and less frequently in brainstem (Josephs *et al.*, 2008; Geser *et al.*, 2010; Josephs and Dickson, 2016; Nelson *et al.*, 2018). Immunoelectron microscopy showed that the TDP-43 inclusions have a fibrillary ultrastructure composed of bundled 10–20-nm diameter straight filaments (Lin and Dickson, 2008; Lin *et al.*, 2009), often accompanied by electron dense granules (Cairns *et al.*, 2007b; Robinson *et al.*, 2013).

In brains with LATE-NC, haematoxylin and eosin stains may reveal neuronal dropout and astrocytosis in the CA1 sector of the hippocampus, as well as in the subiculum, entorhinal cortex, and amygdala (Amador-Ortiz and Dickson, 2008). Atrophy can be marked in these areas (Fig. 1A–C). In severely affected hippocampi, the neuropil becomes rarefied and loss of neuronal components is accompanied by reactive astrocytosis (Amador-Ortiz *et al.*, 2007a). Pronounced leucocyte infiltrates or perivascular cuffing are not typically seen, but hypertrophic microglia can be numerous (Bachstetter *et al.*, 2015). The neuronal cell loss is segmental in some subjects, observed in some but not all sections from the same brain area (Ighodaro *et al.*, 2015). Hippocampal sclerosis pathology is unilateral in ~40–50% of cases in which both sides were evaluated (Nelson *et al.*, 2011b; Zarow *et al.*, 2012; Kero *et al.*, 2018), not unlike FTLTDP (Irwin *et al.*, 2018).

Hippocampal sclerosis is present in a subset of cases with severe LATE-NC, and was the first characteristic pathological feature that distinguished it from ADNC (Dickson *et al.*, 1994). Nevertheless, hippocampal sclerosis is neither specific to LATE-NC nor sufficient for the diagnosis of LATE. The neuropathological diagnosis of hippocampal sclerosis is fraught with difficulty. The most recent consensus guidelines for ADNC and related disorders stated that hippocampal sclerosis pathology is ‘defined by severe pyramidal cell loss and gliosis in CA1 and subiculum of the hippocampal formation that is out of proportion to AD neuropathologic change in the same structures’ (Montine

et al., 2012). There is, however, significant topographic and phenotypic heterogeneity in hippocampal degeneration, creating difficulties in establishing strict criteria for widespread use. Moreover, hippocampal sclerosis is a pathological endpoint associated with various underlying disease processes, including epilepsy, hypoxia, hypoglycaemia, certain infections, and numerous neurodegenerative conditions (Josephs *et al.*, 2007; Thom *et al.*, 2009; Yokota *et al.*, 2010; Malek-Ahmadi *et al.*, 2013; Murray *et al.*, 2013; Ling *et al.*, 2017; Popkirov *et al.*, 2017; Sen *et al.*, 2018). Having originated in a 19th century study of epilepsy by Wilhelm Sommer (Sommer, 1880; Thom, 2009), the term hippocampal sclerosis is still used widely by radiologists and pathologists in the context of seizure disorders (Isnard and Bourdillon, 2015; Thom and Sisodiya, 2015). Detailed discussions of histopathological features and subtypes of hippocampal sclerosis can be found elsewhere (Probst *et al.*, 2007; Rauramaa *et al.*, 2013; Hatanpaa *et al.*, 2014; Dutra *et al.*, 2015; Thom and Sisodiya, 2015; Cykowski *et al.*, 2017). Brains with hippocampal sclerosis, but lacking TDP-43 pathology (TDP-43–/HS+), do not represent LATE-NC. For example, brains with hippocampal sclerosis caused by acute hypoxia or associated with epilepsy are negative for TDP-43 proteinopathy (Amador-Ortiz *et al.*, 2007b; Lee and Lee, 2008; Nelson *et al.*, 2011b) and do not fulfil criteria for LATE-NC (Fig. 1H). In summary, TDP-43 proteinopathy is a necessary feature of LATE-NC that may or may not be accompanied by hippocampal sclerosis.

As has been the case in other neurodegenerative diseases (Braak *et al.*, 1993, 2006; Thal *et al.*, 2000; Zaccai *et al.*, 2008; Alafuzoff *et al.*, 2009), careful assessments of autopsy data, from both longitudinal studies of clinic-based research subjects as in the NIA-funded Alzheimer’s Disease Centers, and from community-based studies, have expanded our understanding of LATE. While subjects with advanced age and hippocampal sclerosis often have TDP-43 proteinopathy (Amador-Ortiz *et al.*, 2007b; Nelson *et al.*, 2011b; Robinson *et al.*, 2014; Nag *et al.*, 2015, 2018), TDP-43 proteinopathy in limbic structures is more prevalent than hippocampal sclerosis (Kovacs *et al.*, 2013; Josephs *et al.*, 2014b; Keage *et al.*, 2014; Murray *et al.*, 2014; Rahimi and Kovacs, 2014; Aoki *et al.*, 2015; Nag *et al.*, 2015, 2017; Hokkanen *et al.*, 2018; Robinson *et al.*, 2018b). The TDP-43-positive (+) and hippocampal sclerosis-negative (HS–) cases are a subset of LATE-NC that represent 5–40% of research subjects in autopsy series. Prior researchers have used terms for brains with TDP-43 proteinopathy and with some degree of cell dropout and gliosis, but lacking frank hippocampal sclerosis, as a ‘precursor to HS’, ‘pre-HpScl’, or ‘pre-HS-Aging’ (Hatanpaa *et al.*, 2008; Aoki *et al.*, 2015; Hokkanen *et al.*, 2018). As suggested by the terminology, TDP-43+/HS– brains may represent an early or transitional phase on the same disease continuum as TDP-43+/HS+ cases. There are

Figure 1 LATE neuropathological changes (LATE-NC). (A–E) Coronal sections of human hippocampi stained using haematoxylin and eosin (H&E). Note that the photomicrographs in A–C are presented at the same magnification. (A) LATE-NC with hippocampal sclerosis (HS). The hippocampus is atrophic and the neuropil rarefied. (D) Higher magnification in CA1 subfield, with lack of normal cellular architecture and with extensive gliosis. (C) Control age-matched hippocampus. (E) CA1 of the control hippocampus to demonstrate the normal cellular architecture and intact eosinophilic neuropil (asterisk). The hippocampus shown in B is less atrophic, with less obvious neuropil disruption, in comparison to the case in A at low magnification; however, an adjacent section revealed TDP-43 proteinopathy. Hippocampal fields are labelled in B: dg = dentate granule layer; Sub = subiculum. TDP-43 proteinopathy can be recognized using antibodies raised against either non-phosphorylated or phosphorylated TDP-43 epitopes. (F) Dentate granule cells in a case lacking TDP-43 pathology. Note that cell nuclei are normally immunopositive for non-phosphorylated TDP-43 protein. In a case with LATE-NC (G), by contrast, an antibody against phosphorylated TDP-43 protein recognizes only the pathological inclusions in the nucleus (green arrow) and cytoplasm (red arrow). Unlike the antibody against non-phosphorylated TDP-43, the antibody against phosphorylated TDP-43 is negative in non-affected cells. Most cells in G are visualized with the counterstain, haematoxylin, which stains cell nuclei blue. The Venn diagram in H illustrates schematically the imperfect overlap between cases with TDP-43 proteinopathy, hippocampal sclerosis, and LATE-NC. A subset of cases with TDP-43 pathology have comorbid hippocampal sclerosis pathology; the change zone between non-hippocampal sclerosis and hippocampal sclerosis cases is indistinct because many cases seem to be in transition with incipient hippocampal neuron loss and gliosis. Importantly, cases with hippocampal sclerosis pathology but no TDP-43 proteinopathy (e.g. hippocampal sclerosis pathology associated with anoxia or epilepsy) are not classified as LATE-NC. (I) Phospho-TDP-43 proteinopathy in two neurons in hippocampal CA1, along with phospho-TDP-43 immunoreactive dystrophic neurites. (J) Tangle-like

(continued)

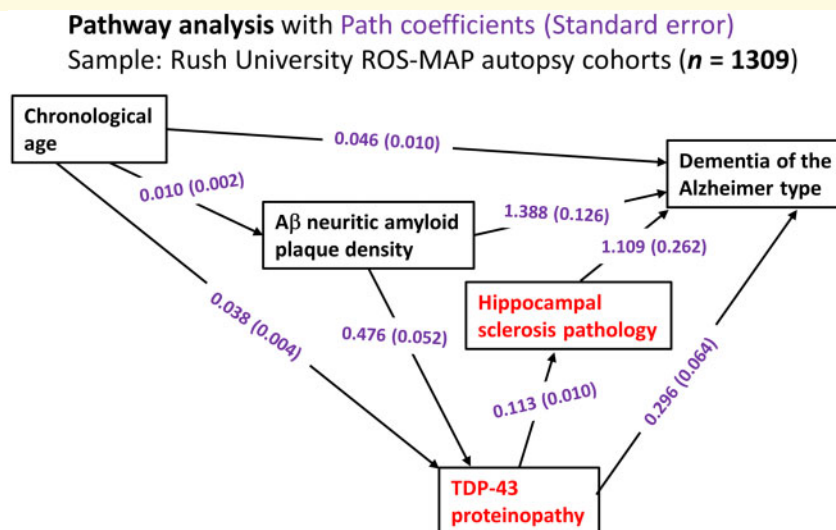

Figure 2 Statistical analyses on data related to LATE from the Rush University community-based autopsy cohort depicting the results of pathway analyses. Data were analysed from research volunteers (total $n = 1309$) in two clinical-pathological studies of ageing from Rush University as described previously (Power *et al.*, 2018). In this sample, the mean age of death was 89.7 years [standard deviation (SD) 6.5 years, range 65–108 years]. These analyses incorporated age, density of amyloid- β neuritic amyloid plaques (to factor in ADNC), TDP-43 proteinopathy, hippocampal sclerosis pathology, and the endpoint of Alzheimer's-type clinical dementia. The components of the pathway analyses most strongly associated with LATE-NC are shown in red. The numbers are path coefficients with standard error in parentheses (shown in purple). These numbers help to quantify the effects of individual pathways. For instance, the data are compatible with there being two pathways from TDP-43 proteinopathy to dementia, one direct pathway (TDP-43 proteinopathy \rightarrow dementia) and the other indirect pathway that includes hippocampal sclerosis pathology (TDP-43 proteinopathy \rightarrow hippocampal sclerosis \rightarrow dementia): in the statistical model, the TDP-43 proteinopathy is independently associated with both hippocampal sclerosis pathology and clinical dementia status. Further, the data indicate that a subset of TDP-43 proteinopathy is 'downstream' of ADNC-type neuritic amyloid plaque pathology. In a practical sense, this means that brains with more neuritic amyloid plaques are more likely to have TDP-43 proteinopathy, with all other known factors being the same. A β = amyloid- β .

other clues about LATE that were gathered from autopsy cohort studies. For example, even when hippocampal sclerosis was unilateral or segmental, the TDP-43 proteinopathy was almost always bilateral (Nelson *et al.*, 2011b; Ighodaro *et al.*, 2015). These observations have implications about how LATE evolves, which remains an important and open question.

Data gathered in large autopsy series have been analysed to test hypotheses about progression of LATE. Multivariable regression-based assessment can be used to generate models to test whether cross-sectional data align with proposed sequential pathways of neuropathological changes. Results of one such pathway analysis, from the Rush University community-based autopsy studies, are shown in Fig. 2. These analyses were performed as described previously (Power *et al.*, 2018) and the findings are compatible with at least three hypotheses: (i) a subset of

cases with TDP-43 proteinopathy develop hippocampal sclerosis caused or exacerbated by overlapping process(es) that promoted the TDP-43 proteinopathy, or directly by the TDP-43 proteinopathy itself; (ii) TDP-43 proteinopathy is associated independently with dementia, even in cases lacking hippocampal sclerosis; and (iii) pathogenetic mechanisms associated with ADNC (in Fig. 2, data are provided on neuritic amyloid- β plaques) are also associated with increased TDP-43 proteinopathy. Current rodent models of TDP-43 proteinopathy with hippocampal sclerosis-like pathology are few (Ke *et al.*, 2015). TDP-43 proteinopathy was shown to be transmissible in mouse models similar to pathological tau and amyloid- β from Alzheimer's disease brains (Porta *et al.*, 2018), but the published TDP-43 models are thought to be more directly relevant to FTLTDP than LATE. For now, the lack of adequate longitudinal biomarker data and the limitations of current animal

Figure 1 Continued

phospho-TDP-43 immunoreactive cytoplasmic inclusions in amygdala (red arrows) with fewer phospho-TDP-43 immunoreactive neurites in the background. (K) An intraneuronal phospho-TDP-43 inclusion (red arrow) and a phospho-TDP-43 deposit (green arrow) surrounding a capillary (shown with blue arrows); these TDP-43 immunoreactive structures have been demonstrated to exist within astrocyte end-feet (Lin *et al.*, 2009). Note also the presence of a cell with cytoplasmic puncta (green arrow), perhaps in an early phase of phosphorylated TDP-43 proteinopathy. Scale bar in A = 4 mm for A–C; D = 200 μ m; E = 100 μ m; F = 30 μ m; G = 35 μ m; I = 30 μ m; and K = 25 μ m.

models hamper our study of disease mechanism(s) and further investigations are needed.

LATE MRI studies

MRI studies have provided a complementary window into brain changes in LATE, highlighting brain atrophy both within and outside of the medial temporal lobes of brains with autopsy-verified LATE-NC. Prior studies featured research volunteers who underwent MRI with autopsy follow-up. Several of these studies focused on the subset of cases with hippocampal sclerosis (i.e. presumed severe LATE-NC), therefore, most of the published data were lacking information about less severely affected cases. With that caveat in mind, a common finding in MRI studies is that hippocampal atrophy is greater in cases with LATE-NC than in those with pure Alzheimer's disease (Jagust *et al.*, 2008; Josephs *et al.*, 2008, 2017a; Dawe *et al.*, 2011; Kaur *et al.*, 2014; Dallaire-Theroux *et al.*, 2017; Hanko *et al.*, 2019). Barkhof *et al.* (2007) found that many subjects with medial temporal atrophy lacked primary underlying ADNC. In this study cohort, the sensitivity and specificity of severe atrophy for ADNC was 63% and 69%, respectively, consistent with prior findings (Jack *et al.*, 2002). Josephs *et al.* (2008) reported that subjects with neuropathology consistent with LATE-NC tended to be older, with more cognitive impairment, and with more pronounced hippocampal atrophy than TDP-43– subjects. Zarow *et al.* (2011) also described atrophy and deformation of the hippocampus considerably greater in those with hippocampal sclerosis and LATE-NC than in those with only ADNC (Zarow *et al.*, 2011). In hippocampal sclerosis associated with LATE-NC, hippocampal atrophy was often asymmetric, and it tended to progress in a rostral-caudal gradient in the hippocampus. Using post-mortem MRI, Dawe *et al.* (2011) reported stronger correlations between hippocampal atrophy and LATE-NC (with hippocampal sclerosis pathology) than between hippocampal atrophy and ADNC, and subjects with both ADNC and LATE-NC had greater hippocampal atrophy than those with only ADNC. A recent study found that the volume and shape of the amygdala is associated with underlying LATE-NC and that these structural changes are indicative of cognitive decline beyond what can be explained with other pathological indices (Makkinejad *et al.*, 2019).

Post-mortem MRI research has also provided strong evidence that LATE-NC is associated with substantial brain atrophy outside the medial temporal lobes (Kotrotsou *et al.*, 2015). Figure 3A shows updated data from the Rush University autopsy cohort. After controlling for demographics, ADNC and other age-related pathologies, LATE-NC was related to not only the mesial temporal lobe atrophy, but also to atrophy in the inferior frontal, anterior temporal, and insular cortices. It is noteworthy that this regional atrophy pattern corresponds with the distribution of TDP-43 proteinopathy at autopsy (Josephs *et al.*, 2016; Nag *et al.*, 2018) (Fig. 3B). These data are

in agreement with pathological studies of LATE-NC, as well as neuroimaging in subjects with LATE-NC risk genotypes, showing widespread brain involvement (Neltner *et al.*, 2014; Cykowski *et al.*, 2016; Josephs *et al.*, 2016; Nelson *et al.*, 2016a; Nho *et al.*, 2016).

Recommendations for routine autopsy evaluation and classification of LATE-NC

It is recommended that TDP-43 immunohistochemistry be performed as part of the neuropathological evaluation in all older subjects. At a minimum, immunohistochemical staining for TDP-43 is recommended in three brain areas: amygdala, mid-level hippocampus, and middle frontal gyrus. We recommend evaluating these regions as they are commonly obtained at autopsy of aged subjects and capture presumed progression of LATE-NC in the brain. This sampling includes the brain area affected early in the disease course (amygdala, Stage 1), an intermediate stage where the pathological change is robustly associated with cognitive impairment (hippocampus, Stage 2), and a region affected at more advanced stages (middle frontal gyrus, Stage 3) (Nag *et al.*, 2018). Any detected TDP-43 proteinopathy is sufficient to define an anatomical region-based stage: for example, a minute amount of detected TDP-43 proteinopathy in the hippocampus indicates at least Stage 2. We emphasize that the proposed sampling for LATE-NC autopsy screening is a minimal evaluation, whereas more detailed sampling and staging should be considered for specific research settings (Josephs *et al.*, 2014a, 2016; Uchino *et al.*, 2015; Nag *et al.*, 2017, 2018; Zhang *et al.*, 2019). Figure 3B depicts staging schemes for LATE-NC, including sampling recommended for neuropathological evaluation of brain of older adults. This does not address regions that would be assessed in separate TDP-43 pathological staging schemes developed for ALS or FTLTDP (Brettschneider *et al.*, 2013; Fatima *et al.*, 2015; Tan *et al.*, 2015; Verde *et al.*, 2017; Neumann and Mackenzie, 2019).

Practical questions arise in relation to diagnostic 'boundary zones' between LATE-NC, FTLTDP, and ADNC. While both LATE-NC and FTLTDP may affect neocortical areas and may be comorbid with hippocampal sclerosis, LATE-NC usually has a later age of onset, an amnesic dementia, and limbic predominance of pathological change (Nelson *et al.*, 2011b). On the other hand, recommendations for LATE-NC do not stipulate any age cut-offs, because the exact age ranges of disease susceptibility for FTLTDP or LATE-NC are not yet fully understood. For prior pathology-based comparisons between subtypes of TDP-43 proteinopathies (not related to age of onset), previous studies should be consulted (Amador-Ortiz *et al.*, 2007a; Tan *et al.*, 2015). More widespread and severe cortical atrophy is typically present in advanced FTLTDP than LATE-NC. There may indeed be features that could definitively distinguish LATE-NC cases

A Brain atrophy associated with autopsy-confirmed LATE-NC: Data from Rush University ROS-MAP community-based autopsy cohorts

B LATE-NC related stages based on anatomic distribution of TDP-43 pathology

Simplified staging of TDP-43 proteinopathy* for routine LATE-NC diagnosis (consensus recommendation)		Josephs TDP-43 proteinopathy staging (KA Josephs <i>et al.</i> , 2013)		Rush University TDP-43 proteinopathy staging (S Nag <i>et al.</i> , 2017)

		4	Insula, Inf temporal cortex	4	Midtemporal and orbitofrontal cortex
5	Inf olive, midbrain				
3	Middle frontal gyrus (MFG)	6	Basal ganglia, MFG	5	MFG

*-Any TDP-43 proteinopathy is seen in that anatomic region

Figure 3 Brain regions that are affected in LATE. (A) Post-mortem MRI with autopsy confirmation allows discrimination of regions of brain atrophy associated with LATE-NC. These data indicate grey matter regions inside and outside of the medial temporal lobe with atrophy in cases with autopsy-confirmed LATE-NC from a community-based autopsy sample. The figure was prepared similarly to the methods used in Kotrotsou *et al.* (2015), with some modifications. Cerebral hemispheres from 539 participants of two cohort studies of ageing (Rush Memory and Aging Project and Religious Orders Study) were imaged with MRI *ex vivo* and also underwent detailed neuropathological characterization. The cortical and subcortical grey matter were segmented into 41 regions. Linear regression was used to investigate the association of regional volumes (normalized by height) with the score of LATE-NC at autopsy (scores: 0 = no TDP-43 inclusions, or inclusions in amygdala only; 1 = TDP-43 inclusions in amygdala as well as entorhinal cortex or hippocampus CA1, and neocortex; 2 = TDP-43 inclusions in amygdala, entorhinal cortex or hippocampus CA1, and neocortex, and hippocampal sclerosis pathology) controlling for amyloid plaques and neurofibrillary tangles, Lewy bodies, gross and microscopic infarcts, atherosclerosis, arteriolosclerosis, cerebral amyloid angiopathy, as well as age, sex, years of education, post-mortem interval to fixation and to imaging, and scanners. Unique colours have been assigned to different model estimates (units: mm²) for grey matter regions with significant negative correlation between their volumes and LATE pathology ($P < 0.05$, false discovery rate-corrected); darker colours indicate greater brain atrophy in that region. Results are overlaid on both hemispheres of the T₁-weighted template of the IIT Human Brain Atlas (v.4.2). Lateral, medial and inferior to superior 3D views of the results are also shown. (B) Classification of LATE-NC according to anatomical region(s) affected by TDP-43 proteinopathy. The present working group recommended a simplified staging scheme for routine assessment of LATE-NC. This requires sampling and TDP-43 immunohistochemical staining of amygdala, hippocampus, and middle frontal gyrus. More detailed TDP-43 immunohistochemical staging schemes that are directly relevant to LATE-NC were previously published by Josephs *et al.* (2014a, 2016) and Nag *et al.* (2018). MFG = middle frontal gyrus.

(histopathologically or molecularly) from subtypes of FTLTDP (Arai *et al.*, 2010; Hasegawa *et al.*, 2011; Tsuji *et al.*, 2012; Laferriere *et al.*, 2019); however, more work is needed in this area. For now, definitive criteria to differentiate severe LATE-NC from FTLTDP await discovery of specific features that discriminate among various TDP-43 proteinopathies (Tan *et al.*, 2017a).

Although LATE-NC and ADNC are recognized by differing neuropathological hallmarks, they may share upstream risk factors and disease mechanisms. Genetic variants predisposing to one protein misfolding disorder may also cause or exacerbate others (see below), and there may be interactions between the misfolded proteins themselves (Trojanowski and Lee, 2000; Higashi *et al.*, 2007; Hu *et al.*, 2008; Uryu *et al.*, 2008; Kadokura *et al.*, 2009; Davis *et al.*, 2017; Spires-Jones *et al.*, 2017; Tan *et al.*, 2017b; Nelson *et al.*, 2018). Brains that harbour ADNC, including some subjects with early-onset familial Alzheimer's disease or Down syndrome, tend to also contain TDP-43 proteinopathy at rates higher than those lacking ADNC (Ala *et al.*, 2000; Jellinger, 2000; Lippa *et al.*, 2009; Davidson *et al.*, 2011; Zarow *et al.*, 2012). Individual neurons with both tau neurofibrillary tangle pathology and TDP-43 inclusions have been described, particularly in the amygdala, entorhinal cortex, and dentate gyrus of the hippocampus (Amador-Ortiz *et al.*, 2007b; Kadokura *et al.*, 2009; Smith *et al.*, 2017; Robinson *et al.*, 2018c; Josephs *et al.*, 2019). Several published accounts have evaluated the connections between primary age-related tauopathy (PART) and age-related TDP-43 proteinopathy (Josephs *et al.*, 2017b; Smith *et al.*, 2017; Zhang *et al.*, 2019), and TDP-43 proteinopathy has also been described in brains with coexisting argyrophilic grains or glial tauopathy (Fujishiro *et al.*, 2009; Yokota *et al.*, 2010; Arnold *et al.*, 2013; Kertesz *et al.*, 2015). The implications of comorbid amyloid- β and various tau pathologies in the context of LATE-NC are still incompletely understood, so further studies are required. There is also evidence that Lewy body disease and TDP-43 proteinopathy may coexist (Nakashima-Yasuda *et al.*, 2007; McAleese *et al.*, 2017; Miki *et al.*, 2018; Trieu *et al.*, 2018). On the other hand, many cases with 'end-stage' ADNC or Lewy body disease lack TDP-43 proteinopathy, so we recommend reporting the presence or absence of LATE-NC as a separate diagnostic entity, even when there are comorbid amyloid- β , tau and/or α -synuclein proteinopathies.

Additional research is required to guide future consensus-based recommendations in this evolving field. In terms of immunohistochemical reagents used to detect TDP-43 proteinopathy, there is no current consensus that a specific antibody can be recommended. Many neuropathologists use sensitive phospho-TDP-43 antibodies (Hasegawa *et al.*, 2008; Alafuzoff *et al.*, 2015); small aggregates can be readily seen using these reagents. Others use antibodies against non-phosphorylated epitopes, especially for detecting early changes (pathological nuclear to cytoplasmic redistribution) that may precede inclusion body formation

(Vatsavayai *et al.*, 2016; Braak *et al.*, 2017; Braak and Del Tredici, 2018; Nana *et al.*, 2019). It is unclear whether the absence of nuclear TDP-43 is reversible, but animal studies using inducible pathogenetic systems would suggest so (Ke *et al.*, 2015). Further, there is some evidence that TDP-43 antigenicity can be vulnerable to fixation artefacts, and epitope retrieval methodology can influence results (Hatanpaa *et al.*, 2008). Additional practice guidelines for studying LATE-NC need formal blinded cross validation studies as has been done for amyloid- β , tau and α -synuclein pathological biomarkers. Future studies will be needed to validate and refine systems for staging LATE-NC, and grading local pathological severity, as they relate to clinical and neuroimaging outcomes, especially since at least three staging schemes have been proposed as summarized in Fig. 3B.

Clinical and neurocognitive features of LATE

The clinical course of subjects with autopsy-proven LATE-NC has been characterized as an amnesic cognitive syndrome that can evolve to incorporate multiple cognitive domains and ultimately to impair activities of daily living, i.e. the dementia syndrome (Nelson *et al.*, 2010; Nag *et al.*, 2015; Robinson *et al.*, 2018a, b). The cognitive impairment is greater than can be accounted for by ADNC or other pathologies (Gold *et al.*, 2000; Kawas and Corrada, 2006; Imhof *et al.*, 2007; Giannakopoulos *et al.*, 2008; Nelson *et al.*, 2011b; Kravitz *et al.*, 2012; Boyle *et al.*, 2013; Erten-Lyons *et al.*, 2013). Initial reports on subjects with LATE-NC were focused on subjects with severe pathology (Dickson *et al.*, 1994; Snowden *et al.*, 1997; Crystal *et al.*, 2000; Vinters *et al.*, 2000; Leverenz *et al.*, 2002; Kuslansky *et al.*, 2004; Zarow *et al.*, 2005, 2008; Attems and Jellinger, 2006; Chui *et al.*, 2006; Leverenz and Lipton, 2008), which helped to show that LATE-NC can be associated with dementia. More recent autopsy series, with both large sample sizes and broad ranges of clinical and pathological findings, have enabled statistical approaches to model the likely relative impact of each disease type. With these methods, LATE-NC was associated with substantial cognitive impairment that was independent of other coexisting pathologies (Nelson *et al.*, 2010; Keage *et al.*, 2014; Murray *et al.*, 2014; Josephs *et al.*, 2015; Nag *et al.*, 2017). Table 1 shows primary data on the relationship between LATE-NC (stratified by the recommended three-stage system) and cognition. The neurological features associated with LATE-NC were different from the behavioural or aphasic clinical syndromes seen in FTLTDP cases (Nelson *et al.*, 2011b; Jung *et al.*, 2014; Wilson *et al.*, 2019). While TDP-43 proteinopathy has been documented in some cognitively unimpaired subjects (Arnold *et al.*, 2013; Keage *et al.*, 2014; Uchino *et al.*, 2015; Elobeid *et al.*, 2016; Nascimento *et al.*, 2016; Nag *et al.*, 2018; Nascimento *et al.*, 2018), it is likely that this represents

Table 1 Selected parameters from a large community-based autopsy cohort, stratified by LATE-NC stages

Characteristics	Consensus proposed LATE-NC TDP-43 stages				P-value
	0	1	2	3	
<i>n</i>	666	263	258	189	-
Age at death (SD)	87.9 (6.8)	89.9 (6.2)	91.8 (5.6)	91.9 (5.4)	<0.001

MMSE score	22.8 (8.1)	21.2 (8.9)	18.2 (9.8)	14.0 (10.0)	<0.001
Episodic memory score	-0.60 (1.28)	-0.76 (1.31)	-1.36 (1.34)	-2.06 (1.23)	<0.001

Data were analysed from the Rush University ROS-MAP community-based autopsy cohort; *n* = 1376.

These data were analysed as described previously (Nag *et al.*, 2018) from the Rush University Religious Orders Study (ROS), showing clinical, pathological, and cognitive status features. The new consensus guidelines for LATE-NC staging were applied to highlight the associations between LATE-NC severity (operationalized with new recommended staging method) including hippocampal sclerosis (HS) pathology and cognitive function tests. Note that many of these subjects in all the LATE-NC stages have additional pathologies including ADNC as described previously (Schneider *et al.*, 2007; James *et al.*, 2016).

MCI = mild cognitive impairment; MMSE = Mini-Mental State Examination.

preclinical disease in subjects dying before onset of clinical symptoms; such clinical resilience to pathological changes has been described in many disorders (Perkins *et al.*, 2003; Shojania *et al.*, 2003; Roulson *et al.*, 2005; Latimer *et al.*, 2017; Robinson *et al.*, 2018b).

Although there is overlap in clinical features of autopsy-confirmed LATE-NC and ADNC (Pao *et al.*, 2011; Brenowitz *et al.*, 2014; Murray *et al.*, 2014; Nag *et al.*, 2017), careful analyses may identify distinctive neurocognitive features. Preliminary evidence suggests that subjects with relatively 'pure' LATE-NC (lacking severe comorbid pathologies) tend to have a more gradual clinical decline compared to those with 'pure' ADNC (Murray *et al.*, 2014; Boyle *et al.*, 2017). In contrast, those with comorbid ADNC and LATE-NC showed faster decline and more severe cognitive impairment than those with either ADNC or LATE-NC alone (Josephs *et al.*, 2014b, 2015; Nag *et al.*, 2017). In studies with both detailed longitudinal cognitive testing and comprehensive neuropathological evaluations, subjects with LATE-NC had prominent impairment in episodic memory (Table 1), but other cognitive domains and global cognitive status were also commonly affected especially in the later disease stages (Nag *et al.*, 2015, 2017, 2018; Wilson *et al.*, 2019). Correlative studies indicate that certain neurocognitive assessments, such as verbal fluency measures, are not independently associated with hippocampal volume, but are instead correlated with neocortical grey matter volumes (Ajilore *et al.*, 2015; Pelletier *et al.*, 2017). Correspondingly, subjects with relatively preserved verbal fluency (cortically-dependent), despite profound deficiency in word list delayed recall (hippocampal-dependent), have been shown to be at risk for LATE-NC (Nelson *et al.*, 2011b). This pattern of neurocognitive test scores in LATE differs from that seen in subjects with ADNC

alone (Nelson *et al.*, 2011b) or FTLD-TDP (Brenowitz *et al.*, 2014).

Neuropsychiatric disturbances have been reported in some subjects with LATE-NC (Ighodaro *et al.*, 2015), and a retrospective, cross-sectional, multicentre study found evidence of increased risk of 'agitation/aggression' symptoms in subjects with ADNC and comorbid TDP-43 proteinopathy in comparison to subjects with ADNC lacking TDP-43 proteinopathy (Sennik *et al.*, 2017). However, not all prior studies found that LATE-NC was associated with non-amnesic manifestations (Velakoulis *et al.*, 2009; Nelson *et al.*, 2011b; Vatsavayi *et al.*, 2014; Sahoo *et al.*, 2018). Future investigations are warranted to test for specific neuropsychiatric, motor, or autonomic signs that distinguish LATE from other degenerative disorders.

Public health impact of LATE

The public health impact of LATE is likely to be quite significant. Two basic study design elements that influence recognition of LATE-NC in autopsy cohorts are the age range in the cohort, and the date of the study. Researchers were unaware of TDP-43 proteinopathy prior to 2006, so studies prior to this time could not assess the specific impact of LATE. LATE-NC is mostly seen in the oldest-old, whereas in early clinical-pathological correlation studies of dementia (Roth *et al.*, 1966; Blessed *et al.*, 1968), the research subjects had died in their early 70s. LATE-NC needs to be assessed in population studies that include all age ranges. More recent clinical studies have demonstrated biomarker evidence of 'suspected non-Alzheimer's disease pathophysiology' (SNAP) causing amnesic type cognitive impairment with substantial hippocampal atrophy but lacking detectable amyloid- β amyloidosis (Caroli *et al.*, 2015;

Rush University community-based cohort data ($n = 1376$)

NACC multicentre autopsy cohort data ($n = 806$)

Figure 4 Different neurodegenerative disease conditions stratified by age: LATE-NC, severe ADNC, and FTD. FTD/FTLD cases were not present in data shown in **A–D**. Note that published studies to estimate disease prevalence for the various diseases have used importantly different study designs—thus, **E** is a clinical (no autopsy) study because population-based autopsy cohorts lack substantial numbers of FTD/FTLD cases. (**A** and **B**) Data from a community-based autopsy cohort—the Rush University ROS-MAP cohort (overall $n = 1376$). The TDP-43 pathology is operationalized using standard methods as described previously (Nag *et al.*, 2018) and then the current paper’s suggested simplified staging system was applied; sample sizes for each age group (in years) are: <75 ($n = 34$); 75–80 ($n = 82$); 80–85 ($n = 192$); 85–90 ($n = 375$); 90–95 ($n = 407$); 95–100 ($n = 222$); and >100 ($n = 64$). Note that in this community-based sample, the proportion of cases with advanced ADNC is <50% in all age groups. (**C** and **D**) Data from the National Alzheimer’s Coordinating Center (NACC), which derives from 27 different research centres, as described previously (Besser *et al.*, 2018; Katsumata *et al.*, 2018). Overall sample size is $n = 806$, stratified thus by age groups (in years): <75 ($n = 155$); 75–80 ($n = 118$); 80–85 ($n = 165$); 85–90 ($n = 170$); 90–95 ($n = 122$); 95–100 ($n = 57$); and >100 ($n = 19$). The NACC research subjects were more likely to come to autopsy after being followed in dementia clinics, and the sample includes a higher percentage of subjects with severe ADNC. The percentage of subjects with LATE-NC is still >20% in each age group. Note that in both the community-based cohort (**A**

(continued)

Burnham *et al.*, 2016; Jack *et al.*, 2016, 2017; Abner *et al.*, 2017; Wisse *et al.*, 2018). For example, the evaluation of 1535 participants in the Mayo Clinic Study of Aging showed significantly greater prevalence of SNAP compared with preclinical Alzheimer's disease, and multimorbidity was increased in SNAP (odds ratio 2.16) (Vassilaki *et al.*, 2018). LATE is probably an important contributor in this group of subjects (see below).

Among subjects autopsied past 80 years of age, most studies indicate that >20% of brains had pathological features consistent with LATE-NC (Fig. 4). It is noteworthy that the majority of these cases had additional comorbid pathologies, so the measured clinical-pathological correlation (relative contribution of each pathology to cognitive impairment) depends on how the investigators defined diagnostic thresholds and cut-points. The frequency of LATE-NC in autopsy series have varied, ranging from 5% to 50% of brains that were evaluated using TDP-43 immunohistochemistry, approximately twice the frequencies that were detected in prior studies that could only assess hippocampal sclerosis pathology (Leverenz *et al.*, 2002; Lippa and Dickson, 2004; Arai *et al.*, 2009; Nelson *et al.*, 2011b; Rauramaa *et al.*, 2011; Tremblay *et al.*, 2011; Corrada *et al.*, 2012; Zarow *et al.*, 2012; Malek-Ahmadi *et al.*, 2013; Keage *et al.*, 2014; Jellinger and Attems, 2015; Uchino *et al.*, 2015; Takao *et al.*, 2016; Latimer *et al.*, 2017; McAleese *et al.*, 2017; Hokkanen *et al.*, 2018; Kero *et al.*, 2018; Robinson *et al.*, 2018a). Differences in study design, including the application of various criteria for defining pathological abnormalities, pathological methods, recruitment strategy, and cohort demographics, all contribute to the variability in the reported frequency of LATE-NC.

One approach that can be used to assess the public health impact of a disease is the evaluation of attributable risk (Porta, 2014). Although generally used to study the impact of risk factors on disease prevalence in a population (Bruzzi *et al.*, 1985), this statistical method can be applied to neuropathological studies to indicate the relative impact of different neuropathologies on clinical dementia. More specifically, the assessment of attributable risk can query how the frequency of LATE-NC, in relation to other common brain lesions detected at autopsy, is associated with the probability

of a dementia diagnosis (Boyle *et al.*, 2019). This analytical approach theoretically makes it possible to estimate the proportion of dementia that might be prevented if LATE-NC could be eliminated, and to compare that with other neuropathologies. The results of an analysis of attributable risk in the Rush University Religious Orders Study is shown in Table 2; methods have been described in detail previously (Boyle *et al.*, 2019). These data are compatible with the hypothesis that a significant (~15–20%) proportion of clinically diagnosed Alzheimer's disease dementia (i.e. the Alzheimer's clinical syndrome) in advanced age is attributable to LATE-NC; the impact is about half the magnitude of ADNC in this group of older subjects, and the impact is similar to the combined effects of vascular neuropathologies.

Also pertinent to the current and future public health impact of LATE is the age range of subjects with highest risk for the disease. The tendency for LATE-NC to occur among the oldest-old has been appreciated for decades, since the groundbreaking studies on age-related hippocampal sclerosis (Crystal *et al.*, 1993; Dickson *et al.*, 1994), a pathological manifestation later shown to be associated with LATE-NC. In multiple subsequent large autopsy samples, LATE-NC was observed with increasing frequency in each year of life after age 85 (Nelson *et al.*, 2013; Keage *et al.*, 2014; Uchino *et al.*, 2015; Hokkanen *et al.*, 2018) (Fig. 4). This is in contrast to amyloid- β plaques, which are common (seen in >50% of subjects) in all elderly age groups, but are not universal and not more frequently seen at autopsy with every year of advanced old age (Braak *et al.*, 2011; Nelson *et al.*, 2011a, 2013; Brenowitz *et al.*, 2014; Neltner *et al.*, 2016). LATE appears to be ~100-fold more prevalent than FTD syndromes, which tend to affect younger subjects (Knopman and Roberts, 2011; Coyle-Gilchrist *et al.*, 2016) (Fig. 4E; note the y-axis scale). Females are generally more likely to survive to advanced old age than males (Neltner *et al.*, 2016), which places them at increased lifetime risk for LATE. Otherwise, there is no compelling evidence to date of strong sex-related or ethnoracial differences in susceptibility to LATE (Brenowitz *et al.*, 2014; Murray *et al.*, 2014; Latimer *et al.*, 2017; Oveisgharan *et al.*, 2018), but further studies in diverse populations are needed. Since most

Figure 4 Continued

and **B**) and clinic-based cohort (**C** and **D**), the proportion of subjects with severe ADNC decreased in advanced old age, while in the same cases the proportion of subjects with LATE-NC increased. (**E**) Epidemiological data on FTD syndromes for comparison to LATE. Data are provided about crude prevalence rates for FTD syndromes that have been associated with FTLD-TDP. Several of these clinical syndromes are likely to have considerable numbers of cases with FTLD-tau (bvFTD and nfvPPA) or ADNC (other PPA) rather than FTLD-TDP, so the actual prevalence of FTLD-TDP pathology is probably lower than these data suggest. Note that the clinical syndromes associated with FTLD-TDP have a prevalence that are several orders of magnitude lower than LATE-NC. These data, described in detail previously (Coyle-Gilchrist *et al.*, 2016), derive from multisource referral over 2 years, which identified all diagnosed or suspected cases of FTD subtypes in two UK counties comprising the PiPPIN (Pick's Disease and Progressive Supranuclear Palsy: Prevalence and Incidence) catchment area in the East of England. Two cities in the PiPPIN catchment area were Norfolk and Cambridge. Diagnostic confirmation used current consensus diagnostic criteria after interview and re-examination. Total sample size was $n = 986\,483$ subjects. Shown are crude prevalence rates for the major FTLD-TDP associated syndromes by age and syndrome. bvFTD = behavioural variant frontotemporal dementia; nfvPPA = non-fluent agrammatic variant primary progressive aphasia; svPPA = semantic variant PPA. Note that subjects between ages 55 and 80 are at greatest risk for FTD, and, the FTLD-TDP associated FTD syndrome prevalence is <30 per 100 000 (**E**), in sharp contrast to the data shown in **A–D**.

Table 2 A statistical analysis of attributable risk from research volunteers in two clinical-pathological studies of ageing from Rush University

Neuropathological indices	Fraction attributable % (95% CI) ^a
Alzheimer's disease (ADNC)	39.4 (31.5–47.4)
Vascular disease pathology ^b	24.8 (17.3–32.1)
LATE-NC	17.3 (13.1–22.0)
α -Synucleinopathy/Lewy body pathology	11.9 (8.4–15.6)

Shown are fractions of dementia of the Alzheimer type cases that were attributable to individual neuropathological indices in advanced age. In this sample, the mean age of death was 89.7 years (SD 6.5 years, range 65–108 years). For these analyses, multi-variable logistic regression models examined associations of neuropathological indices with the outcome of Alzheimer's-type clinical dementia and quantified the percentage of cases attributable to each. Methods have been described in detail previously (Boyle *et al.*, 2019). These data give strong indication that the public health impact of LATE is large, on the same order of magnitude as ADNC, vascular pathologies, and Lewy body pathology.

^a95% CIs were derived using bootstrapping.

^bVascular pathologies included: cerebral amyloid angiopathy, atherosclerosis, arterio-sclerosis and gross infarcts.

relevant current data were derived from autopsy cohorts, the prevalence of LATE-NC may be higher in younger subjects than currently recognized if there is a survival bias (those with LATE-NC live to older ages), underscoring the need for more longitudinal studies that incorporate clinical biomarkers. Since the demographic group made up of subjects past 85 years of age is predicted to greatly expand in the coming decades (Gardner *et al.*, 2013; Nelson *et al.*, 2013), LATE is likely to become a far greater public health burden in the future unless preventative or therapeutic strategies are developed.

Genetics of LATE

Genetic studies provide insights into disease-related mechanisms and, potentially, future therapeutic targets. The following five genes (in the chronological order in which they were identified) have been reported to harbour risk alleles associated with pathological manifestations we refer to as LATE-NC: granulin (*GRN*) on chromosome 17q, transmembrane protein 106B (*TMEM106B*) on chromosome 7p, ATP-binding cassette sub-family member 9 (*ABCC9*) on chromosome 12p, potassium channel subfamily M regulatory beta subunit 2 (*KCNMB2*) on chromosome 3q, and apolipoprotein E (*APOE*) on chromosome 19q (Dickson *et al.*, 2010; Pao *et al.*, 2011; Beecham *et al.*, 2014; Murray *et al.*, 2014; Nelson *et al.*, 2014, 2015b; Aoki *et al.*, 2015; Katsumata *et al.*, 2017; Yang *et al.*, 2018). See Supplementary Table 1 for summary information on these genes and their associated phenotypes. For this discussion, we include the endophenotype that was used in the published research (usually hippocampal sclerosis) rather than LATE-NC.

Gene variants in *GRN* and *TMEM106B* were shown to be associated with hippocampal sclerosis and TDP-43

proteinopathy risk using allele tests, based on the known relationship of those two genes to FTLT-TDP (Baker *et al.*, 2006; Boeve *et al.*, 2006; Cruts *et al.*, 2006; Van Deerlin *et al.*, 2010). These gene variants have now been most consistently associated with risk of LATE-NC. For the association between the *GRN* and hippocampal sclerosis, Dickson *et al.* showed that hippocampal sclerosis in aged subjects was associated with the T-allele of the *GRN* single nucleotide polymorphism (SNP) rs5848 (Dickson *et al.*, 2010; Murray *et al.*, 2014). Aoki and colleagues reported that the frequency of the C-allele of *TMEM106B* rs1990622 in hippocampal sclerosis was lower than that in non-hippocampal sclerosis controls (Aoki *et al.*, 2015). Following the initial studies, the findings were replicated of increased risk for hippocampal sclerosis associated with each copy of the T-allele of *TMEM106B* rs1990622 (Nelson *et al.*, 2014, 2015b; Dickson *et al.*, 2015; Yu *et al.*, 2015).

Since *GRN* and *TMEM106B* were both implicated in FTLT-TDP, their strong association with LATE-NC provides compelling evidence for pathogenetic overlap between FTLT-TDP and LATE. From a mechanistic perspective, the cognate proteins for these genes have been shown to play important roles in endosomal/lysosomal biology, and there is experimental evidence for interaction of these gene products (Chen-Plotkin *et al.*, 2012; Nicholson and Rademakers, 2016; Klein *et al.*, 2017; Zhou *et al.*, 2017; Paushter *et al.*, 2018). The *TMEM106B* gene appears to be pleiotropic for multiple diseases (Gallagher *et al.*, 2014; Ou *et al.*, 2015; Hsiao *et al.*, 2017; Cherry *et al.*, 2018; Chornenkyy *et al.*, 2019), and the LATE-NC risk allele in *TMEM106B* may influence healthy brain ageing (Rhinn and Abeliovich, 2017; Ren *et al.*, 2018). Separate studies have found that *GRN* gene products (granulins) play roles in inflammation and wound repair (Ahmed *et al.*, 2007; Miller *et al.*, 2013). Notably, the *GRN* risk variant rs5848 has been associated with increased inflammatory mediators in CSF (e.g. AXL and CLU) (Fardo *et al.*, 2017). More work is required to enable better understanding of how molecular pathways relevant to FTLT-TDP are involved in LATE.

An important recent finding by several different groups is that the *APOE* ϵ 4 allele, which is a risk factor for ADNC and Lewy body disease, is also associated with increased risk for TDP-43 proteinopathy in the elderly (Robinson *et al.*, 2018c; Wennberg *et al.*, 2018; Yang *et al.*, 2018). Other studies did not find an association between *APOE* genotypes and risk for hippocampal sclerosis (Troncoso *et al.*, 1996; Leverenz *et al.*, 2002; Nelson *et al.*, 2011b; Pao *et al.*, 2011; Brenowitz *et al.*, 2014; Hall *et al.*, 2019; but see Farfel *et al.*, 2016). Few subjects with the *APOE* ϵ 4 allele survive into advanced old age without any amyloid- β plaques (Saunders *et al.*, 1993; Schmechel *et al.*, 1993), and it remains to be seen exactly how the *APOE* ϵ 4 protein influences TDP-43 proteinopathy. Nevertheless, recent studies from large research cohorts have provided additional insights into the presence of pathogenetic mechanisms that are shared between neurodegenerative diseases.

Since the presence or absence of risk alleles in *TMEM106B*, *GRN*, and *APOE* cannot by themselves or in combination confidently predict the risk for LATE-NC in a given subjects (Katsumata *et al.*, 2017; Nelson *et al.*, 2019), there must be other factors that influence the disease phenotype. The connections of the *ABCC9* and *KCNMB2* genes with risk of LATE-NC were discovered via genome-wide association studies (GWAS), which are neither helped nor biased by prior mechanistic hypotheses. The finding of the associations between *ABCC9* gene variants and LATE-NC (Nelson *et al.*, 2015*b*), and brain atrophy detected with MRI (Nho *et al.*, 2016), were reported in separate samples from the initial GWAS (Nelson *et al.*, 2014). Neither *ABCC9* nor *KCNMB2* gene variants were associated with LATE-NC in cohorts other than those described above. *ABCC9* and *KCNMB2* are genes coding for proteins that serve to regulate potassium channels (Zarei *et al.*, 2007; Nelson *et al.*, 2015*a*). The *ABCC9* risk genotype also implicates thyroid hormone dysregulation in LATE-NC; the locus was found to be associated with altered brain expression of genes induced by thyroid hormone (Nelson *et al.*, 2016*a*). Thyroid hormones have been found to be dysregulated in subjects with autopsy-confirmed LATE-NC in recent studies (Trieu *et al.*, 2018; Nelson *et al.*, 2019), and high thyrotropin was associated with reduced hippocampal volume in a population-based study (Ittermann *et al.*, 2018). A gene variant near *ABCC9*, which lies within both the *SLCO1A2* and *IAPP* genes, was also found in a GWAS study to be associated with neurodegeneration disproportional to amyloid- β accumulation (Roostaei *et al.*, 2016), which may indicate LATE in those cases. The *KCNMB2* gene has been associated with suicidal ideation in US military veterans (Kimbrel *et al.*, 2018) and may be related to depression, which is common in the elderly. Further, when *KCNMB2* is over-expressed in the hippocampus of mice, it rescues memory deficits (Yu *et al.*, 2018). More work is required to enable better understanding and identification of the molecular pathways involved in LATE.

Prior genetic studies on TDP-43 proteinopathy and hippocampal sclerosis have varied in important ways, including patient inclusion/exclusion criteria, disease definitions, and age composition, which may explain their differing findings with regard to genotype/phenotype associations. The prospects for successful future genetic discoveries will be improved by the development of specific and standardized LATE-NC endophenotypes. FTL-D-TDP provides an example in which pathological subtyping of patients has been beneficial for genetic correlation studies: there are, for example, strong associations between *TMEM106B* and *GRN* gene variants with FTL-D-TDP type A pathology (Rademakers *et al.*, 2008; Aoki *et al.*, 2015). Preliminary studies suggest that distinguishing morphology of TDP-43 pathology in LATE-NC may also be relevant to genetic risk (Josephs *et al.*, 2019). We speculate that genetic profiling may eventually become a key consideration for recruitment to clinical trials, and possible future precision medicine

approaches, since some genotypes may be differentially responsive to specific interventions.

LATE biomarkers

Optimal biomarkers for LATE, including biofluids or PET ligands, would be specific for the disease-defining feature, namely TDP-43 proteinopathy (Steinacker *et al.*, 2018). At this time, no biofluid or PET biomarker satisfies this essential criterion of molecular specificity. Nor do PET ligands for LATE seem to be on the near-term horizon. The problems of intracellular location and small pathological burden of TDP-43 proteinopathy are obstacles that limit signal-to-noise ratio for biomarkers.

The NIA-AA Research Framework group recommended a system for classifying subjects based on amyloid- β amyloid (A), tau (T) and neurodegeneration/neuronal injury (N) biomarkers, which is termed AT(N) (Burnham *et al.*, 2016; Jack *et al.*, 2016). Each biomarker category can be binarized as positive (+) or negative (–) resulting in eight possible biomarker profiles. Certain AT(N) profiles indicate increased likelihood that LATE-NC might be present. The ‘N’ in AT(N) is in parentheses to indicate that it represents cumulative brain injury/neurodegeneration from all aetiologies and is not specific for any one aetiology. An assumption is that in Alzheimer’s disease, neurodegeneration is associated with tauopathy, and therefore in an A+T–(N)+ subject, the N+ is likely due to a comorbid non-Alzheimer’s disease pathophysiological process(es). If (N)+ is ascertained by an imaging measure that captures neurodegeneration as reflected medial temporal atrophy or hypometabolism, then this implicates LATE (often with hippocampal sclerosis) as a likely non-Alzheimer’s disease comorbidity. Similar logic applies to subjects with an A–T–(N)+ profile, the N+ is presumably due to a non-Alzheimer’s disease pathological process(es), and if the (N)+ measure is hippocampal atrophy, or medial temporal hypometabolism, then LATE is implicated (Fig. 5).

SNAP is a non-specific biomarker-defined category that affects ~15–30% of subjects in prior clinical series (Jack *et al.*, 2012; Vos *et al.*, 2013; Wisse *et al.*, 2015; Burnham *et al.*, 2016; Gordon *et al.*, 2016), and includes a variety of non-Alzheimer’s disease aetiologies, but prominent among these is LATE. Autopsy studies indicate that LATE-NC can exist without other brain pathologies, but commonly co-occurs with ADNC (Jellinger, 2000; Attems and Jellinger, 2006; Josephs *et al.*, 2014*b*, 2015, 2016); biomarker studies are consistent with those results. Botha *et al.* (2018) have shown that tau-PET-negative dementia can mimic Alzheimer’s disease clinically, suggesting that LATE is probably a common cause of tau-negative dementia. Further, a fluorodeoxyglucose (FDG) PET measure (the ratio of inferior to medial temporal metabolism) was elevated in autopsy proven LATE with hippocampal sclerosis compared to autopsy proven Alzheimer’s disease cases lacking LATE-NC (Botha *et al.*, 2018). LATE-NC was confirmed at autopsy in two subjects with tau-PET-negative

Figure 5 Biomarkers are currently not specific to LATE-NC. (A) Radiological scans from an 86-year-old female who suffered amnesic cognitive impairment compatible with ‘Probable Alzheimer’s disease’ diagnosis. However, the amyloid- β PET scan was negative, tau PET scan was also negative, and the MRI showed appreciable atrophy of the medial temporal lobes bilaterally. This combination is considered ‘A–T–N+’ and was diagnosed during life as ‘suspected non-Alzheimer’s pathology’ (SNAP). Autopsy within a year of the brain scans confirmed the presence of TDP-43 pathology and hippocampal sclerosis, which now is diagnosable as LATE-NC. (B) Another common biomarker combination, in the brain of a 91-year-old male with dementia. In this subject, the amyloid PET scan was positive, yet the tau PET scan was negative. The MRI again showed atrophy of the medial temporal lobes. The combination of pathologies—in this case presumed early ADNC and comorbid LATE-NC—is common, especially in the brains of subjects in advanced age.

scans who both had elevated inferior to medial temporal FDG metabolism ratios. These data are compatible with the hypothesis that cognitively impaired tau-PET-negative subjects with marked medial temporal hypometabolism are likely to have LATE-NC. Other studies correlating autopsy findings with post-mortem magnetic resonance measures of regional tissue T_2 relaxation times (Dawe *et al.*, 2014), hippocampal shape (Dawe *et al.*, 2011), and regional cortical volume measures (Kotrotsou *et al.*, 2015) indicate that neuroimaging signatures of ADNC and LATE-NC may differ (see above). The shape differences in the medial temporal lobes associated with LATE-NC versus ADNC provide potential imaging biomarkers of LATE (Dawe *et al.*, 2011; Makinejad *et al.*, 2019), whereas the evaluation of multiple brain regions is warranted as demonstrated in Fig. 3.

A non-specific biomarker of cumulative brain injury (N) may be useful in the context of LATE. If a biomarker for LATE is not forthcoming, then a quantitative *in vivo* indicator might remain the difference between the magnitude of

an observed (N) biomarker minus the predicted (N) value given the results of all other known biomarkers. A predictive (but not diagnostic) LATE measure could be envisioned as the ‘residual of the regression’ of expected on observed medial/basal temporal neurodegeneration, given all knowable information about other pathological processes. Recent studies indicate that neurofilament light chain (NfL) might be a preferred biofluid (N) biomarker (Zetterberg, 2016; Kortvelyessy *et al.*, 2018) but perturbation of NfL in LATE (plasma or CSF) remains to be tested. Moreover, elevated levels of NfL occur in many different causes of brain injury so NfL lacks disease specificity.

Although no specific LATE biomarker exists at present, the AT(N) system was designed explicitly to enable expansion to incorporate new biomarkers in categories beyond AT(N) (Jack *et al.*, 2018). If or when a biomarker of LATE is validated, AT(N) could be expanded to ATL(N), where ‘L’ stands for LATE. The ultimate objective would be comprehensive characterization of many relevant brain

pathologies *in vivo* using combinations of biomarkers. Future diagnostic biomarkers may be less centred on ADNC, and able to incorporate the common combinations of diseases that occur in ageing brain better. This concept is illustrated in Supplementary Table 2.

If a specific biomarker for LATE is developed, this may complement ongoing efforts to develop an optimal neuropathological assessment. LATE-NC may in the future be assessed along three dimensions: stage (i.e. anatomical distribution); subtype (i.e. differing histopathological patterns in a given region); and grade (i.e. severity or pathological load). While systems for subtyping or grading LATE-NC have yet to be validated, these may in the future be useful for early diagnosis, improved clinical prognosis, and development of new strategies to treat or prevent the disease.

Implications for Alzheimer's disease and LATE clinical trials

Formalization of LATE diagnostic criteria and increased awareness of this disease should help guide the design and interpretation of Alzheimer's disease clinical trials. Comorbid ADNC and LATE-NC becomes increasingly more prevalent with advancing age, and the mechanisms underlying each of these common lesions have independent effects on cognitive performance (Nelson *et al.*, 2010). LATE-NC, when coexisting with ADNC, will have the potential to obscure the effects of a potential disease modifying agent on cognitive assessment results in living subjects. The primary outcome measures in disease-modifying Alzheimer's disease clinical trials will remain cognitive or functional scales for the foreseeable future (Cummings *et al.*, 2016; Register, 2018). Thus, the presence of LATE-NC will complicate interpretation of Alzheimer's disease-specific treatment effects that are inferred from observed cognitive outcomes. Until there are biomarkers for LATE, clinical trials should be powered to account for TDP-43 proteinopathy.

LATE is among the common age-related diseases that can mimic the amnesic presentation of Alzheimer's disease (Nelson *et al.*, 2013), and it is one of many reasons why biological rather than clinical disease definitions are important in the era of disease modifying clinical trials (Jack *et al.*, 2018). Biomarkers have roles for both inclusion and exclusion. It will be important, at recruitment of subjects into future disease-modifying Alzheimer's disease clinical trials, to stratify according to major known predictors, including clinical features, genetics, and known biomarkers. This stratification will enable enrichment for subjects on the ADNC continuum (Sevigny *et al.*, 2016) while excluding subjects likely to have high risk for LATE-NC (Botha *et al.*, 2018). Even with best efforts at baseline, the multiplicity of diseases that occur in brains of older subjects will still require analyses according to subgroups. This is another reason why clinical trials in dementing diseases of ageing will require large sample sizes.

Research into Alzheimer's disease has provided additional topical caveats (Gulisano *et al.*, 2018; Hunter *et al.*, 2018; Morris *et al.*, 2018). For example, there is a danger that we fundamentally misunderstand the nature and complexity of processes related to TDP-43 proteinopathy, and this could lead to significant biases in the ways that we approach clinical diagnosis and clinical trials of LATE. For now, as with Alzheimer's disease, the misfolded proteins provide a disease marker and a potential target for therapies.

Clinical trials directed at preventing or treating LATE, in isolation or in concert with other brain diseases, should be a major direction for future research. Performing such trials optimally will first require development of a specific LATE biomarker. For now, five alternative, but not mutually exclusive, approaches exist for developing disease-modifying therapies: (i) focus on pathways and gene products such as *APOE* ϵ 4 that seem to be in common between Alzheimer's disease, Lewy body disease, and LATE; (ii) focus on pathways and gene products such as *TMEM106B* and *GRN* that are shared between FTLTDP and LATE; (iii) focus on pathways and gene products such as *ABCC9* and *KCNMB2* that have been implicated by GWAS; (iv) focus on potential research subjects with the A–T–(N+) biomarker profile, who are now excluded from many Alzheimer's disease-related clinical trials; and/or (v) focus on strategies to eliminate TDP-43 aggregates or to prevent the formation of these aggregates.

Conclusions and future directions

A key goal of this working group effort was to catalyse future research on LATE, an under-recognized condition that affects many older subjects. It is important to promote awareness in multiple scientific areas and to focus on translational and interdisciplinary approaches.

Development of specific LATE biomarker(s) should be a high scientific priority. While a sensitive and specific biomarker using neuroimaging or biofluids would be ideal, other disease markers could capitalize on existing metrics such as the AT(N) research guidelines with or without imaging or biofluid risk profiling. Developing biomarkers or other criteria to identify subjects with LATE would augment observational studies that seek to unravel the natural history of LATE, and its coevolution with other ageing-related diseases. With sufficient longitudinal observations, cause and effect inferences may become possible, and clinical trials implemented.

Further pathology studies will also be necessary. The consensus pathological classification scheme that we propose should be considered preliminary because much remains to be learned about LATE. The application of pathological subtyping has been useful in the context of FTLTDP (Lee *et al.*, 2017; Mackenzie and Neumann,

2017; Pottier *et al.*, 2018), and pathological subtyping may help refine LATE-NC endophenotypes for diagnostic and genetic studies (Josephs *et al.*, 2019). At this point, there is no consensus about how or whether to apply such criteria for LATE-NC. A detailed characterization of the molecular pathology of TDP-43 is required for different cell types across brain regions in large population-representative samples. This should include characterization of various phosphorylation states, cleavage fragments, and other post-translational modifications of TDP-43. Further, each anti-TDP-43 antibody used should be assessed for potential cross-reactivity with other proteins or LATE-NC features *in situ*. It will also be important to determine the prevalence of all co-pathologies associated with LATE-NC, the impact of the molecular conformations and modifications of TDP-43, the cellular types involved, and the natural history of the disease. These advances will also assist in developing animal models.

Additional epidemiological, clinical, neuroimaging, and genetic studies will be important to better characterize the public health impact and clinical phenotypes for LATE. Further, LATE must be studied in more diverse populations and cohorts. Careful clinical assessments over time and into the oldest age groups is essential, along with detailed biological measures and autopsy, so that the complexity of ageing changes can be assessed (Brayne, 1993). *In vivo* and *ex vivo* imaging studies to determine the focal and more diffuse changes in the brains of subjects with LATE will also be important. Future studies may generate better insights into the clinical indices and cognitive features that are associated with increased probability of LATE-NC. Risk factors, protective influences, and other correlates could thus be identified to help prevent or predict LATE. For example, autoimmune disease may play a role in TDP-43 proteinopathy and LATE-NC in particular (Miller *et al.*, 2013; Trieu *et al.*, 2018). Optimally, future studies will complement traditional GWAS and gene-focused analyses with multi-omics studies to capture a greater appreciation of the complex mechanisms and diagnostic or therapeutic opportunities in the study of LATE.

Animal models and basic science research into LATE are imperative, with the caveat that the aged human brain is challenging to model accurately. Functional studies, including transmission animal models that use TDP-43 fibrils (Porta *et al.*, 2018) or extracts from brains with LATE-NC injected into animals or cell cultures (Laferriere *et al.*, 2019), can be combined with genetic studies to test hypotheses and to add statistical power for preclinical and hypothesis-testing experiments. Molecular studies that focus on TDP-43 and the upstream triggers and downstream molecular consequences are necessary to elucidate mechanisms of disease. Models that account for co-pathologies are rare at present, but have the potential to be highly informative. Ultimately, it is hoped that these collective research efforts will one day result in successful preventative and therapeutic strategies.

Acknowledgements

We sincerely thank the research volunteers, clinicians, staff, and other colleagues for their hard work. The LATE working group meeting organizational committee consisted of Drs Peter Nelson, Nina Silverberg, Dennis Dickson, Julie Schneider, John Trojanowski, and Helena Chui. The working group in-person meeting (October 17–18 in Atlanta, GA, USA) included most of the co-authors, and Drs Nina Silverberg, Eliezer Masliah, Cerise Elliott, and Linda Van Eldik attended and contributed. Statistical analyses in Figs 2 and 3 were performed by co-author Dr Lei Yu. Thanks to Dr Hannah Keage at the University of South Australia for editorial help.

Funding

Direct support for meeting logistics was provided via a NIA/NACC grant (supplemental to the parent NIH grant U01 AG016976 to W.A.K.). Support from the National Health and Medical Research Council of Australia (NHMRC) included NHMRC Senior Principal Research Fellowship (1079679) and other NHMRC grants (1132524, 1095127, 1037746) to G.H. Grant support from U.S. National Institutes of Health included grants P01 AG003949 (D.W.D.), R01 AG037491 (D.W.D.), P50 AG016574 (D.W.D.), R01 AG054449 (M.E.M.), P30 AG028303 (P.T.N. and G.A.J.), P30 AG012300 (C.L.W.), P30 AG049638 (T.J.M.), P30 AG010124 (J.Q.T.), P30 AG010161 (K.A., J.A.S., P.A.B.), P50 AG047366 (T.J.M.), P50 AG025688 (A.I.L.), P50 AG005131 (R.A.R.), R37 AG011378 (C.R.J.), R01 AG041851 (C.R.J.), R01 AG042210 (J.A.S.), R01 AG017917 (J.A.S.), R01 AG034374 (P.A.B.), UF1 AG053983 (T.J.M.), UF1 AG057707 (T.J.M.). UK grants included ARUK-PhD2014–19, and NIHR Senior Investigators award Ref: 534906 NF-SI-0616–10090 to co-author C.B. National Institute for Health Research, Senior Investigator Award, was awarded to C.B. for C.B. and S.H. The views expressed are those of the authors and not necessarily those of the NHS, the NIHR or the Department of Health and Social Care. S.H. is supported by the Addenbrooke's Charitable Trust, the Paul G. Allen Family Foundation and Alzheimer's Research, UK. S.R.K.H. is supported by Alzheimer's Research, UK. See Appendix 1 for additional acknowledgments.
