Optical clearing is a versatile approach to improve imaging quality and depth of optical microscopy by reducing scattered light. However, conventional optical clearing methods are restricted in the efficiency-first applications due to unsatisfied time consumption, irreversible tissue deformation, and fluorescence quenching. Here, we developed an ultrafast optical clearing method (FOCM) with simple protocols and common reagents to overcome these limitations. The results show that FOCM can rapidly clarify 300-μm-thick brain slices within 2 min. Besides, the tissue linear expansion can be well controlled by only a 2.12% increase, meanwhile the fluorescence signals of GFP can be preserved up to 86% even after 11 d. By using FOCM, we successfully built the detailed 3D nerve cells model and showed the connection between neuron, astrocyte, and blood vessel. When applied to 3D imaging analysis, we found that the foot shock and morphine stimulation induced distinct c-fos pattern in the paraventricular nucleus of the hypothalamus (PVH). Therefore, FOCM has the potential to be a widely used sample mounting media for biological optical imaging.

optical clearing | tissue clearing | deep tissue imaging

Deep tissue imaging with subcellular resolution is one of the most demanded techniques in biological science, since it can restore the morphology of cells and analyze the system-level information (1–3). Up to now, imaging deep inside tissue is still a major challenge due to high scattering properties of biological sample such as brain tissue (4–6). Generally, mechanical tissue sectioning methods are used to image the whole sample (7, 8). However, they may involve sample deformation, losing detail information especially from the edge of each slice, and usually require considerable time and labor. However, current emerged optical imaging techniques can either achieve single-cellular resolution to a depth of several millimeters in the mouse brain by using scattered light (9–12) or recover near diffraction-limited resolution at around 400 μm deep into mouse brain by compensating optical aberrations (13–15). However, these optical systems are usually suffered from low imaging speed and high price. Tissue clearing is an affordable alternative to imaging deep by reducing the tissue scattering and unifying the refractive index (RI) distribution.

Current pioneering optical clearing methods are classified as: (*i*) SeeDB (16–18) and *Clear^T* (19) immerse the tissue into a high RI solution to match the RI; (*ii*) CLARITY (20–22), PACT, and PARS (23) remove cell membranes and protein by SDS to decrease the scattering of the sample while preserving native epitope with acrylamide hydrogel; (*iii*) 3DISCO (24), iDISCO (25), uDISCO (26) and FDISCO (27) as dichloromethane and dibenzyl ether are key organic compounds render tissue transparent by lipid removal and protein denaturation; and (*iv*) Scale (28) and Scale S (29) partially denatured protein for hyperhydration with urea. CUBIC (30, 31) further applied delipidation reagents to obtain better results (32, 33).

However, the current optical clearing methods have the disadvantages of large time consumption, morphology distortion, and complex protocols, which greatly restrict their applications especially in the efficiency-first field. In addition, in hydrogel embedding and solvent-based clearing methods, the toxic reagents cause severe fluorescence quenching and the general membrane dyes cannot be targeted due to lipid removal. Moreover, tissue may become fragile after clearing process, making it inconvenient to transfer the sample from incubate chamber to the imaging platform. Here, we report an ultrafast optical clearing method (termed FOCM), which combined dehydration of water-miscible polar solvent and hydration of urea together with almost no tissue deformation, less fluorescent toxicity, and ease of operation. With FOCM, a 300-μm-thick brain section could be cleared within 2 min by four commonly used reagents: dimethyl sulfoxide (DMSO), urea, D-sorbitol, and glycerol. Thus, FOCM enabled a practical and efficient way to reduce tissue scattering and improve optical imaging quality.

Results

FOCM Combines Dehydration of Solvent with Hyperhydration, Enabling an Ultrafast Tissue Clearing with Negligible Distortion. Considering the clearing efficiency, we used DMSO as a solvent for its features of low toxicity, high dissolving ability, and protein partially denatured capacity. The previous studies demonstrated that the detected signals could be increased as the scattering was substantially reduced by DMSO in both in vivo and in vitro skin (6, 34). Urea was proved to be a good choice in ScaleS and CUBIC for its clearing

---

Significance

Most biological tissue is opaque, and the inside fine structures are invisible even with a microscope. Optical clearing methods can reduce the scattering and enable us to "look" inside the biological samples. Current optical clearing methods suffer from large time consumption, tissue distortion, and fluorescence quenching, which greatly limit their applications. Here, we describe a nontoxic ultrafast optical clearing method (FOCM), which could clarify 300-μm-thick brain slices within 2 min without morphology distortion. The fluorescence can be preserved up to 86% even after 11 d. Besides, the cheap reagents and easy operation makes our method have great potential to be widely used. Besides the brain slices, our method can also be applied to other biological tissues.

Fig. 1. Ultrafast tissue clearing process with FOCM. (*A*) Transparency of samples (300-μm thick) at the 0 min, 2 min, and the time of clearing completed with different methods. (*B*) A fixed hemisphere of a C57BL/6 mouse (9 wk old) before and after clearing with FOCM. (*C*) Schedules and clearing time comparison of different clearing methods. (Scale bars: 5 mm.)

ability. The other reagents including sorbitol and glycerol were added to enhance the transparency and counterbalance the tissue distortion (*SI Appendix*, Fig. S1). The final RI of FOCM reagent is 1.495 at 25.1 °C.

To examine the clearing capacity, we implemented FOCM to 300-μm-thick brain slices (Fig. 1*A*), brain hemisphere (Fig. 1*B*), and internal organs (*SI Appendix*, Fig. S2), respectively. Compared with CLARITY and CUBIC, which aim to achieve a very efficient clearing results of whole organ/body with delipidation, FOCM aims at ultrafast tissue slices clearing with high fluorescent preservation and simple protocol. To be specific, it only took less than 2 min with FOCM to make 300-μm-thick brain slices transparent (Movie S1). The ultrafast clearing process reduced the clearing time ~450 times versus CLARITY, ~60 times versus CUBIC, ~90 times versus Sca/eS, and ~75 times versus SeeDB (Fig. 1*C*). Besides, there was only 2.12% tissue expansion after FOCM treatment compared with 22.0% expansion with

CLARITY, 15.9% expansion with CUBIC, 24.5% expansion with Sca/eS, and 13.5% shrinkage with SeeDB. To investigate the relationship between tissue expansion or shrinkage with cell morphology distortion, we merged the images of soma with dendrites before and after clearing. To present the merge results clearly, we cut the image with the original large field of view to a smaller one. The results show that all of the methods preserved the morphology of soma as in phosphate-buffered saline (PBS), but only FOCM could merge the dendrites before and after clearing. The possible reason might be tissue expansion or shrinkage and the unavoidable human-made distortion during multisteps treatment in CLARITY, CUBIC, Sca/eS, and SeeDB (Fig. 2). Notably, with the utilization of urea, 300-μm-thick fragile brain slices became much firmer and could be easily handled. (*SI Appendix*, Fig. S3).

Fluorescent Signals Preserving After FOCM. To examine the fluorescent signal quenching after FOCM, adult Thy1-GFP-M mouse

Fig. 2. Tissue morphology preserving with FOCM (*A*) Sample size (300 μm thick) changes before (*Left*) and after (*Center Left*) clearing by CLARITY, CUBIC, Sca/eS, SeeDB, and FOCM. In addition, the comparison of slices outlines before and after clearing was shown in *Center Right*, and distortion of microscopy imaging with Thy1-GFP-M mice before and after clearing was shown in *Right*. (*B*) Statistical data showed the sample morphology changes after different methods of treatment. The histogram was shown as the mean ± SEM (*n* = 3). Statistical significance (***$P < 0.001$, **$P < 0.01$, *$P < 0.05$) was assessed by one-way ANOVA followed by Bonferroni's multiple comparison tests. Scale bars: *Center Right*, 5 mm; *Right*, 10 μm.

brain slices were incubated with different clearing solutions and imaged under the same imaging condition (Olympus FV1000 with 40× UPLSAPO objective lens). Fig. 3 compares the fluorescence preservation effects with various methods in RI matching reagents. The results show that 86% of GFP fluorescent signals by FOCM could be preserved after 11 d (Fig. 3E), compared with 42.6% by CLARITY (Fig. 3A), 74.1% by CUBIC (Fig. 3B), 54.3% by ScaleS (Fig. 3C), and 63.7% by SeeDB (Fig. 3D). We also examined whether FOCM was compatible with general staining

methods such as immunofluorescence and chemical dye (35) without cell morphology disorganization. Here, c-fos antibody was applied to label active neurons in hippocampus (Fig. 3G) and DiO solution to label neuron bundles in the striatum (Fig. 3H). We first obtained the control images in PBS before FOCM. Then the same regions were imaged under the same imaging condition after FOCM. From the merged images we found that FOCM had a good compatibility with both immunofluorescence and chemical dye with negligible tissue distortion. Notably, DiO was used to

label cell membrane, which confirmed that FOCM could maintain the integrity of neuron cell membrane system. Besides, the virus-labeled mouse slices were also used to test the fluorescent signals preserving capability of FOCM, shown in Fig. 3I. We injected AAV9-Syn-mCherry into the motor cortex of a 9-wk-old C57BL/6 mouse. The results illustrated that the virus-expressed proteins were well preserved by FOCM.

Imaging Depth and Quality Improvements with FOCM. For FOCM achieving extremely fast optical clearing than other methods, we considered whether the short clearing process could improve the imaging quality in deep tissue. To examine its imaging capability, Thy1-GFP-M mice were imaged through the 200-μm-deep imaging volume with LSCM (Olympus BX61 with 40× UPLSAPO objective lens). Before FOCM clearing, the noise started to increase at the depth of 60 μm and details were severely lost at the depth of 120–200 μm in PBS. However, after FOCM clearing, all images through the whole volume remained details of dendrites and cell bodies (Fig. 4 A–E). The images calculation showed that before clearing, the signal-to-background ratio (SBR) declined rapidly from 56.9 ± 2.6 to 15.2 ± 2.7 at the depth of 60–120 μm. By contrast, the SBR maintained in 50–80 through the 200-μm volume after FOCM clearing (Fig. 4F). Besides, we also tested 200-μm-volume LSCM imaging of a mouse brain slice, which immunolabeled with collagen IV (Fig. 4 G–K). The variation of SBR in depth was consistent with the former that the SBR decreased from 40.4 ± 7.6 to 9.2 ± 1.2 at the depth of 60–120 μm in PBS, but remained at least 26.9 ± 2.2 at all depths after FOCM

clearing (Fig. 4L). The above results show that FOCM can improve imaging depth nearly three times in LSCM with SBR increasing average 38.2 at the depth of 80 μm and deeper. In addition, FOCM is also compatible with two-photon microscopy (Olympus BX61 with 25× WMP2 XLPLN objective lens). The imaging depth is increased from 250 μm to 1,020 μm (*SI Appendix,* Fig. S4).

It should be mentioned that FOCM preserved the fine structures of samples while improving the imaging depth. The magnification images [Olympus, UPLSAPO 60×, numerical aperature (N.A.) 1.35, working distance (WD) 0.15 mm] provide the clear dendrites and synaptic buttons at the depth of 0, 20, and 40 μm after FOCM treatment, compared with the details losing at the depth of 20 and 40 μm before clearing (Fig. 5).

Overall, our data demonstrated that FOCM fast clearing methods can significantly improve the imaging depth and quality with LSCM and two-photon microscopy.

Three-Dimensional Reconstruction of Neural Morphology with FOCM. Realizing an efficient and fine reconstruction was one of the important applications of FOCM. To examine it, the adult C57BL/6 mouse slices were immunofluorescent labeled and treated with FOCM. After that, the 3D reconstruction of neuron cells including astrocytes and microglia were obtained through continuous z axis scanning with LSCM (Olympus FV1000 with 60× UPLSAPO objective lens) (Fig. 6 A–D) (Movies S2 and S3). Besides the single neuron cell reconstruction, we also carried out a triple labeling to the blood vessel, astrocyte, and neuron simultaneously.

Fig. 5. Fine neuronal structure preserving by FOCM. (*A*) Three-dimensional reconstruction of neuron dendrites before FOCM clearing (*Upper*) and after clearing (*Lower*). (*B*) Images of dendrites (*Left*) and synaptic buttons (*Right*) at the depth of 0, 20, and 40 μm before clearing. (*C*) Images of dendrites (*Left*) and synaptic buttons (*Right*) at the depth of 0, 20, and 40 μm after FOCM clearing. (Scale bars: *C, Left*, 10 μm; *C, Right*, 1 μm.)

We first simulated the classical connection structures of soma, blood vessel, and astrocyte. In the reconstruction results, we found that the astrocytes connected the neuron cell with blood vessels as a bridge (Movie S4).

Fluorescence Spatial Colocation Analysis with FOCM. Fluorescence colocation (also called image merging) is a common imaging processing approach to examine whether the multifluorescence signals come from the same place, such as from the same cells in a small volume of tissue. However, the strong scattering of biological sample expands the focusing spot of excitation light in deep tissue and fluorophores above or below the focal plane will be excited as well. Thus, when we captured an image in a certain depth, the signals from two close cells might be recorded as from a single cell. In fact, the false-positive results may occur in every merging operation. To overcome this problem, we proposed the "fluorescence spatial colocation" achieved by FOCM to ensure the correctness of image merging.

Previous studies showed that the insular cortex is the nucleus in reward pathway and it also can be activated by drug addiction and interoception (36–42). To set insular cortex as an instance of image merging, C57BL/6 mice were injected with B subunit of cholera toxin (CT-B) conjugated with Alexa Fluor 488 into the Nucleus Accumbens (NAc) (43–48). One week later, morphine was injected 2 h before the fixed slices were incubated with c-fos antibody following IgG conjugated to Cy3. Finally, we got the double-labeled imaging with green signals in cell membrane (CT-B) and red signals (c-fos) in soma. The two signals located at the same position represented the neuron both projected to NAc and responded to the stimulation (Fig. 7 A and B). After the fast clearing with FOCM, we examined the positions of the signals in different z axis. To set the example, we detected two colocated signals at the depth of 12 μm and 56 μm (Fig. 7 C and D). Normally, both the two merged signals in 2D images will be considered as positive results. However, as FOCM achieved a fast clearing and higher SBR images in depth, we were able to distinguish the accurate location of signals in time via 3D reconstructions (Fig. 7E). According to the size of signal spots, we set the estimated soma diameter as 8 μm. When two reconstructed signal models blend with each other (signal distance is less than 8 μm in 3D space), we consider the two signals labeled the same cell. Through the reconstruction results, we found that the image at the depth of 12 μm seemed to merge together, yet their spatial positions were separated. However, the signals located at the depth of 56 μm, whose spatial positions were bound together, represented a truly colocation (Fig. 7 F and G). Therefore, nontoxic ultrafast FOCM processing with 3D reconstructions can provide a simple way to reduce errors in image merging.

Quantity Diversity of Neuronal Activity in PVH. The paraventricular nucleus of the hypothalamus (PVH) is a hypothalamic nucleus lying adjacent to the third ventricle that can be activated by a variety of stressful and physiological changes (49, 50). It controls the hypothalamic-pituitary-adrenal (HPA) axis and glucocorticoid release (Fig. 8D). The published data showed that the signals distribution patterns of c-fos in 2D images under the stimulation of morphine and foot shock had no significant difference (51). However, counting signals in 2D images might lose much information at the edge of each slice. Through 3D fluorescence reconstructions with FOCM, we were able to acquire a more complete signal distribution in a certain area. To set an example, the brain sectioned slices were incubated in c-fos antibody following IgG conjugated to Cy3. With FOCM clearing, the distribution of the c-fos signals in a 100-μm-thick brain slice was obtained (Fig. 8A). As the 3D signal imaging comprehensively contained the information of cell distributions, we examined whether there is a difference between conventional single imaging calculation and 3D imaging calculation. In active neurons counting, the representative images were selected to count the labeled cells number as single imaging calculation. The results showed 90.5 ± 12.2 active cells with foot shock and 101.0 ± 22.9 with morphine injection, which was no significant difference. However, when calculated with 3D imaging, there were 706.5 ± 78.2 active cells with foot shock and $1,139.0 \pm 146.7$ with morphine injection. The results indicate a significant difference between the two stimulations, which is different with the previous study (51) (Fig. 8B). Besides, the number of active neurons in subregions of PVH were also calculated. The results show that in control group, 111.0 ± 14.4 active neurons in PaLM (paraventricular hypothalamic nucleus, lateral magnocelluar part), which was significantly different with 54.0 ± 6.8 in PaMM (paraventricular hypothalamic nucleus, medial magnocellular part) and 54.4 ± 3.7 in PaV (paraventricular hypothalamic nucleus, ventral part). However, in foot shock group and morphine group, no significant difference was found between the subregions of PVH (Fig. 8C). Furthermore, we present the distribution of the active neurons at various depths with continuous imaging (Fig. 8E). These results confirm that FOCM with simple

protocols and ultrafast optical clearing capability can effectively help the scientists to obtain more reliable and convincing statistical results.

Discussion

We developed FOCM, a DMSO-based ultrafast optical clearing method that contained urea, sorbitol, and glycerol and was compatible with various labeling methods. The advantages of FOCM include ultrafast processing speed, nontoxicity, well-preserved fluorescence signals, little distortion, and simple protocol and common reagents.

It should be mentioned that different clearing methods have their specific aims and application fields. For example, CLARITY and CUBIC aim at whole organ/body clearing with very efficient transparent quality, while FOCM aims at ultrafast tissue slices clearing with high fluorescent preservation and simple protocol. Besides, with the advantages of nontoxicity and simple and ultrafast processing with less fluorescence quenching, FOCM has the potential to be a regularly used imaging step. Although the solvent-based clearing methods and ScaleSQ are also efficient clearing methods, considering the ability of morphology and fluorescence preservation, we did not compare them with FOCM.

Different with the previous studies (32), such as ScaleS, which listed DMSO as a RI matching reagent, it acts as a water-miscible polar solvent in FOCM. The results (Fig. 1*A*) demonstrate that the clearing efficiency with DMSO as solvent (FOCM) is much higher than that with DMSO as RI matching reagent (ScaleS) for 300-μm-thick brain slices. Besides, through combining "dehydration of water-miscible polar solvent" and "hydration of urea," we can counter the tissue shrinkage caused by organic solvent-based clearing methods and the tissue expansion caused by hyper-hydration methods (Fig. 2*A*).

The advantages of speedy clearing, nontoxicity, good fluorescence preservation, little distortion, and simple protocol by FOCM may have huge impact and the potential to solve some specific problems include emergent clinical diagnosis and high-throughput analysis of connectome, providing an alternative to those who expect speedy clearing. We believe that FOCM can be very helpful not only for the specific issues addressed above, but also for general problems to improve the processing efficiency.

Materials and Methods

Mice. All animal studies were approved by Animal Advisory Committee at Zhejiang University and the National Institutes of Health's Guidelines for the Care and Use of Laboratory Animals. Adult male and female mice C57BL/6 and

(Scale bars: 100 μm.)

Thy1-GFP-M mice were used in the development of optical clearing method and imaging processing. All mice were reserved in stable condition of temperature (25 °C) and humidity (60%), with a 12-h light/dark cycle (9:00 AM to 9:00 PM) and unlimited access to food and water.

Mouse Brain Samples. Mice were rapidly anesthetized with chloral hydrate [5%, wt/vol, 0.1 mL/10 g, intraperitoneal (i.p.)] and transcardially perfused with ice-cold 0.01 M PBS (Solarbio) and paraformaldehyde (4% in PBS wt/vol, Sinopharm Chemical Reagent Co., Ltd). Brain tissues were collected and incubated in the same paraformaldehyde solution at 4 °C for 24–48 h for uniform fixation through the sample. After fixation, the tissue was washed in 0.01 M PBS at room temperature for 6–12 h for whole brain or hemibrain. To remove the water remaining in the brain tissue, the sample was incubated in sucrose [30% (wt/vol) in PBS] at 4 °C for 24–48 h until the specimen sinked to the bottom of tube. After that, 300-μm-thick brain slices were sectioned using a cryostat (CM3050S, Leica). Sections were immediately started for immunostaining or stored at −20 °C in antifreeze solution (mixture of same volume of glycerol and 0.01 M PBS) for a month for further experiment.

FOCM Reagents Preparing. For whole organ or hemibrain optical clearing, FOCM reagent was prepared as 20% (wt/vol) urea (Vetec, V900119), 30% (wt/vol) D-sorbitol (Vetec, V900390), and 5% (wt/vol) glycerol (Vetec, V900122) dissolved in DMSO (Vetec, V900090). For brain sections optical clearing, FOCM reagent was prepared as 30% (wt/vol) urea, 20% (wt/vol) D-sorbitol, and 5% (wt/vol) glycerol dissolved in DMSO. When preparing the reagent, urea and D-sorbitol were dissolved in DMSO and stirred at room temperature (25 °C) overnight. After complete dissolution, glycerol was added and stirred further. The reagents can be stored at room temperature for several months and shaken gently before use.

Tissue Optical Clearing. For tissue sections clearing, after washing and labeling samples, PBST (0.01 M PBS with 0.1% Triton X-100) should be sopped up by KimWipes. Incubated samples in FOCM for 1–5 min (depending on the thick of slices) with gently shaken at room temperature in dishes. After FOCM clearing, the sample should be mounted immediately to isolate air. For whole organ or hemibrain clearing, incubate samples in FOCM for 3 d at 25 °C and 65 rpm in 50-mL glass centrifuge tubes with 30 mL of reagent. However, we recommend 20- to 300-μm slices clearing rather than a block of tissues.

Mounting Processing. To mount brain slices, stainless steel square holder (25 × 25 mm with a 10 × 8 mm hole) with appropriate thickness was glued to a glass coverslip (25 × 50 mm). The holder was filled with FOCM reagent and placed the clearing tissue into the holder. Another glass coverslip (23 × 23 mm) was covered on the holder to block the tissue from the air (*SI Appendix*, Fig. S5).

Tissue Optical Clearing with Other Clearing Methods. The clearing methods including CLARITY, CUBIC, Sca*l*eS, and SeeDB (Figs. 1–3) followed the protocol as below. Considering 300-μm-thick slices clearing, the incubation time of every method was reduced accordingly.

CLARITY. Hydrogel monomers (HM) solution [4% (wt/vol) acrylamide, 0.05% (wt/vol) bisacrylamide, 4% (wt/vol) paraformaldehyde (PFA), and 0.25% (wt/vol) VA-004 in PBS] was prepared for tissue incubation. Brain slices were embedded at 37 °C for 2.5 h until the hydrogel was solid. Sodium dodecyl sulfate (SDS) buffer was prepared freshly by diluting 20% (wt/vol) SDS and 1 M boric acid buffer fivefold in distilled water. Through passive CLARITY clearing, the slices were washed with SDS buffer with gentle shaking at 7 °C for around 12 h until the samples were transparentized. The brain slice was kept in 85% (vol/vol) glycerol at room temperature (21).

CUBIC. Sca*l*eCUBIC Reagent-1A [10% (wt/wt) urea, 5% (wt/wt) N,N,N′,N′-Tetrakis (2-hydroxypropyl) ethylenediamine and 10% (wt/wt) Triton X-100 were mixed and added 1/200 volume of 5 M NaCl] and Sca*l*eCUBIC Reagent-2 [50% (wt/wt) sucrose, 25% (wt/wt) urea, and 10% (wt/wt) triethanolamine in water] was prepared for tissue clearing. Brain slices were incubated in Sca*l*eCUBIC Reagent-1A for 1 h at 37 °C with gentle shaking followed by PBS washing for 30 min at room temperature. After PBS clearing, the slices were incubated for 30 min at room temperature and stored in Sca*l*eCUBIC Reagent-2 (30) (http://cubic.riken.jp).

ScaleS. Sca*l*eS0 [20% (wt/vol) sorbitol, 5% (wt/vol) glycerol, 1 mM methyl-β-cyclodextrin, 1 mM γ-cyclodextrin, 1% (wt/vol) N-acetyl-L-hydroxyproline, 3% (vol/vol) DMSO were mixed with PBS], Sca*l*eS1 [20% (wt/vol) sorbitol, 5% (wt/vol) glycerol, 4 M urea, and 0.2% (wt/vol) Triton X-100 were mixed with water], Sca*l*eS2 [27% (wt/vol) sorbitol, 2.7 M urea, 0.1% (wt/vol) Triton X-100, and 8.3% (vol/vol) DMSO were mixed with water], Sca*l*eS3 [36.4% (wt/vol) sorbitol, 2.7 M urea, and 9.1% (vol/vol) DMSO were mixed with water], Sca*l*eS4 [40% (wt/vol) sorbitol, 10% (wt/vol) glycerol, 4 M urea, 0.2% (wt/vol) Triton X-100, and 20% (vol/vol) DMSO were mixed with water] was prepared for tissue clearing. Brain slices were successively incubated in Sca*l*eS0, Sca*l*eS1, Sca*l*eS2,

and ScaleS3 at 37 °C for 30 min in every procedure. Then samples were washed with PBS at 4 °C for 30 min. After that, slices were treated for 30 min at 37 °C with ScaleS4 and stored in ScaleS4 at room temperature (29).

SeeDB. Standard SeeDB [20%, 40%, 60%, 80%, 100% (wt/vol), and 80.2% (wt/wt) fructose solution] was prepared for tissue clearing. Brain slices were successively incubated in 20%, 40%, 60%, 80%, 100% (wt/vol) fructose solution at 25 °C for 30 min in every procedure. Afterward, clearing slices were kept in 80.2% (wt/wt) fructose solution at room temperature (18).

Antibodies Selection. Primary antibodies: rabbit polyclonal antibody to Col-lagenIV (Abcam, ab6586) for labeling cerebrovascular at the concentration of 1:250; chicken polyclonal antibody to GFAP (Abcam, ab4674) for labeling astrocytes at the concentration of 1:250; rabbit polyclonal antibody to GFAP (Boster, PB0046) for labeling astrocytes at the concentration of 1:200; rabbit polyclonal antibody to Iba1 (Wako, 019–19741) for labeling microglia at the concentration of 1:500; and rabbit polyclonal antibody to c-fos (SYSY, 226003) for labeling c-fos protein at the concentration of 1:2,000.

Secondary antibodies: goat anti-rabbit IgG (H + L) highly cross-absorbed secondary antibody, Alexa Fluor 488 (Thermo Fisher Scientific, A11034); goat anti-rabbit IgG (H + L) highly cross-absorbed secondary antibody, Alexa Fluor Plus 555 (Thermo Fisher Scientific, A32732); and goat anti-chicken IgY (H + L) cross-absorbed secondary antibody, Alexa Fluor 633 (Thermo Fisher Scientific, A21103).

Immunostaining of Mouse Brain Slices. Took brain sections out of the antifreeze solution and washed slices with PBST three times at 25 °C and 65 rpm in a shaker (each time lasted for 1 h). Incubated in primary antibody/PBST solution for 48 h at 25 °C and 65 rpm in a shaker. The primary antibody then was washed off with PBST three times in the same condition. Incubated in sec-ondary antibody/PBST solution for 24 h at 25 °C and 65 rpm. The secondary antibody then was washed off with PBST three times in same condition.

Membrane Labeling of Mouse Brain Slices. One milligram of DiO (Beyotime, C1038) powder was dissolved in 1 mL of anhydrous ethanol with heating and ultrasonic disruption. For brain sections, samples were washed with PBST three times at 25 °C and 65 rpm in a shaker (each time lasted for 1 h). Incubated sections in 500 μL of PBST with 2.5 μL of DiO solution at 25 °C and 65 rpm in a shaker for 24 h. Samples then were washed with PBST three times in the same condition.

CT-B Injection. C57BL/6 adult mice were deeply anesthetized and fixed in the stereotaxic. An electrode containing 300 nL of cholera toxin subunit b, Alexa Fluor 488 conjugate (CT-B, 1 mg/mL, Thermo Fisher Scientific, C22841) was implanted into unilateral NAc (left hemisphere, 1.5 mm lateral to the sagittal sinus, 1.42 mm bregma, 4.4 mm depth) and injected all volume of CT-B. The mouse was killed for further experiment after recovering for 2 wk.

Drugs and Foot Shocks Treatments. Morphine-HCl (15 mg/kg, i.p., Shenyang Pharmaceutical) was dissolved in 0.9% NaCl (wt/vol, saline). For foot shocks treatments, 15 randomly arranged foot shocks (1 mA, 2 s) were administrated on mice within 10 min in a fear conditioning chamber.

Laser Scanning Confocal Microscopy. Confocal images were taken using an inverted confocal microscope FV1000 (Olympus) under the control of Olympus Fluoview FV1000 version 2.1b software. In FV1000, we used He-Ne (543.5 nm) and laser diode (473 and 635 nm) laser lines. A 10× air objective lens (Olympus, UPLSAPO 10×, N.A. 0.4, WD 3.1 mm), a 20× air objective lens (Olympus, UPLSAPO 20×, N.A. 0.75, WD 0.6 mm), a 40× air objective lens (Olympus, UPLSAPO 40×, N.A. 0.95, WD 0.18 mm), and a 60× oil objective lens (Olympus, UPLSAPO 60×, N.A. 1.35, WD 0.15 mm) were used to acquire all fluorescent images. For maximum intensity projection, we set the imag-ing interval in z axis as the half of z axis resolution of different objectives

(4.22 μm per slice for 10× objective, 1.09 μm per slice for 20× objective, and 0.48 μm per slice for 60× objective).

Two-Photon Excitation Microscopy. Two-photon images were taken using an upright two-photon excitation microscopy FV1200MPE (Olympus). In FV1000MPE, we used MaiTai at 920 nm for two-photon excitation. A 40× water objective (Olympus, LUMPLFLN, numerical aperture = 0.8, working distance = 3.3 mm) was used to acquire all fluorescent images.

Imaging Processing. For image enhancement, the image (Fig. 6C) were im-ported into Matlab and transformed to gray images. To enhance the contrast between the signals and noise, the distribution of gray value was adjusted. We removed the noise by median filter and then images are transformed to bi-nary. The objects, which occupy an area smaller than 30 pixels, were removed by erosion morphological operation and the binary image was multiplied by gray image and got the processed images. Finally, maximum intensity pro-jection was applied to all sequenced processed images in ImageJ.

Three-dimensional reconstruction images (Figs. 4 A, B, G, and H, 5A, 6, and 7 E–G) were performed by using IMARIS (bitplane). For the cell segmentation and reconstruction in Fig. 6, the surfaces function was used at the region containing the cell with well-preserved morphology. For the cell location reconstruction in Fig. 7G, the spots function was applied at the region with targeted cells. We set soma diameter as 8 μm to estimate the location of each cell. For the c-fos signal calculation in Fig. 8, the spots function was also used at the region of PVH, PaLM, PaMM, and PaV. We set soma diameter as 10 μm to detect the amount of c-fos signals automatically.

Quantification of Fluorescence Intensities. For normalized fluorescence quenching analysis (Fig. 3F), peak values of neuron bodies ($n = 3-6$) at the same position from day 0 to day 11 were recorded. After the subtraction of back-ground values, all signal values were normalized and plotted on the line diagram.

For SBR calculation (Fig. 4), a certain area of the image was selected. Pixels belonging to specific signals were recorded while pixels belonging to specific background were also recorded. Then, we calculated the SBR as the average value of recorded signal pixels divided by the average value of background pixels. Raw images were processed by ImageJ, and the selected background areas were adjacent to signal areas. The signal intensity distribution analysis was executed by Matlab. In each image, we chose a line across the back-ground to signal land and each value represented the fluorescent intensity of every pixel in the line.

Statistical Analysis. Data were presented as mean ± SEM in all figures. For comparison of sample size changes (Fig. 2B), fluorescence quenching (Fig. 3F), and the statistical results of the number of active neurons in PVH (Fig. 8C), analysis of one-way ANOVA was used. After the ANOVA was significant, the Bonferroni's multiple comparison test was used. For SBR analysis in different imaging depth, the multiple t test was used.
