<sup>1</sup>Cellular Neurosciences, Max Delbrück Centre for Molecular Medicine, Berlin 13092, Germany, <sup>2</sup>Ben Gurion University, Beer-Sheva 84105, Israel, <sup>3</sup>Department of Neurobiology, University of Alabama, Birmingham, Alabama 35294, <sup>4</sup>Department of Biotechnology, University of Rijeka, 51000 Rijeka, Croatia, and <sup>5</sup>Department of Neurosurgery, Charité University Hospital, Berlin 10117, Germany, and <sup>6</sup>Singapore Institute of Neurotechnology (SINAPSE), Singapore 117456

Mitochondria not only provide cells with energy, but are central to Ca<sup>2+</sup> signaling. Powered by the mitochondrial membrane potential, Ca<sup>2+</sup> enters the mitochondria and is released into the cytosol through a mitochondrial Na<sup>+</sup>/Ca<sup>2+</sup> exchanger. We established that NCLX, a newly discovered mitochondrial Na<sup>+</sup>/Ca<sup>2+</sup> exchanger, is expressed in astrocytes isolated from mice of either sex. Immunoblot analysis of organellar fractions showed that the location of NCLX is confined to mitochondria. Using pericam-based mitochondrial Ca<sup>2+</sup> imaging and NCLX inhibition either by siRNA or by the pharmacological blocker CGP37157, we demonstrated that NCLX is responsible for mitochondrial Ca<sup>2+</sup> extrusion. Suppression of NCLX function altered cytosolic Ca<sup>2+</sup> dynamics in astrocytes and this was mediated by a strong effect of NCLX activity on Ca<sup>2+</sup> influx via store-operated entry. Furthermore, Ca<sup>2+</sup> influx through the store-operated Ca<sup>2+</sup> entry triggered strong, whereas ER Ca<sup>2+</sup> release triggered only modest mitochondrial Ca<sup>2+</sup> transients, indicating that the functional cross talk between the plasma membrane and mitochondrial domains is particularly strong in astrocytes. Finally, silencing of NCLX expression significantly reduced Ca<sup>2+</sup>-dependent processes in astrocytes (i.e., exocytotic glutamate release, *in vitro* wound closure, and proliferation), whereas Ca<sup>2+</sup> wave propagation was not affected. Therefore, NCLX, by mediating astrocytic mitochondrial Na<sup>+</sup>/Ca<sup>2+</sup> exchange, links between mitochondria and plasma membrane Ca<sup>2+</sup> signaling, thereby modulating cytoplasmic Ca<sup>2+</sup> transients required to control a diverse array of astrocyte functions.

## Introduction

Ca<sup>2+</sup> signaling is central for the regulation of astrocyte functions and for interastrocytic and astrocyte–neuron communication. Neuronal activity, via the activation of metabotropic receptors, triggers transient increases in the cytosolic Ca<sup>2+</sup> concentration in astrocytes that leads to the release of gliotransmitters such as ATP and glutamate, which can signal to adjacent neurons (Agulhon et al., 2008; Perea et al., 2009). Astrocytic Ca<sup>2+</sup> transients after metabotropic receptor activation are initiated by release of Ca<sup>2+</sup> from the ER stores and by the entry from the extracellular space

through store-operated Ca<sup>2+</sup> channels. The spatiotemporal pattern of cytoplasmic Ca<sup>2+</sup> signals is dynamically organized and allows for a great complexity of astrocytic Ca<sup>2+</sup> responses.

Mitochondria, in addition to their metabolic role, participate in intracellular Ca<sup>2+</sup> signaling via dynamic buffering and shuttling cytosolic Ca<sup>2+</sup>. Powered by the mitochondrial membrane potential, Ca<sup>2+</sup> enters mitochondria via the mitochondrial uniporter (Baughman et al., 2011; De Stefani et al., 2011; Pizzo et al., 2012) and is extruded from mitochondria via Na<sup>+</sup>-dependent or -independent pathways (Drago et al., 2011). Mitochondria rapidly sense cellular Ca<sup>2+</sup> signals and act as local Ca<sup>2+</sup> buffers in the vicinity of Ca<sup>2+</sup> release sites such as the ER or plasma membrane Ca<sup>2+</sup> channels. By buffering and shuttling Ca<sup>2+</sup>, they modulate local and bulk cytoplasmic Ca<sup>2+</sup> changes (Szabadkai and Duchon, 2008; Contreras et al., 2010), thereby controlling cell-type-specific functions. Different cell types may vary with regard to mitochondrial Ca<sup>2+</sup> handling, in particular Ca<sup>2+</sup> extrusion mechanisms (Pizzo et al., 2012). At the neuronal synapse, for example, the mitochondrial Na<sup>+</sup>/Ca<sup>2+</sup> exchanger participates in shaping Ca<sup>2+</sup> signals, thus modulating neuronal activity and synaptic plasticity (Kann and Kovács, 2007; Pizzo et al., 2012). Activity of the mitochondrial exchanger has also been documented in astrocytes, where it is closely linked to exocytotic release of

glutamate and mediates a robust cytosolic and mitochondrial  $\text{Na}^+$  transport (Bernardinelli et al., 2006; Reyes and Parpura, 2008; Verkhratsky et al., 2012).

The benzothiazepine CGP37157 effectively blocks the activity of the mitochondrial exchanger. However, CGP37157, like other benzothiazepines, also modulates the activity of other  $\text{Ca}^{2+}$  channels and transporters that participate in glial  $\text{Ca}^{2+}$  signaling, among them SERCA, L-type, and the store-operated channels (Czyz and Kiedrowski, 2003; Thu le et al., 2006; Neumann et al., 2011). Molecular tools that selectively control the exchanger's activity or expression were not available because the identity of the mitochondrial exchanger gene was unknown. We have recently found that mitochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchange can be mediated by a member of the  $\text{Na}^+/\text{Ca}^{2+}$  exchanger superfamily, NCLX (Palty et al., 2010), and devised siRNA-based tools that control NCLX activity and thus can demonstrate its impact on mitochondrial and global cellular  $\text{Ca}^{2+}$  dynamics.

In the present study, we show that NCLX is the mitochondrial exchanger in astrocytes and plays a distinct role in controlling the ER- versus store-operated channel-dependent  $\text{Ca}^{2+}$  signals in astrocytes. By differentially controlling these  $\text{Ca}^{2+}$  signaling pathways, NCLX plays an essential role in facilitating a diverse array of astrocytic cellular activities ranging from release of glutamate to wound healing and proliferation.

## Materials and Methods

### Astrocyte cell culture

Procedures for animal work were approved by the Federal Ministry of Berlin (Landesamt für Gesundheit und Soziales) or the University of Alabama-Birmingham institutional animal care and use committee.

Enriched astrocyte cultures were prepared from cortices of 0- to 2-d-old newborn Naval Medical Research Institute mice or C57BL/6 mice of either sex, as described previously (Lyons and Kettenmann, 1998). Briefly, mice were killed by decapitation and cortical tissue was carefully freed from blood vessels and meninges, trypsinized, and gently triturated with a fire-polished pipette in the presence of 0.05% DNase (Worthington Biochem). After two washes, cells were cultured in DMEM with 10% fetal calf serum in Petri dishes (10 cm in diameter), in 25 cm<sup>2</sup> flasks, or on poly-L-lysine-coated glass coverslips at 37°C in a humidified 5%  $\text{CO}_2$ /95% air atmosphere. After 1 d, cells were washed twice with HBSS to remove cellular debris.

For glutamate release experiments and the associated subset of calcium-imaging experiments, astrocyte cultures were prepared from visual cortices of 0- to 2-d-old C57BL/6 mice of either sex as described previously (Reyes et al., 2011). Astrocytes were grown in culture medium containing  $\alpha$ -MEM without phenol red (Invitrogen) supplemented with fetal bovine serum (10% v/v; Thermo Scientific Hyclone), L-glutamine (2 mM), D-glucose (20 mM), sodium pyruvate (1 mM), penicillin (100 I.U./ml), streptomycin (100  $\mu\text{g}/\text{ml}$ ), and sodium bicarbonate (14 mM), pH 7.35. After 7–18 d in culture, cells were purified for astrocytes (>99% for the astrocytes from visual cortices). In some cases, after the purification procedure, astrocytes were returned to the incubator up to 1 d before transfection.

### Reagents and plasmids

CGP37157 (7-chloro-5-(2-chlorophenyl)-1,5-dihydro-4,1-benzothiazepin-2-(<sup>3</sup>H)-one; Ascent Scientific) was freshly prepared before each experiment at a stock concentration of 40 mM in DMSO and was used at a final concentration of 20  $\mu\text{M}$ . ATP and all other reagents were obtained from Sigma-Aldrich.

The plasmid expressing mitochondrial-targeted ratiometric-pericam (pcDNA3.1<sup>+</sup>-mtRP) was kindly provided by Atsushi Miyawaki (Wako, Japan). Double-stranded ON-TARGETplus SMARTpool siRNAs, used to silence NCLX expression, and siGLO RISC-Free siRNA were obtained from Dharmacon or Thermo Fisher Scientific.

### Transfection procedures

For silencing NCLX expression, astrocytes were transfected with an ON-TARGET mixture of siRNAs (siNCLX) or a pool of control ON-TARGETplus nontargeting siRNAs (siControl) at a final concentration of 10 nM siRNA. As additional controls, in some experiments, cells were treated only with a transfection reagent (mock-treated) or untreated. Astrocytes were analyzed 3 d after the transfection. Lipofectamine RNAiMAX (1  $\mu\text{l}/1200 \mu\text{l}$  of medium; Invitrogen) or TransIT-TKO (6  $\mu\text{l}/\text{flask}$  containing 4 ml of medium; Mirus) was used to transfect astrocytes with siRNA. The fluorescent transfection marker siGLO RISC-Free siRNA was used in the cytoplasmic  $\text{Ca}^{2+}$ -imaging experiments and glutamate release experiments to identify siRNA-transfected cells. Analysis of siGLO fluorescence, visualized using a standard tetramethylrhodamine isothiocyanate filter set (Chroma Technology), indicated that siRNA was delivered to all astrocytes and retained intracellularly throughout the duration of experiments.

To determine mitochondrial  $\text{Ca}^{2+}$  responses after knock-down of NCLX expression in astrocytes, the siNCLX or control siRNAs (siControl) were cotransfected with pcDNA3.1<sup>+</sup>-mtRP (1  $\mu\text{g}$ ) using Lipofectamine 2000 (1  $\mu\text{l}/\text{each}$  300  $\mu\text{l}$  of medium; Invitrogen) according to the manufacturer's protocol. Transfection efficiency was ~1–5%. Mitochondrial expression of the pericam sensor mtRP was documented in a two-photon laser scanning microscope (Till Photonics) equipped with a water-immersion objective (40 $\times$ , numerical aperture [NA] 0.8; Olympus). mtRP was excited by a Chameleon Ultra II laser (Coherent) set to a wavelength of 920 nm, and z-stacks of 150  $\times$  150  $\mu\text{m}$  images with a step size of 2  $\mu\text{m}$  were acquired.

### Cell fractionation and Western blot analysis

**Cell/tissue lysis.** Astrocytic monolayers or homogenized total brains were lysed with RIPA buffer (Sigma-Aldrich) supplemented with protease inhibitors (Roche Diagnostics), agitated at 4°C for 30 min, and centrifuged for 20 min at 14,000 rpm. The supernatants were then collected and frozen at  $-70^\circ\text{C}$  until use.

**Subcellular fractionation.** ER, cytosol, and mitochondria-enriched fractions from primary astroglia cultures were obtained as described previously (Bozidis et al., 2007). Briefly,  $\sim 4\text{--}5 \times 10^7$  cells were washed once with PBS, suspended in MTE solution (270 mM D-mannitol, 10 mM Tris, 0.1 mM EDTA, pH 7.4), and then lysed by sonication. The homogenate was centrifuged at 1400  $\times$  g for 10 min and the supernatant (total fraction) was recovered and further centrifuged for 10 min at 15,000  $\times$  g. The resulting pellet (crude mitochondria) and supernatant (crude ER) were separated for further purification, loaded on the top of a sucrose gradient, centrifuged, isolated, and washed once. Pellets were resuspended in PBS and frozen at  $-70^\circ\text{C}$  until use.

The plasma-membrane-enriched fraction was purified using a cell surface protein isolation kit (Pierce/Thermo Fisher Scientific) according to the manufacturer's instructions.

**Protein quantification and immunoblotting.** Protein concentration was determined using the BCA assay (Pierce/Thermo Fisher Scientific). First, the plasma-membrane-enriched fraction was dialyzed 3 times in 2 L of PBS and then assayed using the BCA method. Extracted proteins (20  $\mu\text{g}/\text{lane}$ ) were separated on 10% or 12% SDS-PAGE and transferred onto polyvinylidene difluoride membrane (GE Healthcare Europe). Membranes were probed using the following antibodies: polyclonal anti-NCLX (1:1000; Palty et al., 2004), anti-GAPDH (1:10,000; New England Biolabs), anti-ANT (1:100; Santa Cruz Biotechnology), anti-Sec62 (1:1000; kindly provided by Prof. Dr. T. Sommer, Max Delbrück Center for Molecular Medicine, Berlin), and anti-N-cadherin (1:1000; BD Biosciences).

### Real-time quantitative RT-PCR

Efficacy of silencing was determined by real-time quantitative RT-PCR analysis, which was performed 3 d after the delivery of siRNA (as described above). Astrocytes were harvested and total RNA was extracted with the InviTrap Spin universal mini kit (Invitex) according to the manufacturer's instructions. This was followed by first-strand cDNA synthesis using the SuperScript II reverse transcriptase enzyme (Invitrogen) with 1  $\mu\text{g}$  of total RNA and oligo-dT primers. Quantitative RT-PCR

was performed with gene-specific assays purchased from Dharmacon/Thermo Fisher Scientific) according to the manufacturer's instructions. GAPDH served as the internal control to quantify relative changes in gene expression.

#### Glutamate measurements in stimulated solitary astrocytes

**Stimulation of astrocytes.** To evoke an increase in cytosolic  $\text{Ca}^{2+}$  of solitary astrocytes and consequential exocytotic glutamate release, we mechanically stimulated astrocytes using glass pipettes filled with external solution as described in detail previously (Hua et al., 2004). This approach has physiological relevance and allows spatiotemporal control of the stimulus application without affecting plasma membrane integrity (Hua et al., 2004; Malarkey and Parpura, 2011). To control for the contact between the pipette and the solitary astrocyte, we monitored pipette resistance using a patch-clamp amplifier (PC-ONE; Dagan). The strength of the stimulus, measured as the increase in the pipette resistance upon establishment of a pipette-astrocyte contact, was comparable under all conditions tested (Mann-Whitney  $U$  test,  $p = 0.27$ – $0.34$ ).

**Glutamate measurements.**  $\text{Ca}^{2+}$ -dependent glutamate release from cultured solitary astrocytes was measured using the L-glutamate dehydrogenase (GDH)-linked assay as described previously (Hua et al., 2004; Montana et al., 2004; Lee et al., 2008). Astrocytes were bathed in an enzymatic assay solution containing external solution supplemented with  $\text{NAD}^+$  (1 mM, catalog #N6522; Sigma-Aldrich) and GDH (~53–137 IU/ml, catalog #G2626; Sigma-Aldrich, pH = 7.4). External solution contained the following (in mM): 140 NaCl, 5 KCl, 2  $\text{CaCl}_2$ , 2  $\text{MgCl}_2$ , 5 glucose, and 10 HEPES, pH 7.4. When released to the extracellular space, glutamate gets converted by GDH to  $\alpha$ -ketoglutarate with the concomitant reduction of the bath supplied coenzyme  $\text{NAD}^+$  to NADH, the latter being a fluorescent product when excited by UV light. Visualization was achieved at room temperature (20–24°C) using a standard DAPI filter set (Nikon). Every experiment was preceded by a sham run on astrocytes bathed in solution lacking GDH and  $\text{NAD}^+$  for photobleaching and background subtraction calculation. After correction, all imaging data were expressed as  $dF/F_0$  (%), where  $dF$  represents the change of fluorescence and  $F_0$  represents the background fluorescence level surrounding the solitary astrocyte, immediately and laterally of its soma, before mechanical stimulation. Imaging acquisition for these experiments is described below as  $\text{Ca}^{2+}$  measurements in solitary astrocytes.

#### Fluorimetric measurements of cytosolic and mitochondrial $\text{Ca}^{2+}$

Cytosolic  $\text{Ca}^{2+}$  levels in astrocytes were recorded using the  $\text{Ca}^{2+}$  indicators fura-2 AM or fluo-3 AM as described previously (Hua et al., 2004; Montana et al., 2004; Lee et al., 2008). Subconfluent astrocytic monolayers on coverslips were loaded for 30 min at room temperature with 2.5  $\mu\text{M}$  fura-2 AM (Invitrogen) in external solution (HEPES buffer; see below), followed by at least a 20 min wash to allow de-esterification. Alternatively, solitary astrocytes were loaded with fluo-3 AM (1  $\mu\text{g}/\text{ml}$ ; Invitrogen) in external solution containing pluronic acid (0.025% w/v; Invitrogen) for 20 min at room temperature, followed by washing in external solution for 20 min at room temperature. Mitochondrial  $\text{Ca}^{2+}$  levels were monitored in astrocytes transiently expressing mtRP. All  $\text{Ca}^{2+}$ -imaging experiments were performed at room temperature. Cells were transferred to the stage of an Axiovert 135 inverted microscope (Carl Zeiss) equipped with a cooled CCD camera (PCO Imaging) and a Polychrome V monochromator (TILL Photonics) and superfused with 3.5–4.0 ml/min  $\text{Ca}^{2+}$ -full HEPES buffer containing the following (in mM): NaCl 150.0, KCl 5.4,  $\text{MgCl}_2$  1.0,  $\text{CaCl}_2$  2.0, HEPES 10.0, and glucose 10.0, pH 7.4). In  $\text{Ca}^{2+}$ -free HEPES buffer, 2 mM  $\text{Ca}^{2+}$  was replaced by 2 mM  $\text{MgCl}_2$  and 0.5 mM EGTA. Images were acquired through a 20 $\times$  objective for cytoplasmic-imaging experiments using Axon Imaging Workbench 6 software (INDEC BioSystems) at an acquisition rate of 1 frame/1.2 s. Fura-2 AM-loaded cells were excited at wavelengths of 340 and 380 nm and the emitted light passed through a long-pass emission filter at 510 ( $\pm$  40) nm.

Mitochondrial  $\text{Ca}^{2+}$  levels were monitored in cells transiently expressing mtRP using a 40 $\times$  objective at an excitation wavelength of 430 nm ( $\text{Ca}^{2+}$ -sensitive wavelength; Nagai et al., 2001) and 480 nm, presented as  $F_0/F_{430}$  or  $R/R_0$  ( $r = F_{480}/F_{430}$ ). In some of the indicated exper-

iments described in the Results section, cell data were taken only at 430 nm because of significant fluorescence changes at 480 nm, likely related to changes in mitochondrial  $\text{pH}_i$  (Malli et al., 2003). When excited at 480 nm, mitochondrial pericam mtRP is strongly affected by pH, and the excitation of mtRP at 480 nm was in fact previously used effectively for monitoring mitochondrial pH changes (Jiang et al., 2009). Emitted light of cells excited in either wavelength was collected using a 535 nm band-pass filter.  $F_0$  was calculated as the average value obtained during the 50–100 s before the stimulus application.

Cytoplasmic  $\text{Ca}^{2+}$  measurements in solitary astrocytes (associated with glutamate measurements) were performed on an inverted microscope (TE 300; Nikon) equipped with differential interference contrast and wide-field fluorescence illumination (halogen and xenon arc lamps, respectively). Visualization of fluo-3 AM was accomplished using a standard FITC filter set (Chroma Technology). Images were captured through a 40 $\times$  fluor objective (NA 1.3; Nikon) using a CoolSNAP-HQ cooled charge-coupled device camera (Photometrics) driven by V++ imaging software (Digital Optics). For time-lapse image acquisition, a camera and an electronic shutter (Vincent Associates) inserted in the excitation pathway were controlled by the software. All imaging data were background subtracted using regions of the coverslip field containing no cells. Data are expressed as  $dF/F_0 \pm \text{SEM}$  (%) in which  $dF$  represents the change of fluorescence and  $F_0$  represents the fluorescence of the cell soma at rest.

#### Cell viability and nuclear staining

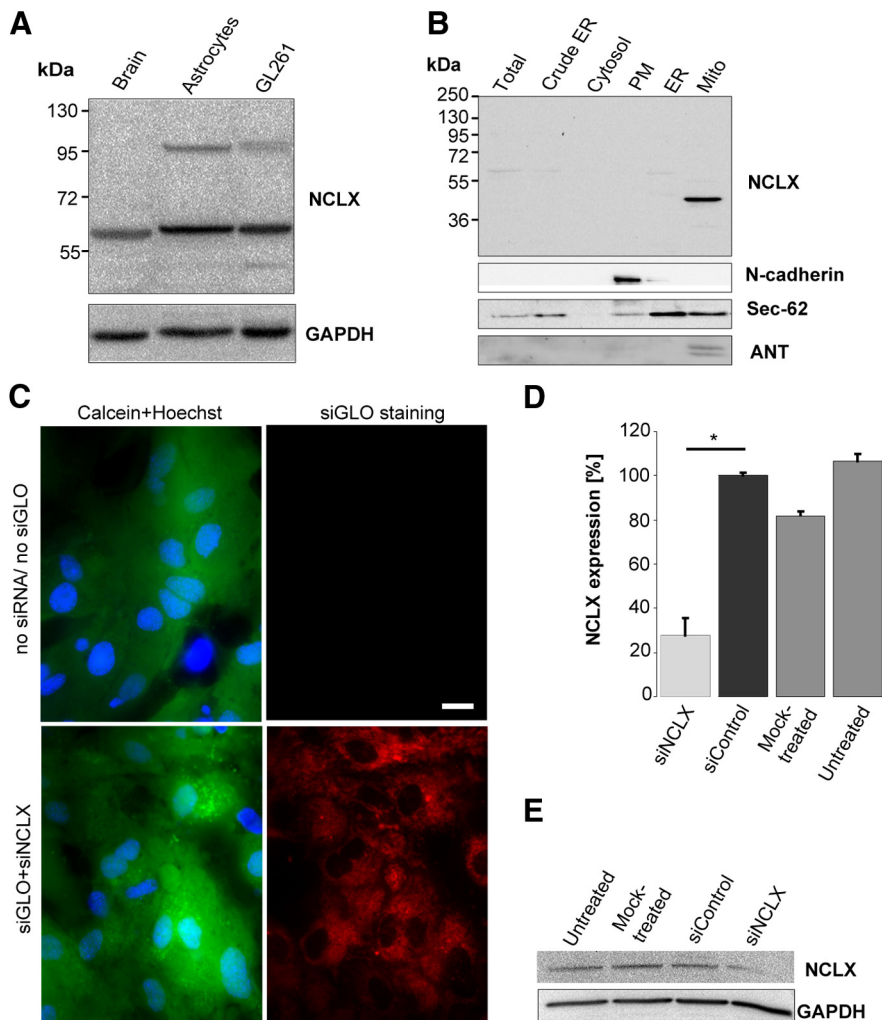

To test the effects that transfection agents and downregulation of NCLX may have on viability of astrocytes, we assessed the ability of these cells to accumulate the vital stain calcein (Hua et al., 2004). Cultured astrocytes were incubated with calcein AM (1  $\mu\text{g}/\text{ml}$ ; Invitrogen) and pluronic acid (0.025% w/v) in complete culture medium at 37°C in a humidified 5%  $\text{CO}_2/95\%$  air atmosphere for 10 min. De-esterification of calcein AM was permitted for 10 min by keeping astrocytes in external solution at room temperature. During the last 5 min, nuclei were stained by adding the cell permeant nuclear stain Hoechst 33342 (5  $\mu\text{g}/\text{ml}$ ; Invitrogen). Calcein was visualized using the FITC filter set, and a DAPI filter set was used for visualization of Hoechst. Image acquisition and processing was done as reported above, except here we used a 60 $\times$  Plan Apo oil-immersion objective (1.4 NA; Nikon).

#### Astrocytic wound-healing assay

Astrocytic wound healing was evaluated using a scratch assay described previously (Gebäck et al., 2009). One day after seeding into 4-well plates, semiconfluent astrocytes were transfected with either 10 nM siNCLX-silencing RNA, siControl or mock-transfected as described, or left untreated and cultured for 3 d to reach full confluence. At day 4, astrocytic monolayers were scratched with a 200  $\mu\text{l}$  sterile pipette tip in the shape of a horizontal double cross (Fig. 7B). After two washes with PBS to remove detached cells and debris, cells were incubated in serum-reduced medium containing 1% FBS. Phase contrast images of the wounds were acquired at 0–72 h after scratching using a 5 $\times$  magnification objective and frame grabber software (Inteq). At each acquisition time point, the culture dish and the cross-shaped wound area was exactly centered and images were acquired at identical positions (Fig. 7A, B). TScratch software (Gebäck et al., 2009; www.cse-lab.ethz.ch/software) was used to determine the percentage area without cells at different time points (open wound area). The final time point was defined as the time point when the initial open wound area was closed by at least two-thirds (in untreated control). At least six replicates per condition were analyzed and the results are expressed as the percentage open wound area.

#### Cell proliferation assay

Astrocyte proliferation was determined by a colorimetric immunoassay measuring 5-bromodeoxyuridine (BrdU) incorporation (Roche Diagnostics) in proliferating cells. Two days after transfection of astrocytes with siRNA, cells were trypsinized and seeded into 96-well plates at a density of  $3.5 \times 10^3$  cells/well. One day after the transfection, medium was changed to medium containing 1% FCS and BrdU was added 3 d after the transfection according to the manufacturer's instructions. The

**Figure 1.** *A*, immunoblot analysis of NCLX expression in brain extracts of newborn mice, primary murine astrocytes, and the murine astrocytoma cell line GL261 (top). GAPDH serves as an internal loading control (bottom). *B*, NCLX is enriched in the mitochondria of astrocytes. NCLX expression in indicated cellular compartments: total, crude ER, cytosol, plasma membrane (PM), ER, and mitochondria (Mito)-enriched fractions (top). The membranes were stripped and reprobed for PM (N-cadherin), ER (Sec-62), and mitochondrial (ANT) markers (bottom). *C*, Astrocytes are viable after 100% efficient siRNA transfection. Top row shows untreated control astrocytes (no siRNA); bottom row shows astrocytes treated with siGLO and siNCLX (siGLO + siNCLX). Left: Astrocytes accumulated calcein (green), indicating their viability. Nuclei are marked with Hoechst 33342 in blue. Right: Red fluorescence of the same area; untreated astrocytes display dim autofluorescence, whereas siRNA (siGLO + siNCLX)-treated cells show punctate stain, consistent with intracellular accumulation of the transfection marker siGLO. Scale bar, 20  $\mu$ m. *D*, Quantitative RT-PCR analysis after cotransfection with mtRP and siNCLX or siControl, respectively. Untreated and mock-treated (transfection agent only) cells were used as additional controls. Experiment was performed four times, each in triplicate. Values are given as means with SEM ( $*p < 0.05$ , Wilcoxon–Mann–Whitney  $U$  test). *E*, Immunoblot analysis showing NCLX expression in untreated and mock-treated astrocytes, or transfected with siControl or siNCLX (top). GAPDH serves as an internal loading control (bottom).

assay was performed 24 h after the addition of BrdU according to the manufacturer's instructions with five replicates for each condition.

#### Astrocytic $Ca^{2+}$ waves

Confluent astrocytes grown on coverslips were loaded with 5  $\mu$ m fluo-4 AM for 30 min at room temperature. After dye loading and washing, the coverslips were mounted in the bath containing HEPES buffer, and  $Ca^{2+}$  waves were evoked mechanically by touching a single astrocyte with a micropipette (Cornell-Bell et al., 1990). The changes in fluo-4 AM fluorescence were acquired with 10 $\times$  Plan objective (Carl Zeiss) at an acquisition speed of 1 frame/1.2 s.

#### Data analysis

The rate of  $Ca^{2+}$  influx (entry) or efflux was obtained by measuring the initial slope of  $Ca^{2+}$  rise or decline, respectively, as illustrated in Fig. 2*D*, *E*, insets. The maximal value of the normalized fluorescence intensity was

taken as the peak amplitude or influx. To evaluate the response time, we determined the width of the peak at its half-amplitude. The cumulative fluorescence resulted from the area under the curve and was derived by integration. Data analysis was performed with MS Excel 2003, Origin 7, KaleidaGraph version 4.1, and ImageJ software.

For the glutamate release analysis, the  $dF/F_0$  values of the test group (siNCLX) were ranked and normalized to siControl to allow comparisons between experimental batches and to accommodate for variations in GDH concentration and culture conditions. In associated experiments, similar ranking of  $Ca^{2+}$   $dF/F_0$  was done for consistency. Resulting proportions are expressed as means  $\pm$  SEM. Data analysis was performed with MS Excel 2003, GB-Stat, and V++ imaging software (Digital Optics).

A custom-made algorithm programmed in C++ was used to calculate the  $Ca^{2+}$  wave velocity at which the wave reached each cell. For this purpose, two parameters were determined; (1) the time at which the increase in cytoplasmic  $Ca^{2+}$  was observed in a given cell and (2) the distance of this cell from the stimulation point. The first parameter was measured by a peak detection algorithm in the derivative of the mean intensity values over time in the labeled regions. Cell detection was done by first obtaining a binary mask of the SD projection of the time stack using automatic triangle thresholding (Zack et al., 1977). Individual cells were identified thereafter by a two-pass connected-component labeling (Shapiro and Stockman, 2001).

#### Statistics

All experiments were done at least three times using astrocytic cultures originating from independent cell preparations. Data are presented as mean with SEM for column graphs, with exception of Figure 3, where we used box plots with median, interquartile range (25<sup>th</sup> and 75<sup>th</sup> percentiles), and minimum and maximum values (whiskers). For the parametrical data, the statistical significance was evaluated using Student's  $t$  test, unpaired and double-tailed. For the experiments with more than two test groups to compare, a multiple parameter one-way ANOVA test was used followed by Bonferroni posttest. For the comparison of nonparametric data, a Mann–Whitney  $U$  test or Kruskal–Wallis test followed by Bonferroni correction and Mann–Whitney  $U$  test pair comparisons were used to evaluate the statistical significance ( $*p < 0.05$ ;

$**p < 0.01$ ;  $***p < 0.001$ ).

## Results

### NCLX is enriched in the mitochondria of astrocytes

Recently, NCLX has been identified as the mitochondrial  $Na^+$ / $Ca^{2+}$  exchanger in several cell types (Palty et al., 2010; Kim et al., 2012). To determine whether NCLX is the mitochondrial exchanger in astrocytes, we first evaluated NCLX expression in lysates from cultures of cortical astrocytes by Western blot analysis. Consistent with the previous studies (Palty et al., 2010), a major band of  $\sim$ 60 kDa and a fainter band at  $\sim$ 100 kDa related to the SDS-stable NCLX dimer were detected. The 60 kDa band was also detected in brain lysates from newborn

mice and in an astrocytoma cell line GL261, whereas the 100 kDa band was not detectable in brain homogenate, but was present in GL261 cells (Fig. 1A).

To analyze NCLX expression in different cellular compartments, we performed subcellular fractionation of cultured astrocytes and determined NCLX expression using Western blot analysis. The fractions were counterstained with organelle-specific markers (Fig. 1B) to determine the separation quality of the fractions. Total, crude ER, and ER-enriched fractions revealed a faint band at ~60 kDa, whereas no band was visible in the plasma membrane or cytosolic fractions. Interestingly, the mitochondrial fraction showed a strong NCLX-positive band of slightly reduced molecular weight (MW), suggesting that the passage of NCLX to the mitochondria may be linked to posttranslational proteolysis. Probing with anti-ANT and anti-N-cadherin antibodies showed a good separation of the mitochondrial and plasma membrane fractions, respectively. Some degree of ER cross-contamination was detected in other fractions when probing the ER marker Sec-62, which is likely related to the physical cross-linking of the ER with other organelles. Nonetheless, these data show that the astrocytic  $\text{Na}^+/\text{Ca}^{2+}$  exchanger NCLX is primarily located in mitochondria.

### Molecular silencing of NCLX in astrocytes

To assess the role of NCLX in modulating astrocytic  $\text{Ca}^{2+}$  signaling and related functions, the expression of the exchanger was knocked down with an NCLX-specific mixture of siRNAs (siNCLX). The fluorescently tagged siRNA siGLO was used as a cotransfection marker to determine optimal conditions for effective NCLX silencing and to detect transfected cells; calcein live cell staining was applied to assess cell viability (>99%). Cells treated with siRNA (siGLO + siNCLX) showed punctate red staining, consistent with intracellular accumulation of the transfection marker siGLO (Fig. 1C, lower right). siGLO fluorescence was visible in all treated viable cells, showing that cells were successfully transfected. The untreated cells showed only dim autofluorescence (Fig. 1C, upper right). All astrocytes showed a similar accumulation of calcein regardless of whether they were treated with siRNA or were untreated controls (Fig. 1C, left column), indicating that the siRNA transfection procedure did not affect cell viability.

The efficiency of NCLX silencing via siRNA was assessed by quantitative RT-PCR. Optimal NCLX gene silencing via siRNA was achieved after 3 d using 10 nM siNCLX. NCLX expression in the presence of siNCLX was reduced to  $24.9 \pm 1.3\%$  of the expression level seen in astrocytes transfected with siControl (Fig. 1D,  $n = 4$  experiments,  $*p < 0.05$ ). NCLX mRNA expression levels remained almost unchanged in cells treated only with the transfection agent (mock-treated) and in untreated control cells ( $84.0 \pm 13.9\%$  and  $101.7 \pm 4.5\%$ , respectively). Consequently, all experiments were performed on astrocytic cultures 3 d after siRNA treatment.

NCLX silencing on mRNA level also affected the expression of the NCLX protein. Western blot analysis of astrocytic extracts showed a reduction in NCLX expression in astrocytes transfected with siNCLX compared with astrocytes transfected with siControl, mock-treated, or untreated cells (Fig. 1E).

### NCLX conducts mitochondrial $\text{Ca}^{2+}$ efflux in astrocytes

To monitor mitochondrial  $\text{Ca}^{2+}$  responses, primary astrocytes were transfected with mtRP (Nagai et al., 2001). Expression of mtRP reached maximal intensity ~48–72 h after transfection. mtRP expression pattern manifested a typical network-like mito-

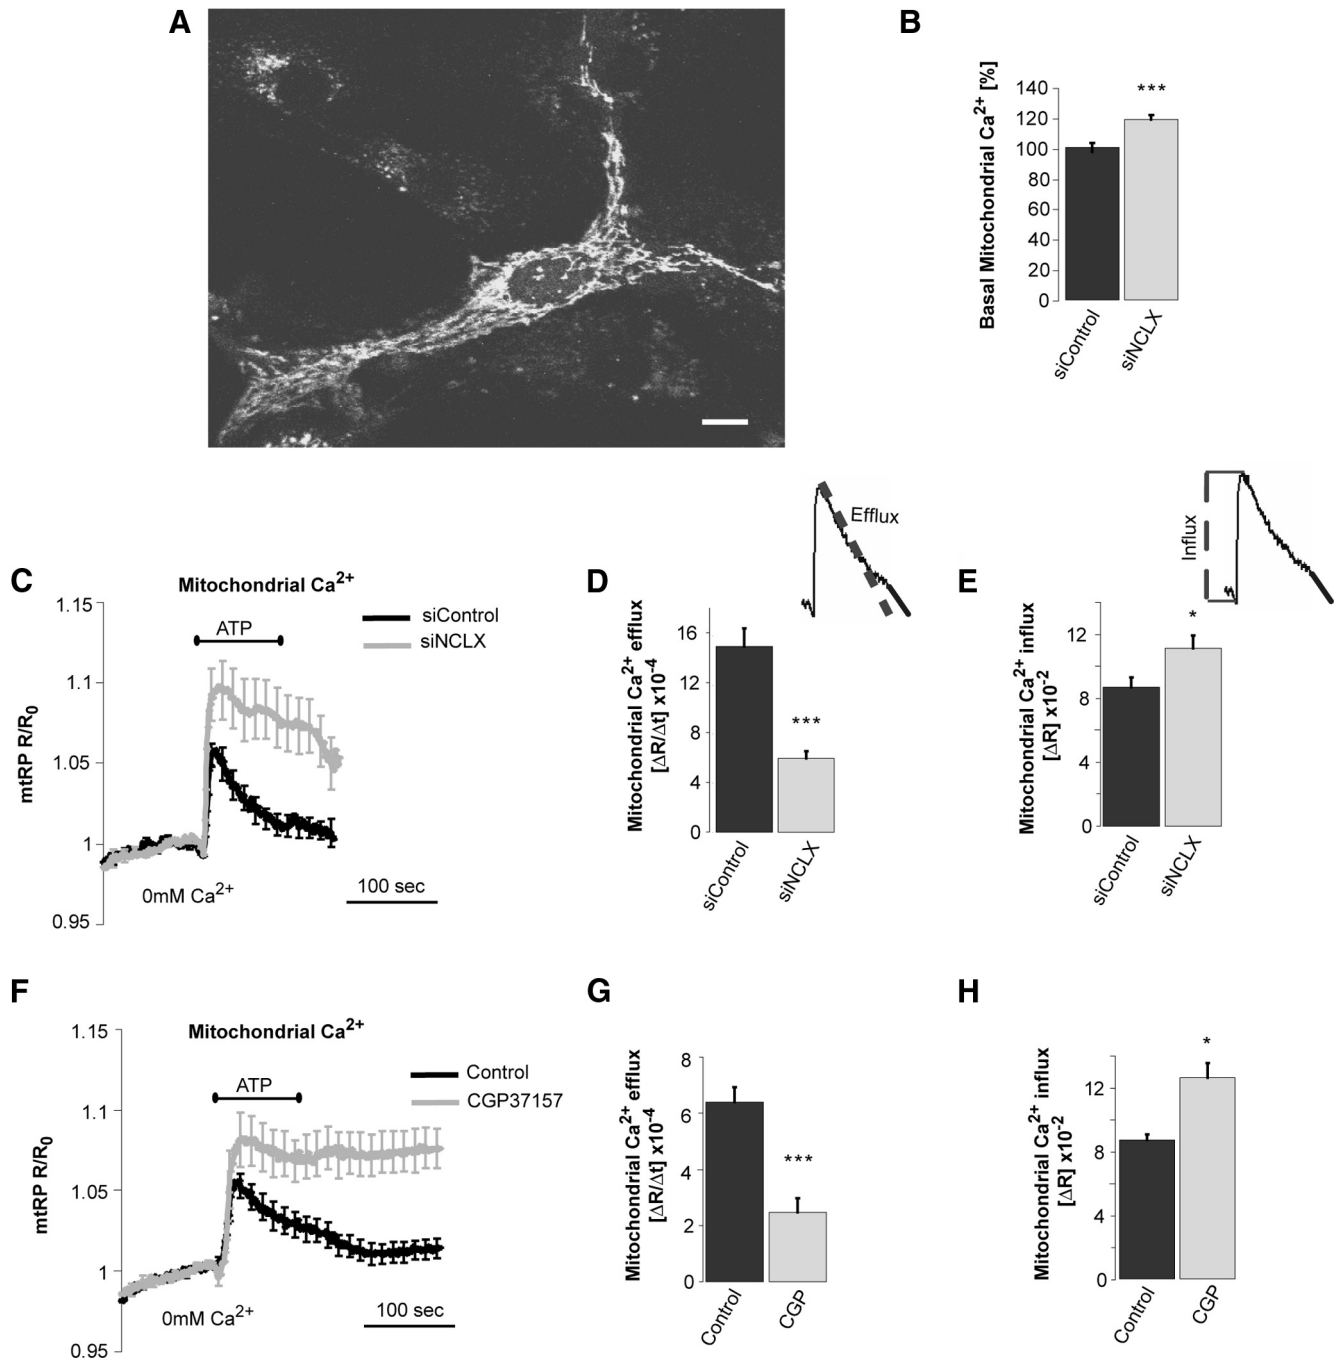

chondrial distribution consistent with the strict mitochondrial localization of this  $\text{Ca}^{2+}$  reporter (Fig. 2A). Resting mitochondrial  $\text{Ca}^{2+}$  levels in astrocytes transfected with siNCLX were higher than values obtained from mitochondria of astrocytes treated with control siRNA (Fig. 2B). Application of ATP (100  $\mu\text{M}$ ) to astrocytes in  $\text{Ca}^{2+}$ -free HEPES Ringer's solution for 100 s elicited a fast rise in the mitochondrial  $\text{Ca}^{2+}$  corresponding to the  $\text{Ca}^{2+}$  uptake phase followed by a slower efflux (Fig. 2C,  $n = 10$  and 11 experiments for siControl and siNCLX-transfected astrocytes, respectively). Mitochondrial  $\text{Ca}^{2+}$  influx and efflux rates were determined as described in Materials and Methods and as indicated in Fig. 2D,E, insets. Comparison of the efflux rates of the ATP-elicited mitochondrial  $\text{Ca}^{2+}$  responses in siNCLX-treated versus siControl-treated cells showed that the mitochondrial efflux rate was decreased by 60.2% in siNCLX-treated cells compared with siControl astrocytes (from  $15.1 \pm 1.5 \times 10^{-4}/\text{s}$  to  $6.0 \pm 0.6 \times 10^{-4}/\text{s}$ ,  $n = 10$  and 11 experiments and  $n = 38$  and 64 regions for siControl and siNCLX conditions, respectively,  $***p < 0.001$ ; Fig. 2D). Moreover, silencing of NCLX significantly increased the net mitochondrial  $\text{Ca}^{2+}$  influx by 28.1% compared with the siControl condition (from  $8.7 \pm 0.6 \times 10^{-2}$  to  $11.1 \pm 0.7 \times 10^{-2}$ ;  $n = 10$  and 11 experiments with siControl- and siNCLX-transfected astrocytes, respectively,  $*p < 0.05$ ; Fig. 2E).

The effect of NCLX activity on mitochondrial  $\text{Ca}^{2+}$  fluxes was also evident when we used the pharmacological inhibitor of mitochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchange; application of 20  $\mu\text{M}$  CGP37157 resulted in a 62.4% reduction of the ATP-induced mitochondrial  $\text{Ca}^{2+}$  efflux in treated astrocytes compared with cells treated with vehicle (DMSO) (control,  $6.4 \pm 0.5 \times 10^{-4}/\text{s}$ ,  $n = 15$  experiments and 106 regions of interest; CGP37157-treated group,  $2.5 \pm 0.5 \times 10^{-4}/\text{s}$ ,  $n = 11$  experiments and 75 regions of interest,  $***p < 0.001$ ; Fig. 2F,G). The average net mitochondrial  $\text{Ca}^{2+}$  influx was increased from  $8.6 \pm 0.4 \times 10^{-2}/\text{s}$  to  $12.5 \pm 0.9 \times 10^{-2}/\text{s}$  in the presence of CGP37157 ( $n = 15$  and 11 experiments with control- and CGP37157-treated astrocytes, respectively,  $*p < 0.05$ ; Fig. 2H).

NCLX inhibition, either by specific molecular silencing or by the pharmacological inhibitor, significantly reduced mitochondrial  $\text{Ca}^{2+}$  extrusion, thereby also indirectly increasing the net  $\text{Ca}^{2+}$  influx. These data indicate that NCLX mediates mitochondrial  $\text{Ca}^{2+}$  efflux in astrocytes and thereby shapes the mitochondrial  $\text{Ca}^{2+}$  transients.

### NCLX shapes the ATP-induced cytosolic $\text{Ca}^{2+}$ response in astrocytes

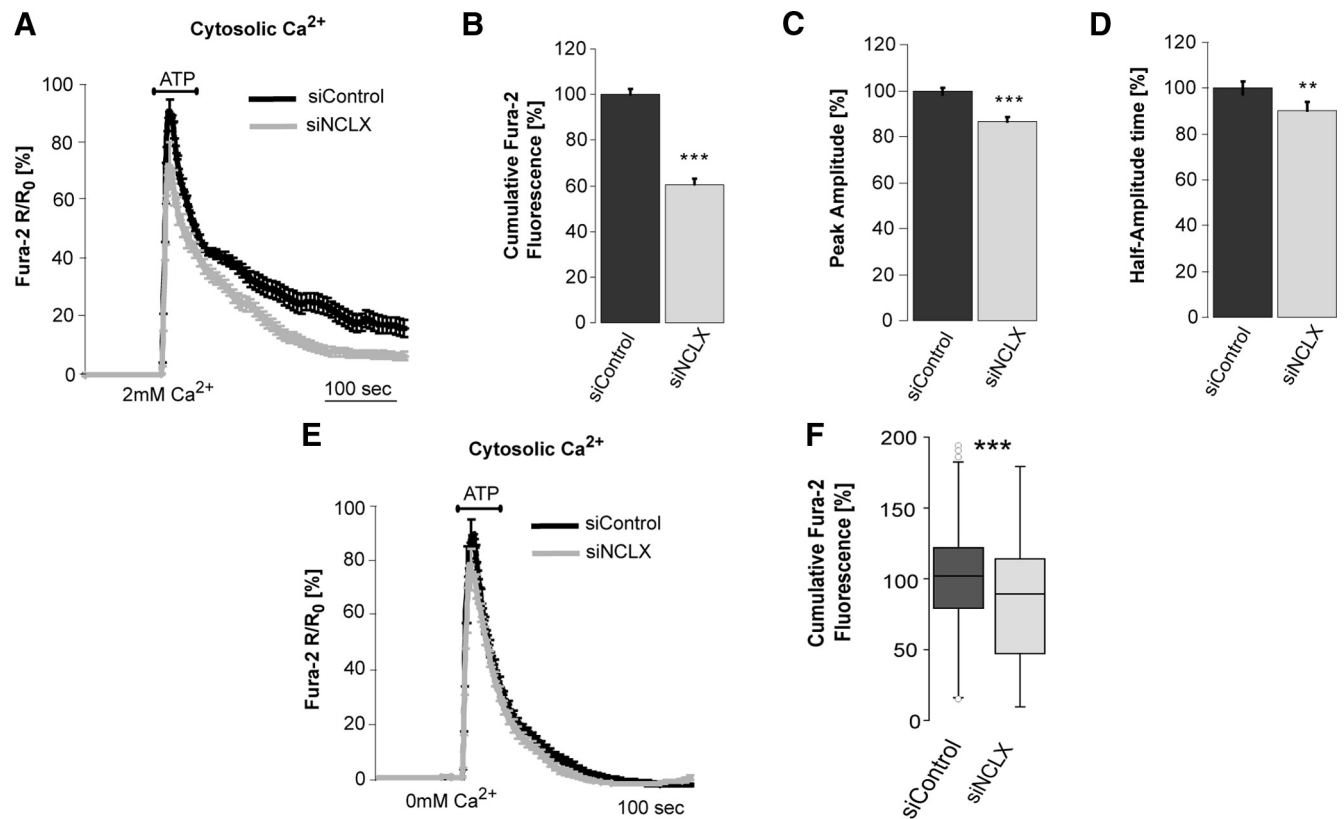

Mitochondrial  $\text{Ca}^{2+}$  transport participates in intracellular  $\text{Ca}^{2+}$  signaling (Hoth et al., 1997; Hajnóczky et al., 1999; Malli et al., 2003; Parekh, 2008). Our finding that NCLX is the mitochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchanger in astrocytes provides us with a molecular basis to evaluate how mitochondria respond to or shape cytosolic  $\text{Ca}^{2+}$  responses in astrocytes and to determine the role of NCLX in this process. Astrocytes were cotransfected with siControl or siNCLX together with the transfection marker siGLO red. After 3 d, cells were loaded with fura-2 AM and cytoplasmic  $\text{Ca}^{2+}$  signals in response to application of 100  $\mu\text{M}$  ATP were monitored from siGLO-red-positive cells, either in  $\text{Ca}^{2+}$ -containing buffer (Fig. 3A–D) or  $\text{Ca}^{2+}$ -free buffer (Fig. 3E–H). As described previously (Kresse et al., 2005), application of ATP in  $\text{Ca}^{2+}$ -containing buffer evoked a rapid increase of cytosolic  $\text{Ca}^{2+}$  mainly due to  $\text{InsP}_3$ -receptor-mediated release of  $\text{Ca}^{2+}$  from the ER stores, followed by an initial rapid decline and a slower decaying phase. The latter “elevated  $\text{Ca}^{2+}$  plateau” has been associated

**Figure 2.** NCLX mediates mitochondrial  $\text{Ca}^{2+}$  efflux in astrocytes. **A–E**, Primary astrocytes were cotransfected with mtRP and siNCLX or siControl and were analyzed after 3 d. **A**, Two-photon microscopy image of astrocytes transfected with mtRP reveals typical mitochondrial pattern of the fluorescent pericam sensor. Scale bar, 10  $\mu\text{m}$ . **B–E**, Mitochondrial  $\text{Ca}^{2+}$  imaging. **B**, Resting mitochondrial  $\text{Ca}^{2+}$  levels of astrocytes transfected with siNCLX- or control siRNA,  $R/R_0$  values were determined from fluorescent mtRP imaging before application of the stimulus and normalized to the control condition ( $n = 5$  cultures,  $n = 134$  and 118 regions). **C**, Mitochondrial  $\text{Ca}^{2+}$  signals of control and siNCLX-transfected astrocytes; 100  $\mu\text{M}$  ATP in  $\text{Ca}^{2+}$ -free HEPES buffer was applied as indicated, averaged curves  $\pm$  SEM. **D–E**, Average rates of the mitochondrial  $\text{Ca}^{2+}$  efflux (slopes; **D**) and influx (amplitudes, **E**) in siControl and siNCLX-transfected astrocytes, comparing  $n = 10$  ( $n = 38$  regions) and  $n = 11$  ( $n = 64$  regions) experiments for each condition ( $***p < 0.001$ ,  $*p < 0.05$ , Wilcoxon, Mann–Whitney U test). **F–H**, Effect of CGP37157 on mitochondrial  $\text{Ca}^{2+}$  efflux. **F**, Mitochondrial  $\text{Ca}^{2+}$  signals from control and CGP37157 (CGP)-treated astrocytes. Cells were superfused with  $\text{Ca}^{2+}$ -free HEPES buffer  $\pm$  20  $\mu\text{M}$  CGP37157 and 100  $\mu\text{M}$  ATP was applied as indicated; shown are averaged curves  $\pm$  SEM. **G–H**, average rates of mitochondrial efflux (**G**) and influx (**H**). Values are given as means with SEM for  $n = 15$  ( $n = 106$  regions) and  $n = 11$  ( $n = 75$  regions) control and CGP37157 experiments, respectively ( $***p < 0.001$ ,  $*p < 0.05$ , Wilcoxon, Mann–Whitney U test).

with  $\text{Ca}^{2+}$  influx from the extracellular space via store-operated  $\text{Ca}^{2+}$  entry (SOCE). The averaged  $\text{Ca}^{2+}$  transients indicate that the amplitude of the elevated  $\text{Ca}^{2+}$  plateau is reduced in NCLX-silenced astrocytes (Fig. 3A,  $n = 12$  and 11 experiments for siControl and siNCLX-transfected astrocytes, respectively). To quantify the effect of NCLX silencing on the cytosolic  $\text{Ca}^{2+}$  tran-

sient, we determined the cumulative fura-2 AM fluorescence, peak amplitude, and half-amplitude time in siControl-treated versus siNCLX-treated astrocytes. The cumulative fluorescence was reduced by 39.3% in NCLX-silenced astrocytes (Fig. 3B), whereas the peak amplitude was reduced by 13.4% (Fig. 3C) and the half-amplitude time of the signal was reduced by 9.8% (Fig.

**Figure 3.** NCLX modulates ATP-induced  $\text{Ca}^{2+}$  responses in astrocytes. Primary astrocytes were cotransfected with siControl or siNCLX and siGLO red indicator. Cells were loaded with fura-2 AM and changes in cytoplasmic  $\text{Ca}^{2+}$  signals were monitored from siGLO-red-positive cells. **A, E**, Recording of average fura-2 AM fluorescence for control and siNCLX-transfected astrocytes in  $\text{Ca}^{2+}$ -containing buffer (**A**) and  $\text{Ca}^{2+}$ -free buffer (**E**);  $100 \mu\text{M}$  ATP was added as indicated, averaged curves SEM. **B–D**, Statistical analysis of the recordings shown in **A**: cumulative response (**B**), amplitudes (**C**), and half-amplitude time (**D**) of the ATP-evoked  $\text{Ca}^{2+}$  responses. Values are given as mean with SEM ( $n = 12$  experiments,  $n = 294$  cells for control, and  $n = 11$  experiments,  $n = 222$  cells for siNCLX-transfected astrocytes, respectively;  $***p < 0.001$ ,  $**p < 0.01$ , Wilcoxon, Mann–Whitney  $U$  test). **F**, Box-plot chart of the cumulative  $\text{Ca}^{2+}$  responses corresponding to recordings in **E** indicating median (dark line), interquartile range (box), and minimum and maximum of the values (whiskers) ( $***p < 0.001$ , Wilcoxon, Mann–Whitney  $U$  test).

3D) in NCLX-silenced astrocytes compared with siControl-treated astrocytes ( $n = 12$  and 11 experiments,  $n = 294$  siControl and  $n = 222$  siNCLX-transfected astrocytes;  $***p < 0.001$ ,  $**p < 0.01$ ).

To determine the contribution of mitochondrial NCLX to the modulation of  $\text{Ca}^{2+}$  signals that originate from ER stores, we superfused cells with  $\text{Ca}^{2+}$ -free buffer and measured ATP-induced cytosolic  $\text{Ca}^{2+}$  signals in NCLX-silenced and siControl astrocytes. ATP triggered a fast rise followed by a fast decline of the cytoplasmic  $\text{Ca}^{2+}$  signal as described above. The elevated plateau phase, seen in  $\text{Ca}^{2+}$ -containing buffer (above) was, as expected, reduced under  $\text{Ca}^{2+}$ -free conditions. Knock-down of NCLX revealed a slight but significant reduction of the mean cumulative  $\text{Ca}^{2+}$  signal in NCLX-silenced astrocytes, with medians shifted from 102.1% in the siControl population to 89.4% in the NCLX-silenced astrocytes ( $***p < 0.001$ ; Fig. 3F). The representation of cumulative  $\text{Ca}^{2+}$  responses as median and interquartile ranges revealed that NCLX silencing is more pronounced in the lower quartiles of the data (25<sup>th</sup> percentile of the box plot): in those cells with overall lower cumulative  $\text{Ca}^{2+}$  responses, the shift was from 79% in the nonsilenced condition to 47.4% after NCLX knock-down (Fig. 3F).

These results indicate that stimulus-induced cytoplasmic  $\text{Ca}^{2+}$  signals in astrocytes, in particular those caused by the entry of  $\text{Ca}^{2+}$  from the extracellular space versus  $\text{Ca}^{2+}$  release from the ER store, are distinctly modulated by the activity of the mitochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchanger NCLX.

### NCLX activity modulates the store-operated $\text{Ca}^{2+}$ entry in astrocytes

SOCE is an important  $\text{Ca}^{2+}$  influx pathway in nonexcitable cells such as astrocytes (Kresse et al., 2005; Pivneva et al., 2008; Verkhatsky et al., 2012). Observations in other cell types showing that the mitochondrial  $\text{Ca}^{2+}$  shuttling machinery is essential to sustaining the activity of SOCE (Hoth et al., 1997; Malli et al., 2003; Parekh, 2008, and the reduction of the  $\text{Ca}^{2+}$ -elevated plateau phase seen in the ATP-induced  $\text{Ca}^{2+}$  signal in NCLX-silenced astrocytes (described above) prompted us to determine the specific influence of mitochondrial NCLX on  $\text{Ca}^{2+}$  influx through the SOCE pathway in astrocytes.

To quantify SOCE activity, we used a previously described protocol. Briefly, ER stores were depleted by application of ATP in the absence of extracellular  $\text{Ca}^{2+}$ . Cells were then superfused with  $\text{Ca}^{2+}$ -containing buffer, which resulted in a  $\text{Ca}^{2+}$  influx due to SOCE activity (Kresse et al., 2005; Fig. 4A). The amplitude of SOCE response measured at the steady phase was decreased from  $100.0 \pm 5.1\%$  to  $59.9 \pm 3.1\%$  after silencing of NCLX ( $n = 9$  experiments;  $n = 175$  and 131 cells for siControl and siNCLX-transfected astrocytes, respectively,  $***p < 0.001$ ; Fig. 4B). Moreover, the SOCE rate (reflected by the slope of the influx phase) was reduced from  $100.0 \pm 3.6\%$  to  $68.0 \pm 3.7\%$  by NCLX silencing ( $***p < 0.001$ ; Fig. 4C). A similar impairment on SOCE function was found in astrocytes superfused with  $20 \mu\text{M}$  CGP3715. The drug reduced SOCE amplitude by 25.5% and the SOCE rate by 34.2% compared with vehicle-treated control ( $n = 8$  and 7

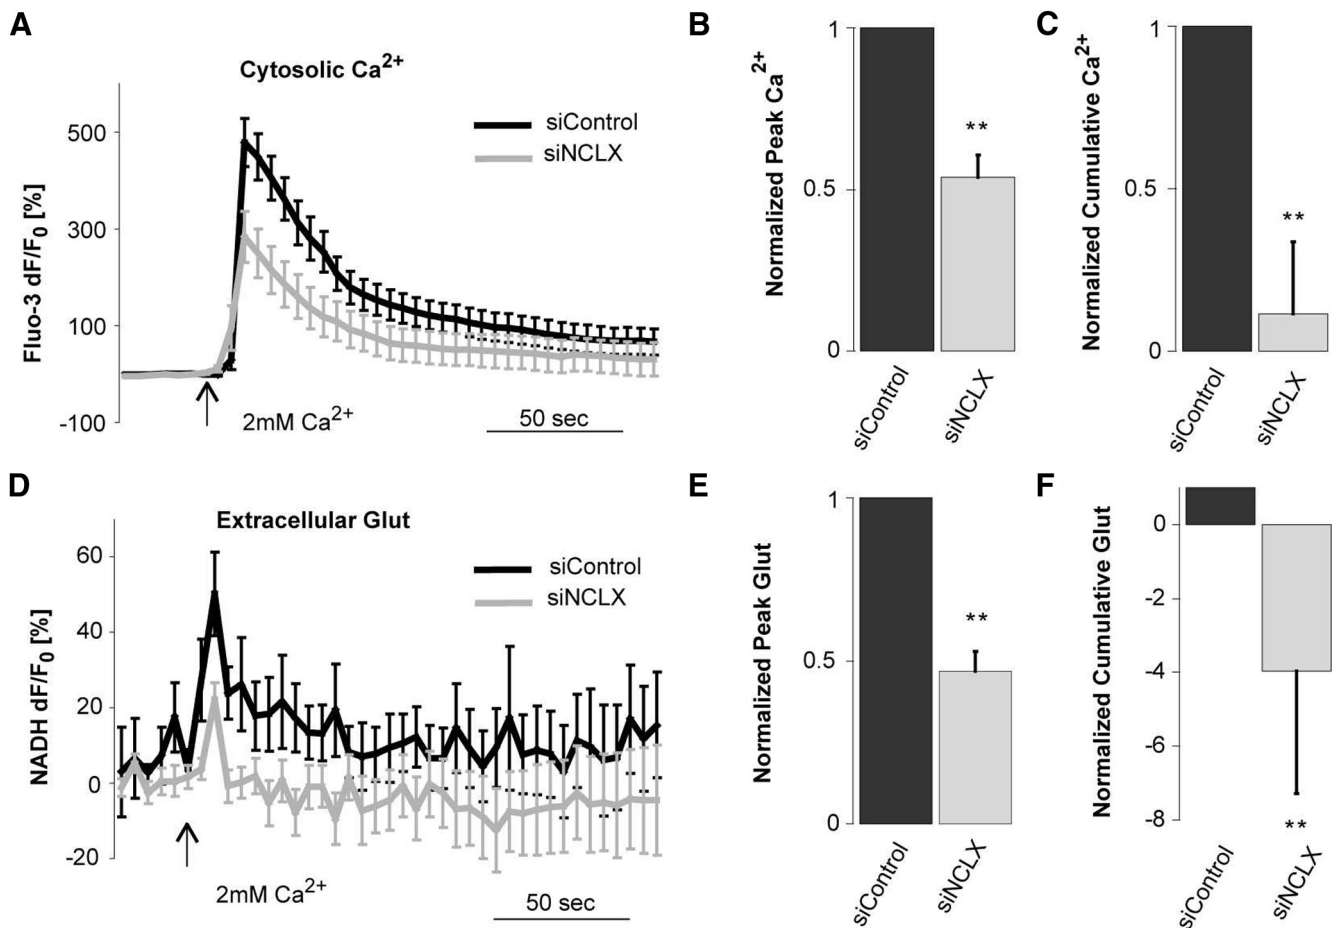

**Figure 4.** NCLX controls SOCE in astrocytes. **A–C**, Imaging of cytosolic  $\text{Ca}^{2+}$  in fura-2 AM-loaded primary murine astrocytes. Astrocytes were cotransfected with siControl or siNCLX and siGLO red indicator. Cells were perfused in  $\text{Ca}^{2+}$ -free HEPES buffer and  $100 \mu\text{M}$  ATP was applied to empty ER  $\text{Ca}^{2+}$  stores; then  $5 \text{ mM}$   $\text{Ca}^{2+}$  was re-added as indicated by the bar to trigger the activation of SOCE. **A**, Traces of average fura-2 AM fluorescence (normalized averages) during SOCE. **B–C**, Amplitudes (**B**) and rates of SOCE (**C**) in siControl ( $n = 9$ ,  $n = 175$ ) and siNCLX-transfected astrocytes ( $n = 9$ ,  $n = 131$ ). Values are given as mean with SEM (\*\*\*)  $p < 0.001$ , Wilcoxon, Mann–Whitney  $U$  test). **D–F**, Untransfected astrocytes were perfused in  $\text{Ca}^{2+}$ -free HEPES buffer without (Control) or with  $20 \mu\text{M}$  CGP37157 or with  $1 \mu\text{M}$  FCCP. After adding  $100 \mu\text{M}$  ATP to empty the ER stores,  $5 \text{ mM}$   $\text{Ca}^{2+}$  was added as indicated. **D**, Mean  $\text{Ca}^{2+}$  response curve of all experiments (normalized averages). **E–F**, Statistical analysis of the amplitudes (**E**) and SOCE rates (**F**) in astrocytes treated with CGP37157 (CGP), FCCP, or without any drug (Control). Values are given as mean with SEM summarized from  $n = 8$  ( $n = 376$  cells),  $n = 7$  ( $n = 425$  cells), and  $n = 5$  ( $n = 168$  cells) experiments for control, CGP37157, and FCCP-treated astrocytes, respectively (\*\*\*)  $p < 0.001$ , Kruskal–Wallis rank-sum test followed by Bonferroni’s posttest and Wilcoxon test pair comparisons). **G–J**, SOCE-induced mitochondrial  $\text{Ca}^{2+}$  signals in astrocytes cotransfected with mTRP and siControl or siNCLX using the same paradigm described in **A**. **G**, Representative curve showing the averaged mitochondrial  $\text{Ca}^{2+}$  response. **H–J**, Rates of the mitochondrial  $\text{Ca}^{2+}$  efflux (**H**), influx (**I**), and cumulative fluorescence (**J**) from  $n = 9$  experiments ( $n = 59$  and  $n = 43$  regions of interest for siControl- and siNCLX-transfected astrocytes, respectively; \*\*\*)  $p < 0.001$ , Student’s  $t$  test for unpaired samples and two-tailed and Mann–Whitney  $U$  test).

experiments,  $n = 376$  and  $425$  cells for control and CGP37157-treated astrocytes, \*\*\*)  $p < 0.001$ ; Fig. 4D–F). Similarly, application of the protonophore FCCP, which leads to a collapse of membrane potential and a diminished calcium-buffering capacity of mitochondria, caused reductions in both the SOCE amplitude and rate (Fig. 4D–F). These results suggest that mitochondrial  $\text{Ca}^{2+}$  shuttling, and in particular NCLX activity, is of major importance for the regulation of  $\text{Ca}^{2+}$  influx into the cell through SOCE.

We next investigated whether  $\text{Ca}^{2+}$  influx via the SOCE pathway evokes mitochondrial  $\text{Ca}^{2+}$  transients and how NCLX activity regulates this cross talk. We adapted the  $\text{Ca}^{2+}$  re-admission protocol described above to mTRP-expressing astrocytes and determined mitochondrial  $\text{Ca}^{2+}$  transients. In this set of experiments, we measured only the wavelength  $F_{430}$  of the mTRP signal because ratiometric measurements of mTRP fluorescence  $F_{480}/F_{430}$  during SOCE for unknown reasons displayed a decrease in the signal-to-noise ratio. SOCE evoked a fast rise in mitochon-

**Figure 5.** NCLX mediates increase of cytosolic  $\text{Ca}^{2+}$  and exocytotic glutamate release in astrocytes after mechanical stimulation. **A–C**, Cytosolic  $\text{Ca}^{2+}$  measurements. **A**, Time lapse of average fluo-3 AM fluorescence, reporting on changes in cytoplasmic  $\text{Ca}^{2+}$ , in solitary astrocytes transfected with either siControl or siNCLX in response to mechanical stimulation; all cells were cotransfected with the transfection marker siGLO. **B**, Normalized fluo-3 AM peak. **C**, Cumulative fluorescence values of mechanically stimulated solitary astrocytes in **A**. **D–F**, Extracellular glutamate measurements. **D**, Average kinetics of extracellular NADH fluorescence showing mechanically induced changes in extracellular glutamate surrounding somata of solitary astrocytes that were transfected as in **A**. **E**, **F**, Normalized peak (**E**) and cumulative glutamate (Glut; **F**) release from mechanically stimulated solitary astrocytes in **D**. Solitary astrocytes transfected with siNCLX displayed significantly (Mann–Whitney  $U$  test,  $**p < 0.01$ ) reduced increase in mechanically induced  $\text{Ca}^{2+}$  signals and glutamate release compared with siControl-transfected cells. The points and bars represent means with SEMs of measurements from individual astrocytes ( $n = 15$ ); Arrows in **A** and **D** represent the time when mechanical stimulation was applied to the cells.

drial  $\text{Ca}^{2+}$  signal followed by a gradual efflux (Fig. 4G). In NCLX-silenced astrocytes, mitochondrial  $\text{Ca}^{2+}$  efflux rate was clearly reduced compared with siControl-transfected cells ( $1.67 \pm 0.22 \times 10^{-4}/\text{s}$  and  $0.28 \pm 0.26 \times 10^{-4}/\text{s}$ , respectively,  $n = 9$  experiments;  $***p < 0.001$ ; Fig. 4H). Concomitantly, upon activation of SOCE, the net influx of  $\text{Ca}^{2+}$  into the mitochondria was increased by 48.8% ( $***p < 0.001$ ; Fig. 4I) and the cumulative mitochondrial  $\text{Ca}^{2+}$  signal was elevated by 60.3% ( $***p < 0.001$ ; Fig. 4J) in NCLX-silenced astrocytes compared with the nonsilenced control.

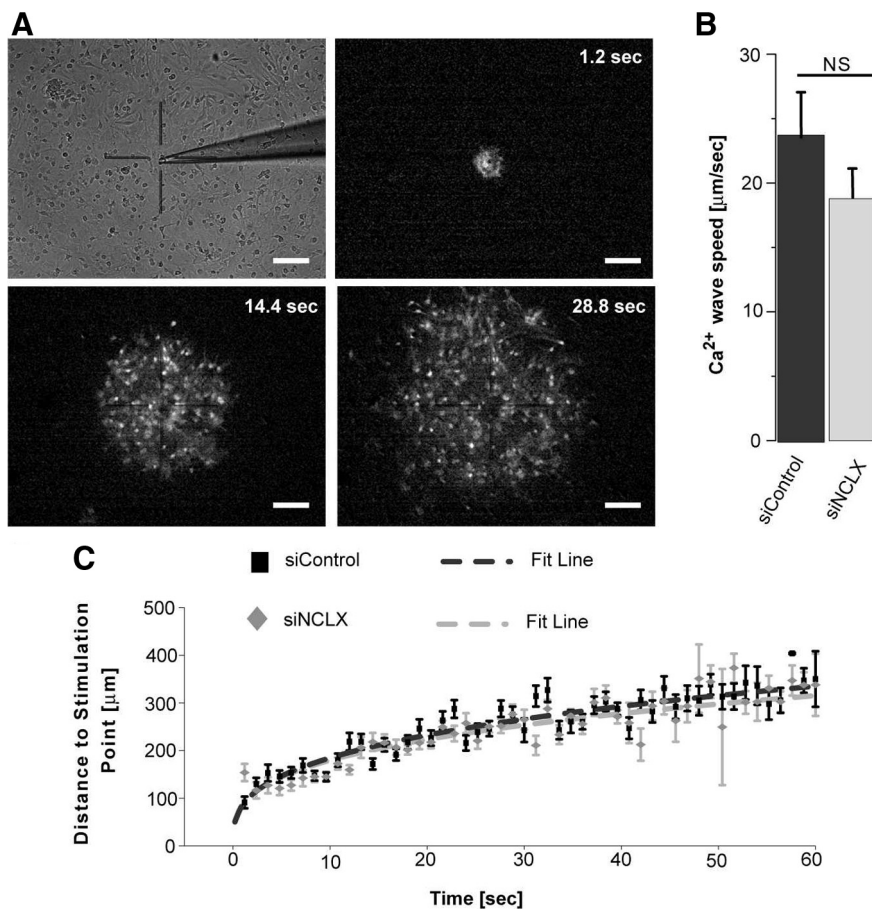

These results indicate that an active cross talk exists between SOCE and mitochondria and that  $\text{Ca}^{2+}$  extrusion through NCLX is crucial for maintaining a strong SOCE activity in astrocytes.

#### NCLX- and $\text{Ca}^{2+}$ -dependent glutamate release from astrocytes

To determine the impact of NCLX on  $\text{Ca}^{2+}$ -dependent functions of astrocytes, we studied the secretion of glutamate via the exocytotic/vesicular pathway induced by mechanical stimulation of astrocytes, which involves an increase of cytosolic  $\text{Ca}^{2+}$  (Innocenti et al., 2000; Hua et al., 2004; Montana et al., 2004). Mitochondria modulate the magnitude of this mechanically induced excitability (Reyes and Pappas, 2008). Interestingly, the pharmacological inhibitor of the mi-

tochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchanger, CGP37157, has been shown previously to reduce mechanically induced  $\text{Ca}^{2+}$  responses and glutamate release from rat solitary astrocytes *in vitro* (Reyes and Pappas, 2008). In the present study, we assessed whether the molecular silencing of NCLX produced similar effects on astrocytic  $\text{Ca}^{2+}$  excitability and gliotransmission.

Astrocytes were transfected with the transfection marker siGLO, along with either siNCLX or a nontargeted siRNA in the control group and then loaded with fluo-3 AM to measure cytosolic  $\text{Ca}^{2+}$ . Similar to the purinergic receptor stimulation described above, mechanical stimulation caused an initial transient  $\text{Ca}^{2+}$  elevation ( $n = 15$ ; peak  $dF/F_0 = 478 \pm 43\%$ ;  $**p < 0.01$ , paired  $t$  test) followed by a slowly decaying response in control solitary astrocytes transfected with the nontargeted siRNA (Fig. 5A). The transient peak was described to indicate the  $\text{Ca}^{2+}$  entry into the cytosol predominately from the ER store and from the extracellular space (Hua et al., 2004; Malarkey et al., 2008). Our data revealed a twofold decrease in both the peak ( $n = 15$ ; peak  $dF/F_0 = 283 \pm 52\%$ ) and a strong, fivefold decrease in cumulative cytosolic  $\text{Ca}^{2+}$  levels in siNCLX-treated cells ( $**p < 0.01$ , Mann–Whitney  $U$  test; Fig. 5A–C). The knock-down of NCLX had a much larger inhibitory effect on the  $\text{Ca}^{2+}$  response than the

**Figure 6.** NCLX does not control the velocity of mechanically evoked  $\text{Ca}^{2+}$  waves in astrocytes. **A**,  $\text{Ca}^{2+}$  waves were induced by mechanical stimulation in confluent astrocyte cultures, transfected with siControl or siNCLX, and loaded with fluo-4 AM to image cytosolic  $\text{Ca}^{2+}$ . **A**, Series of subtraction images showing the concentric propagation of a  $\text{Ca}^{2+}$  wave as induced by poking an astrocyte with a micropipette (bright field image, top). **B**, For each experiment,  $\text{Ca}^{2+}$  wave propagation velocity was calculated by averaging the velocities at which the  $\text{Ca}^{2+}$  wave reached each of the cells on a coverslip. (Wilcoxon, Mann–Whitney  $U$  test,  $p > 0.05$ ,  $n = 5$  astrocytic preparations,  $n = 20$  and 28 coverslips for control and siNCLX, respectively). **C**, Average time course of the propagation of the  $\text{Ca}^{2+}$  wave. The wave was initiated as a fast burst that propagated centrifugally close to a linear velocity. Mean data points could be fitted to a power function: distance =  $A \times \text{time}^b$ . For siControl-treated astrocytes,  $A = 82 \pm 6.7 \mu\text{m}$  and  $b = 0.35 \pm 0.02$  ( $R^2 = 0.92$ ), and for siNCLX-treated astrocytes,  $A = 74 \pm 6.64 \mu\text{m}$  and  $b = 0.36 \pm 0.02$  ( $R^2 = 0.82$ ). The values for  $A$  and  $b$  are given as mean  $\pm$  SD. Values in the graph show mean  $\pm$  SEM. Fitting curves are presented as dashed lines.

pharmacological inhibition of this exchanger by CGP37157, as described previously (Reyes and Parpura, 2008).

We next investigated the role of NCLX in  $\text{Ca}^{2+}$ -dependent exocytotic glutamate release from astrocytes. We used a GDH-linked assay based on accumulation of the fluorescent product NADH (Hua et al., 2004; Montana et al., 2004). Mechanical stimulation of the siControl-treated, solitary astrocytes evoked glutamate release, as indicated by a transient increase in NADH fluorescence ( $n = 15$ ; peak  $dF/F_0 = 50 \pm 11\%$ ;  $**p < 0.01$ , paired  $t$  test; Fig. 5D), corresponding to glutamate surrounding the astrocytic somata. We observed a significant decrease in both normalized peak ( $n = 15$ ; peak  $dF/F_0 = 47 \pm 6\%$ ) and particularly in cumulative fluorescence intensity for glutamate release. After stimulation, basal levels of glutamate release was lower, when NCLX expression was knocked down when compared with the siControl group ( $**p < 0.01$ , Mann–Whitney  $U$  test; Fig. 5E,F). These data indicate that NCLX plays an essential role in mediating cytosolic  $\text{Ca}^{2+}$  responses in astrocytes required for exocytotic glutamate gliotransmission.

### Mechanically induced astrocytic $\text{Ca}^{2+}$ waves are not affected by the activity of NCLX

$\text{Ca}^{2+}$  waves in astrocyte networks constitute a form of intercellular communication and provide astrocytes with a specific form of excitability. In cultured astrocytes,  $\text{Ca}^{2+}$  signals can spread to neighboring cells and can propagate as a wave through many cells (Cornell-Bell et al., 1990; Dani et al., 1992; Schipke et al., 2002). Although different mechanisms have been described to account for the induction and maintenance of intercellular astroglial  $\text{Ca}^{2+}$  waves (Scemes and Giaume, 2006), there is nothing known so far on the role of mitochondria in the maintenance of the intercellular astrocytic  $\text{Ca}^{2+}$  waves and whether  $\text{Ca}^{2+}$  efflux through NCLX contributes to the control of wave propagation in an astrocytic monolayer. We therefore measured velocities of  $\text{Ca}^{2+}$  waves in fluo-4 AM-loaded astrocytes that had been treated with siNCLX or control siRNA (Fig. 6A). An astrocyte within the monolayer was mechanically stimulated, as described above, and wave velocity was calculated for each cell by an algorithm that measures the distance from the stimulation point and the time at which the wave reached a given cell. Although the averaged velocity of the  $\text{Ca}^{2+}$  wave was  $23.9 \pm 3.3 \mu\text{m/s}$  for siControl astrocytes, and  $18.8 \pm 2.3 \mu\text{m/s}$  on average for the NCLX-silenced astrocytes, it was not significantly different (Fig. 6B). A wave was initiated as a rapid onset, followed by centrifugal propagation with almost linear velocity. The averaged time course of the waves is shown in Figure 6C. The mean data points were fitted to the following power functions: in siControl-treated astrocytes, distance =  $82 \pm 6.7 \times \text{time}^{0.35 \pm 0.02}$ ,  $R^2 = 0.92$ , and in NCLX-treated astrocytes, distance =  $74 \pm 6.6 \times \text{time}^{0.36 \pm 0.02}$ ,  $R^2 = 0.82$ . The slight reduction in the  $\text{Ca}^{2+}$  wave velocity that we observed in NCLX-silenced astrocytes was not significant, which suggests that the activity of the mitochondrial exchanger only marginally, if at all, affects the  $\text{Ca}^{2+}$  signaling machinery contributing to propagation of intercellular  $\text{Ca}^{2+}$  waves in astrocytes.

### NCLX participates in control of astrocytic wound healing *in vitro*

Astrocyte migration and proliferation represent important cellular aspects of the brain's response to injury and during regeneration. Intracellular  $\text{Ca}^{2+}$  signaling is critical to the regulation of these cellular responses (Xu et al., 2004; Valero et al., 2008; Wei et al., 2009; Feldman et al., 2010). Therefore, we investigated whether the mitochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchanger NCLX affects these functional parameters in astrocytes.

To assess the effect of NCLX on astrocytic wound healing, we adapted an *in vitro* assay described previously (Környei et al., 2000; Matyash et al., 2002). Monolayers of astrocytes that had

either been treated with NCLX siRNA or with control siRNA, as well as mock-transfected and untreated astrocytes, were scratched as indicated in Figure 7B and the cell-free area was measured immediately after scratching as described by Gebäck et al. (2009) (Fig. 7A). Thereafter, repopulation was analyzed repeatedly 48–72 h after scratching until the wound area was closed by at least two-thirds in the untreated control (end point). Molecular silencing of NCLX with siRNA significantly impaired the astrocytic ability to repopulate the cell-free area (Fig. 7B, C). Although the scratch was closed by more than two-thirds after 48–72 h in siControl cultures, it remained much larger when NCLX was inhibited: the mean open wound area in NCLX-silenced astrocytes was  $48.5 \pm 2.6\%$  on average compared with  $24.6 \pm 2.5\%$  for the siControl conditions ( $n = 3$  experiments,  $n = 20$  scratches,  $***p < 0.001$ ; Fig. 7C), and these observations were confirmed in cultures treated with  $20 \mu\text{m}$  CGP37157 throughout the regrowth phase (data not shown), indicating that NCLX activity is crucial for astrocytic migration and wound closure *in vitro*.

To assess whether NCLX exerts an effect on astrocyte proliferation, we performed cell proliferation assays based on BrdU incorporation in noninjured cultures. Astrocyte proliferation was decreased by 38.6% in NCLX-silenced astrocyte cultures compared with astrocytes transfected with nontargeted siRNA (siControl,  $n = 3$  experiments,  $n = 15$  wells,  $***p < 0.001$ ; Fig. 7D). A possible harmful side effect of the transfection procedure can be excluded because the proliferation in the siControl and mock-transfected cultures was not impaired compared with the untreated control astrocytes.

These findings indicate that the mitochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchanger NCLX is involved in the control of astrocytic wound closure and proliferation.

## Discussion

Mitochondria are critically involved in  $\text{Ca}^{2+}$  handling in astrocytes, thereby modifying astrocytic functions (Verkhatsky et al., 2012). In the present study, we addressed the specific role of NCLX in shaping astrocytic mitochondrial and cytoplasmic  $\text{Ca}^{2+}$  signals and studied its impact on  $\text{Ca}^{2+}$ -dependent astrocyte functions. We show that NCLX, which is enriched in astrocytic mitochondria, mediates  $\text{Ca}^{2+}$  extrusion from mitochondria. In addition, NCLX predominately modulated the SOCE pathway, whereas its effect on the ER-dependent  $\text{Ca}^{2+}$  release was minor. Therefore, NCLX activity has a major impact on modulating cytoplasmic  $\text{Ca}^{2+}$  signals in astrocytes, as well as their functional output, exocytotic glutamate release, wound closure, and proliferation, but does not significantly influence the propaga-

**Figure 7.** NCLX participates in astrocytic *in vitro* wound healing and proliferation. **A**, Confluent astrocytic monolayers were scratched as described in the Materials and Methods, and phase contrast images were acquired at 0 h (top row) and after 48–72 h (bottom row) at low magnification. Left column shows raw images and right column shows the same images after analysis with T-scratch software. Dark gray areas correspond to the open wound area; values at the end point are normalized to a 100% area at the starting point (0 h). Scale bar, 100  $\mu\text{m}$ . **B**, Scheme exemplifying how scratches (white lines) were applied to astrocyte monolayers (gray areas). Black frames correspond to the analyzed areas of interest. **C**, Percentage of open wound area in monolayers that were untransfected, mock-transfected, or transfected with siControl or siNCLX ( $n = 3$  cultures,  $n = 18, 16, 20$ , and  $20$  scratches, respectively). Values are given as means with SEM ( $***p < 0.001$ , Student's *t* test for unpaired samples, two-tailed). **D**, BrdU incorporation into proliferating astrocytes that were untransfected, mock-transfected, or transfected with siControl or siNCLX, given as percentage proliferation normalized to control ( $n = 3$  experiments,  $n = 15$  wells;  $***p < 0.001$ , Mann–Whitney *U* test).

tion of mechanically induced  $\text{Ca}^{2+}$  waves in astrocytic monolayers.

Our immunochemical approach verified that the NCLX protein is expressed in astrocytes and occurs as an  $\sim 60$  kDa and an  $\sim 100$  kDa form that is consistently related to an SDS-resistant NCLX dimer (Palty et al., 2004; Palty et al., 2006). Comparison of NCLX expression in different organelle-enriched fractions of astrocytes revealed a strong enrichment of NCLX in the mitochondria, indicating that it is primarily located in these organelles. The MW of mitochondrial NCLX, interestingly, was slightly reduced to  $\sim 50$  kDa compared with the other cellular compartments. Although the physiological role of such processing is not yet clear and we cannot rule out whether NCLX cleavage occurred during mitochondrial isolation, the reduction in MW is consistent with the sensitivity of NCLX to mitochondrial proteases such as mitochondrial calpains (Kar et al., 2009; Smith and Schnellmann, 2012). Alternatively, because our antibody is targeted to the C-terminal domain of NCLX, cleavage is likely to occur on the NH3-terminal NCLX domains. The N-terminal domains usually harbor the mitochondria-targeting peptide that can be cleaved during mitochondrial insertion (Moss-

mann et al., 2012). Although these mechanisms need to be investigated further, they raise interesting questions regarding posttranslational regulation of NCLX in mitochondria.

### NCLX modulates glial $\text{Ca}^{2+}$ signaling

An important finding of our study is that NCLX activity promotes SOCE in astrocytes. Sustained  $\text{Ca}^{2+}$  influx through SOCE results in prolonged intracellular  $\text{Ca}^{2+}$  transients that are particularly important in controlling slow cellular processes such as secretory activity and cell proliferation (Hoth et al., 1997; Golovina, 1999; Golovina et al., 2001; Berridge et al., 2003).

Several studies have documented a pivotal role of the mitochondrial exchanger in the replenishment of the ER  $\text{Ca}^{2+}$  stores (Arnaudeau et al., 2001; Malli et al., 2005; Kim et al., 2012). We found that ER  $\text{Ca}^{2+}$  release, which can be considered an indicative value for ER  $\text{Ca}^{2+}$  content, was not much altered by the knock-down of NCLX expression. Although the molecular basis for this relatively minor influence of NCLX on ER  $\text{Ca}^{2+}$  needs to be explored further, it may be related to the major role of SERCA in refilling the astrocytic  $\text{Ca}^{2+}$  stores, even under NCLX deficiency. In addition, transfer of  $\text{Ca}^{2+}$  from the mitochondria to the ER  $\text{Ca}^{2+}$  stores is facilitated by the tight physical interactions mediated by an ER–mitochondria-tethering protein complex and direct  $\text{Ca}^{2+}$  transport through these compartments via the voltage-dependent anion channels (Szabadkai et al., 2006; Kornmann et al., 2009; de Brito and Scorrano, 2010). Our results suggest that such cross talk between the ER and mitochondria is relatively weak in astrocytes. This assertion is consistent with our findings that the strong cytosolic  $\text{Ca}^{2+}$  response triggered by ER  $\text{Ca}^{2+}$  release was followed by only a modest mitochondrial  $\text{Ca}^{2+}$  transient compared with a much stronger mitochondrial  $\text{Ca}^{2+}$  transient triggered by  $\text{Ca}^{2+}$  influx into the cells. The latter effect suggests a stronger interaction of NCLX with the SOCE pathway. It is not surprising that astrocytic intracellular  $\text{Ca}^{2+}$  dynamics are inherently linked to those of  $\text{Na}^+$  (Kirischuk et al., 2012). Therefore, in addition to obvious exchange of these ions via NCLX, cytoplasmic  $\text{Na}^+$  concentrations would also be affected by diverse plasma membrane receptors and transporters involved in  $\text{Na}^+$  exchange, among them SOCE and/or P2XRs, and the cytosolic  $\text{Na}^+$  load thus affects a multitude of astroglial homeostatic functions (Kirischuk et al., 2012).

Mitochondrial metabolism is likely to be affected by the activity of NCLX, because  $\text{Ca}^{2+}$  activates several enzymes of the Krebs cycle (Szabadkai and Duchen, 2008). NCLX, by accelerating mitochondrial  $\text{Ca}^{2+}$  shuttling, increases the duration of mitochondrial  $\text{Ca}^{2+}$  transients and thereby is likely to enhance ATP production.

### NCLX activity differentially affects migration/proliferation

We used an *in vitro* model to study the impact of NCLX function on the ability of astrocytes to populate a cell-free area as a model for wound healing. The repopulation of the cell-free “wound” area is primarily due to astrocyte proliferation, although migration does also contribute to this process (Környei et al., 2000). A role of SOCE in wound closure has been proposed previously (Rao et al., 2006). Our study strongly suggests that mitochondrial  $\text{Ca}^{2+}$  transfer through NCLX is essential to facilitate SOCE, and therefore may affect astrocytic proliferation and the regrowth of the astrocytes into the denuded areas of the wound. Although the downstream mitogenic signaling pathways that link the  $\text{Ca}^{2+}$  response to migration and proliferation still need to be investigated, earlier studies have highlighted the role of the mitochondrial exchanger in activating the PI3 kinase pathway by

accelerating SOCE-related cellular  $\text{Ca}^{2+}$  rise (Feldman et al., 2010).

### NCLX activity does not affect astrocytic $\text{Ca}^{2+}$ wave propagation

Propagating  $\text{Ca}^{2+}$  waves are a major communication pathway of the astrocytic network and of neuron–astrocyte communication. Different mechanisms account for the induction and maintenance of intercellular astroglial  $\text{Ca}^{2+}$  waves. These involve the release of gliotransmitters, as well as direct diffusion of  $\text{InsP}_3$  through gap junctions into neighboring astrocytes, where it activates  $\text{InsP}_3$  receptors and subsequent release of  $\text{Ca}^{2+}$  from ER stores (Scemes and Giaume, 2006). On a single-cell level (intracellular  $\text{Ca}^{2+}$  waves), mitochondrial  $\text{Ca}^{2+}$  buffering has been described as an important means to attenuate excess  $\text{Ca}^{2+}$  levels at the  $\text{InsP}_3\text{R}$  microdomains (Boitier et al., 1999) to keep the amplification working. However, little is known about the role of mitochondria in the maintenance of the intercellular astrocytic  $\text{Ca}^{2+}$  waves and whether  $\text{Ca}^{2+}$  efflux through NCLX contributes to the control of wave propagation in an astrocytic monolayer. Our results show that the knock-down of NCLX does not induce a significant change in astrocyte  $\text{Ca}^{2+}$  wave propagation velocity. The less dominant role of the mitochondrial exchanger in wave propagation may be related to at least two issues. First, the rates of mitochondrial  $\text{Ca}^{2+}$  uptake are approximately two orders of magnitude faster than mitochondrial  $\text{Ca}^{2+}$  efflux, which spans over tens of seconds (Fig. 2C; Palty et al., 2010). However, the propagation of the cytosolic astrocytic  $\text{Ca}^{2+}$  wave is much more rapid, thus crossing a single glial cell within less than a second. At this rate, the contribution of the slower mitochondrial exchanger to cytosolic  $\text{Ca}^{2+}$  is predicted to be minimal. Second, in addition,  $\text{Ca}^{2+}$  release from the ER is the dominant pathway providing  $\text{Ca}^{2+}$  during wave propagation. Because ER  $\text{Ca}^{2+}$  release is not strongly affected by the knock-down of NCLX, it is thus less likely to play a dominant role in propagation of the  $\text{Ca}^{2+}$  wave.

### NCLX is instrumental in increasing cytosolic $\text{Ca}^{2+}$ for triggering release of gliotransmitter glutamate

Previous work used a pharmacological approach to assess the role of the mitochondrial  $\text{Na}^+/\text{Ca}^{2+}$  exchanger in cytoplasmic  $\text{Ca}^{2+}$  dynamics in astrocytes: inhibition by CGP37157 resulted in a reduction of mechanically induced  $\text{Ca}^{2+}$  responses and glutamate release recorded from cultured rat solitary astrocytes (Reyes and Parpura, 2008). The molecular identification of NCLX (Palty et al., 2010) now provides a more specific, siRNA-based molecular tool with which to study its role on mechanically induced  $\text{Ca}^{2+}$  responses and glutamate release from astrocytes. Although our data are consistent with previous pharmacological data, they provide new insight on the role of the exchanger. Most notably, the molecular knock-down of NCLX triggered a more profound inhibitory effect on mechanically induced increase of cytosolic  $\text{Ca}^{2+}$  and subsequent exocytotic release of glutamate than the pharmacological approach (Reyes and Parpura, 2008). The reason for the differences between the acute pharmacological versus the siRNA approach could be the multiple sites of CGP37157 action, among them  $\text{Ca}^{2+}$  transporters. The molecular knock-down approach is specific for NCLX, whereas the pharmacological approach may partially mask the full effect of the mitochondrial exchanger on glutamate secretion due to side effects on other transport molecules. Because vesicular glutamate transporter 3 and cytoplasmic glutamate levels in astrocytes regulate the magnitude of exocytotic glutamate release from astrocytes (Ni and Parpura, 2009), a possible explanation for

unparalleled changes in cytoplasmic  $\text{Ca}^{2+}$  and  $\text{Ca}^{2+}$ -dependent glutamate release could be that astrocytes lacking NCLX have less glutamate available for vesicular storage and release. *De novo* glutamate synthesis relies on the mitochondrial matrix enzyme pyruvate carboxylase (Hertz et al., 1999), which is activated by  $\text{Ca}^{2+}$  (Civelek et al., 1996). However, our observation that the knock-down of NCLX results in a sustained increase, rather than a decrease, in mitochondrial free  $\text{Ca}^{2+}$  would not support such a scenario. Therefore, it is tempting to hypothesize that NCLX, by modulation of glutamate release from astrocytes, has a role in synaptic transmission and plasticity at the tripartite synapse.
