We provide neurobehavioral evidence supporting the transferable benefit of music training to alter brain function and enhance cognitive performance in a nonmusical visuospatial task in professional orchestral musicians. In particular, orchestral musicians' performance on a three-dimensional mental rotation (3DMR) task exhibited the behavioral profile normally only attained after significant practice, supporting the suggestion that these musicians already possessed well developed neural circuits to support 3DMR. Furthermore, functional magnetic resonance imaging revealed that only orchestral musicians showed significantly increased activation in Broca's area, in addition to the well known visuospatial network, which was activated in both musicians and nonmusicians who were matched on age, sex, and verbal intelligence. We interpret these functional neuroimaging findings to reflect preferential recruitment of Broca's area, part of the neural substrate supporting sight reading and motor-sequence organization underpinning musical performance, to subserve 3DMR in musicians. Our data, therefore, provide convergent behavioral and neurofunctional evidence supporting the suggestion that development of the sight-reading skills of musical performance alters brain circuit organization which, in turn, confers a wider cognitive benefit, in particular, to nonmusical visuospatial cognition in professional orchestral musicians.

**Key words:** visuospatial; cognition; human; musician; Broca's area; mental rotation

## Introduction

The extensive occupational engagement of musicians who are members of a professional symphony orchestra provides an opportunity to study the potential long-term effects associated with acquiring and sustaining expert musical performance skills. In particular, the human brain has a well known capacity for neuroplastic adaptation in response to skill acquisition (Sterr et al., 1998), which is predicted to occur in musicians in structures that have particular functional relevance for enabling musical performance. For example, increased gray-matter volume in Broca's area, known to subserve the visuospatial analysis and sequencing of rapid motor actions required for musical performance from sight reading (Sergent et al., 1992; Parsons et al., 2005; Bengtsson and Ullen, 2006), was found to be related to years of orchestral playing (Sluming et al., 2002). Sight-reading ability has been shown to be a significant factor influencing a musician's ability to perform a repertoire of rehearsed music (McPherson et al., 1997), which is fundamental for professional symphony orchestra mu-

sicians. It is a complex skill that occurs automatically in the highly skilled sight reader (Wolf, 1976) and involves the extremely rapid implementation of a series of operations through perception, including visuospatial analysis of symbolic input, to the sequential and coordinated motor output of musical performance (Sergent, 1993). Furthermore, sight reading is characterized by high demands on the performer's capacity to process complex visual input under real-time constraints and with no opportunity for error correction (Kopiez et al., 2006). We therefore used the classic three-dimensional mental rotation (3DMR) task of Shepard and Metzler (1971), which could be conveniently administered to both musicians and nonmusicians to quantify visuospatial analysis and mental imagery of motor transformation ability (Kosslyn et al., 1984; Wallace and Hofelich, 1992). 3DMR is a complex high-level nonmusical spatial ability test which, according to traditional theories of mental rotation, involves rapidly sequencing a series of operations, specifically (1) stimulus identification, (2) search, (3) mental rotation, and (4) decision (Shepard and Cooper, 1982). Using functional magnetic resonance imaging (fMRI) to study 3DMR, we tested the hypothesis that orchestral musicians would, in comparison with nonmusicians, show increased activation in Broca's area, known to subserve hierarchical organization of behavior by controlling the selection and nesting of action segments (Koechlin and Jubault, 2006), in addition to the visuospatial network (Cohen et al., 1996), which would be specifically associated with enhanced performance on this test, evi-

(1992) to describe the sight-reading neural network. Top row, Broca's area in left hemisphere activated in musicians only; middle

0.001 for each group and adding them to produce a liberal functional mask, which included all areas with increased BOLD signal in both groups during performance of the 3DMR task (i.e., inclusive masking). Regions of significantly increased activation were localized using the cytoarchitectonic maximum probability maps for Brodman areas 44 and 45 (Amunts et al., 1999) provided in the Anatomy Toolbox in SPM (Eickhoff et al., 2006).

## Results

### Assessment of verbal intelligence

There were no differences in the total number of semantic processing ( $t = 0.48$ ;  $df = 18$ ;  $p = 0.64$ ) or control trials ( $t = 0.37$ ;  $df = 18$ ;  $p = 0.72$ ) attempted, or the total number of correct semantic processing trials ( $t = -1.1$ ;  $df = 18$ ;  $p = 0.30$ ) or number of correct control trials ( $t = 0.77$ ;  $df = 18$ ;  $p = 0.45$ ) between musicians and controls. Musicians had an accuracy rate of 98% in the sentence processing task and 90% in the control condition; the control group had an accuracy rate of 98% in the sentence processing task and 89% in the control condition. There was no difference in mean response times for sentence processing between the groups ( $t = 0.67$ ;  $df = 18$ ;  $p = 0.51$ ). During sentence processing, within-group random effects analysis of the fMRI data revealed that both groups activated similar cortical regions, mainly in left hemisphere, notably, the classic language regions of Broca's and Wernicke's areas (Fig. 2). There were no significant differences in brain activation patterns in the between-group random effects analysis (RFX) analysis.

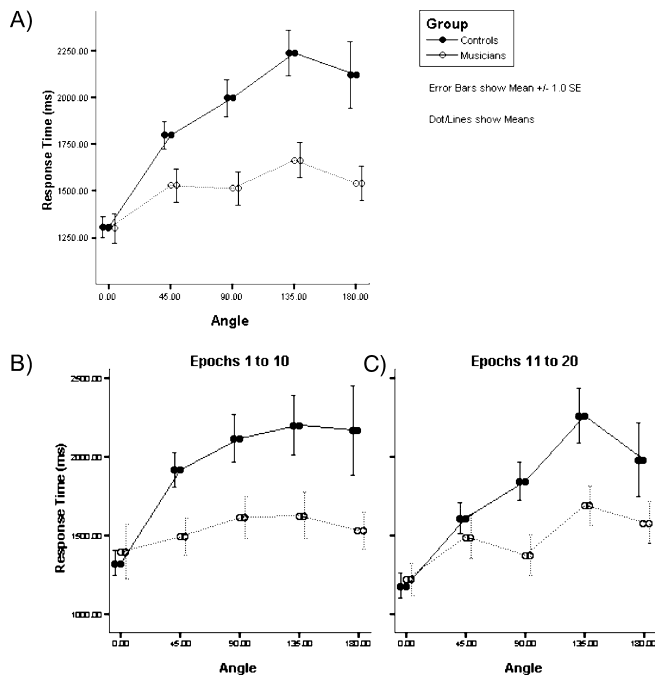

### Behavioral results for 3DMR and 2D shape-matching control tasks

The mean number (range) of trials attempted by the subjects was as follows: musicians, 2D shape-matching, 141 (116–161); 3DMR, 94 (53–137); controls, 2D shape-matching, 139 (97–158); and 3DMR, 71 (45–116). Accuracy rates for the two experimental tasks were as follows: musicians, 2D shape-matching, 94%; 3DMR, 81%; controls, 2D shape-

←

and bottom rows, premotor and parietal cortices activated in both groups. *Biii*, Results of the random-effects group differences analysis projected onto a structural MR scan of a subject selected at random from the volunteers, showing regions with significantly increased BOLD signal in musicians compared with nonmusicians during 3DMR task performance (column 1, left pars operculum,  $x = -45$ ,  $y = 18$ ,  $z = 14$ ,  $t = 6.56$ , 6 voxels; column 2, right angular gyrus,  $x = 42$ ,  $y = -54$ ,  $z = 23$ ,  $t = 4.11$ , 6 voxels; column 3, left anterior cingulate gyrus,  $x = -15$ ,  $y = 38$ ,  $z = 6$ ,  $t = 5.82$ , 14 voxels).

**Figure 3.** *A*, Mean RTs (error bars,  $\pm 1$  SEM) as a function of angle between the paired forms of 3DMR task. The classical behavioral signature of the 3DMR task, in which RT increase linearly as a function of angle between the forms, was evident only in nonmusicians. *B*, Mean RTs (error bars,  $\pm 1$  SEM) as a function of angle between the paired forms of the 3DMR task during epochs 1–10. *C*, Mean RTs (error bars,  $\pm 1$  SEM) as a function of angle between the paired forms of the 3DMR task during epochs 11–20.

matching 95%; and 3DMR, 73%. There were no differences in either the number of control 2D shape-matching trials attempted ( $t = 0.45$ ;  $df = 18$ ;  $p = 0.66$ ) or scored correctly ( $t = 0.09$ ;  $df = 18$ ;  $p = 0.93$ ), indicating that both groups were performing at the same level in this control task. However, orchestral musicians attempted significantly more 3DMR trials ( $t = 2.8$ ;  $df = 11.6$ ;  $p = 0.02$ ) and achieved more correct responses than the control group, both absolutely ( $t = 4.5$ ;  $df = 18$ ;  $p = 0.00$ ) and as a proportion of trials attempted ( $t = 3.4$ ;  $df = 18$ ;  $p = 0.003$ ). The classical behavioral signature of 3DMR, with response times (RTs) increasing linearly as a function of angle-of-rotation (Shepard and Metzler, 1971), was seen only in the control group (Fig. 3*A*). Analysis of median RT (correct trials, excluding outliers not within  $\pm 3$  SD of mean for each individual) was performed using a mixed-design ANOVA, with angle and timing of epoch (epochs 1–10 categorized as “early” and epochs 11–20 as “late”) as within-subject factors. Neither the main effect of epoch ( $F_{(1,18)} = 2.69$ ;  $p = 0.12$ ) nor the interactions involving the epoch term were significant (epoch by angle by group,  $F_{(1,18)} = 0.31$ ,  $p = 0.86$ ; epoch by group,  $F_{(1,18)} = 0.85$ ,  $p = 0.37$ ) (Fig. 3*B,C*), providing evidence that performance was stable across the two halves of the fMRI scanning session. Notably, however, there was a significant group by angle interaction ( $F_{(1,18)} = 7.20$ ;  $p = 0.02$ ) and a simple main-effects analysis identified angle of rotation as being statistically significant in nonmusicians ( $F_{(1,9)} = 16.01$ ;  $p = 0.003$ ), but not orchestral musicians ( $F_{(1,9)} = 1.13$ ;  $p = 0.32$ ). As can be seen in Figure 3*A* (and for comparison across epochs, Fig. 3*B,C*) the nonmusicians display the classic RT slope function, whereas that for the musicians was essentially flat. Simple main-effects analyses confirmed that for nonmusicians, angle of rotation was found to be significant ( $F_{(1,9)} = 16.01$ ;  $p = 0.003$ ), whereas the effect was unreliable for orchestral musicians

( $F_{(1,9)} = 1.13$ ,  $p = 0.32$ ). The overall average slopes of these RT functions were 1.57 ms/° and 5.25 ms/° with intercepts of 1403 and 1510 ms for musicians and nonmusicians, respectively. Overall mean RT for 3DMR was negatively associated with age in musicians ( $r = -0.68$ ;  $p = 0.03$ ), whereas for nonmusicians a nonsignificant trend ( $r = 0.37$ ;  $p = 0.30$ ) consistent with the typical age-related increase in RT was observed. Finally, for the musicians, overall mean RT was negatively correlated with number of years of orchestral playing for the 3DMR task ( $r = -0.63$ ;  $p = 0.05$ ), but not for the control 2D shape-matching task ( $r = -0.07$ ;  $p = 0.83$ ).

### fMRI results for 3DMR experiment

Within-group RFX ( $p_{\text{corrected}} = 0.05$ ) of fMRI data revealed that performing 3DMR is associated with increased BOLD signal in similar brain regions in both musicians and nonmusicians, including bilateral visual association (BA18/19), and premotor (BA6) and superior parietal (BA7) cortices, as has been reported previously (Cohen et al., 1996) (Fig. 2*Bi,Bii*, Table 1). Subsequently, RFX analysis of group differences ( $p_{\text{corrected}} < 0.05$ ) revealed that there were significantly greater activations only in Broca’s area (BA44 and BA45), the right angular gyrus (BA39), and left anterior cingulate cortex (ACC) (BA24/32) during 3DMR performance (Fig. 2*Biii*) in musicians relative to controls. Cytoarchitectonic maximum probability maps for Brodman areas 44 and 45 (Amunts et al., 1999; Eickhoff et al., 2006) localized 62% of activation to BA45 and 38% of activation to BA44 during 3DMR. Furthermore, the slope of the RT function for musicians was negatively correlated with activity only in Broca’s area ( $x = -54$ ,  $y = 24$ ,  $z = 9$ ;  $t = 5.52$ ;  $p = 0.02$ ; two voxels, 70% probability of BA45) such that flatter slopes (i.e., better performance) were associated with increased activation in these voxels. Data at this voxel, extracted for each subject, plotted against their RT slope function is shown in Figure 4.

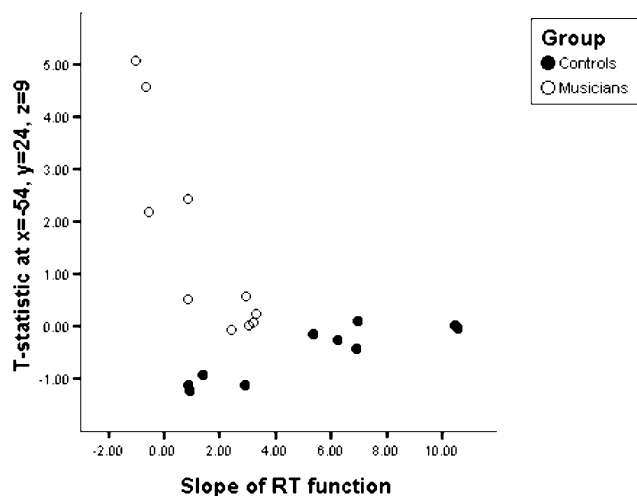

### Discussion

We found convergent behavioral and neurofunctional evidence to support the hypothesis that orchestral musicians will show enhanced performance on the complex visuospatial task of 3DMR corresponding with increased activation in Broca’s area, part of the neural network subserving sight reading. In particular, we found that musicians were, overall, more accurate on the 3DMR task and, although matched on 0° trials, exhibited progressively faster RTs as a function of angular disparity. Furthermore, the averaged non-0° RTs for the musicians were negatively correlated with years of orchestral experience. Neurofunctionally, in addition to the visuospatial network identified previously (Cohen et al., 1996), only musicians activated Broca’s area, which was also found to be negatively correlated with their RT slope function, such that flatter slopes were associated with greater activation in this brain region. The results of the between-group random effects fMRI data analysis, therefore, suggest that increased activation of Broca’s area in the musicians’ group mediates faster mental manipulation of 3DMR stimuli and greater accuracy of decision making.

The prefrontal cortex, including Broca’s area, is one of the last brain regions to reach maturity in the adult brain (Sowell et al., 1999), thus, retaining a high degree of neuroplasticity during adolescence and early adulthood when musicians, who progress to achieve a professional standard of performance, will be practicing their musical skills intensely (Ericsson et al., 1993). Neuroimaging studies have provided convincing evidence of differences in musicians’ brains in structures known to have particular

**Figure 4.** Scatterplot of the t statistic from the first level analysis of fMRI brain data against the slope of the RT function of the behavioral data for each individual at voxel coordinates  $x = -54, y = 20,$  and  $z = 13,$  which was identified as statistically significant ( $p = 0.02$ ) in the correlational SPM analysis only in musicians.

relevance for enabling musical performance, such as increased cross-sectional area of the anterior corpus callosum (Schlaug et al., 1995), increased cortical representation of the left-hand fingers in string players (Elbert et al., 1995), increased gray-matter (GM) volume in anteromedial Heschl's gyrus related to pitch perception (Schneider et al., 2005), and increased GM volume in

Broca's area, related to years of playing in orchestral musicians (Sluming et al., 2002). One explanation for the findings that we report could be that inherent brain structure may predispose musicians to excel at the skills necessary for expert musical performance. Alternatively, there may be an interaction between brain development and acquisition and maintenance of musical visuospatial skills, which promotes generation or retention of functionally relevant cortical tissue, such as use-dependent adaptation in Broca's area (Sluming et al., 2002), which can be preferentially recruited to subserve complex visuospatial, nonmusical tasks such as 3DMR. This latter interpretation is supported by our findings of negative correlation between activation in Broca's area and RT in musicians and also by the neurofunctional dissociation we observed in Broca's area between verbal and visuospatial tasks.

In addition to its well known role in motor sequencing of expressive language Broca's area has been shown to subserve sequencing of nonlanguage motor functions such as preparation and performance of complex hand movements (Stephan et al., 1995; Binkofski et al., 2000), associative sensorimotor learning and integration (Binkofski and Buccino, 2004), production of actions (Bonda et al., 1995; Parsons et al., 1995), and sensory processing of visual stimuli (Mechelli et al., 2005), all of which are crucial elements of expert musical performance (Waters et al., 1997; Kopiez et al., 2006). Furthermore, it has been proposed that this region subserves hierarchical organization of behavior (Koechlin and Jubault, 2006) by implementing a specialized executive system to control the selection and nesting of action segments, with top-down control exerted from anterior (BA45) to

posterior (BA44) regions. Sight reading is a complex process involving a reading skill of encoding musical symbols (Furneaux and Land, 1999) and a transformational sensorimotor skill of positioning the fingers appropriately on the instrument at precisely the correct moment (Wolf, 1976). In particular, reading musical notation is a visuospatial analysis task, in which information conveyed by spatial location and vertical separation of adjacent notes, is directly related to musical pitch interval, thus differing from the feature extraction task of reading printed alphabetic text (Sergent et al., 1992). Highly skilled sight readers are able to transform the array of visual symbols into the motor actions of musical performance at remarkable speed, an ability that is only acquired by practice (Kopiez et al., 2006). The non-musical visuospatial skill of 3DMR is a high-level cognitive task that involves covert simulation of motor rotation requiring both maintenance and manipulation of the mental images. It is possible that faster 3DMR RT by musicians might be explained by better sensorimotor skills developed by years of daily instrument practice. However, this is not supported by RT data for either 0° angle trials in 3DMR or the 2D shape-matching control tasks requiring only identity recognition, and which showed no difference between musicians and nonmusicians. The neurofunctional findings, therefore, suggest that Broca's area subserves the sequential mental manipulation components of 3DMR that are enhanced in orchestral musicians.

The behavioral findings that we report relating to slope of 3DMR RT function in musicians are comparable with previously reported RT slope functions of subjects who have undergone training, either on the 3DMR task itself (Kaushal and Parsons, 1981) or on related tasks for transfer to 3DMR (Wallace and Hofelich, 1992; Wiedenbauer et al., 2007), which show that training-enhanced performance is reflected in reduction of the slope of the RT function. Indeed, Kaushal and Parsons (1981) have shown previously that the slope of the RT function reduces to zero after sufficient numbers of 3DMR trials have been attempted (typically 864). However, musicians exhibited a flat slope RT function within the first five epochs of 3DMR and there was no evidence of a practice effect (in either musicians or non-musicians) during this experiment. Although the limiting rate criterion (i.e., the fastest rate at which mental rotation could be performed), originally proposed by Shepard and Metzler (1988) was 15.6 ms/°, there is now a wealth of evidence to support Cohen and Kubovy's (1993) proposal of 1 ms/° as a limiting value, which reflects the process of mental rotation. The gradient and intercept of the musicians' slope, 1.57 ms/° and 1403 ms, can be taken to indicate that musicians were using a mental rotation strategy and, therefore, already possessed the neural circuitry to support this enhanced level of performance. Our finding that RT is negatively associated with number of years of orchestral playing may be the result of selection, if the less spatially skilled, younger musicians withdrew from the orchestra early in their performing career, which would also highlight the importance of visuospatial skills for professional orchestral musicians. An alternative interpretation of the negative correlation between RT and years of orchestral playing is that orchestral playing confers benefit to the performance of 3DMR and supports the notion that maintaining musical and sight-reading skills throughout adulthood may confer benefits on the more complex visuospatial tasks. Indeed, this interpretation is corroborated by the age-related improvement in performance observed in only musicians.

Both musicians and nonmusicians activated premotor, parietal, and visual association areas which are well known to sub-

serve 3DMR (Cohen et al., 1996) and sight reading (Sergent et al., 1992). The only statistically significant between-group difference in activations, specifically within these commonly activated regions, was increased activation in the right angular gyrus (BA39) (Horwitz et al., 1998) of the posterior parietal cortex in musicians. BA39 has been reported to be activated during spatial localization (Rao et al., 2003), visuospatial attention (Nobre et al., 1997), coordinate judgment, and spatial memory (Chambers et al., 2004). Neuroanatomical and neurophysiological studies suggest a functional coupling between parietal and motor cortices when transforming perception into action (Rizzolatti et al., 1998). Indeed, connectivity is important because the functions that Broca's area supports will be influenced by its functional networks. Our finding of concomitant increased activations in Broca's area and the right angular gyrus may suggest a functional network supporting the spatial processing required for enhanced performance of 3DMR.

Although activations in pregenual ACC (areas BA24/32) were not predicted, this region is known to be activated during implementation of selected actions and particularly those with rapid responses (Bench et al., 1993; Naito et al., 2000). Increased activation within the left hemisphere in both Broca's area and pregenual ACC is consistent with the literature implicating ACC in attentionally demanding tasks (MacDonald et al., 2000), including music performance (Parsons et al., 2005), which suggests that ACC mediates cognitive control within the same hemisphere as the brain areas supporting the task being executed (Stephan et al., 2003). Furthermore, it has been suggested that lateral prefrontal cortex computes on-line information necessary for the choice of appropriate response whereas ACC facilitates implementation of the selected action (Paus, 2001) and, specifically, by monitoring conflicting movements rather than conflicting response choice (Cavina-Pratesi et al., 2006). These functions attributed to ACC are of particular importance for musical performance at a professional level.

In conclusion, we have shown that organization of the covert motor sequencing necessary for enhanced performance of 3DMR by musicians shares a neural substrate with the visuospatial sight-reading skills of musical performance (Sergent et al., 1992; Parsons, 2001). Specifically in musicians, enhanced 3DMR performance was associated with increased BOLD signal within Broca's area, part of the sight-reading neural network (Sergent et al., 1992), which was negatively correlated with 3DMR RT and which we interpret to reflect exploitation of the neuroplastic adaptation of Broca's area in a larger group of musicians from the same orchestra that we observed in a previous investigation (Sluming et al., 2002). Orchestral musicians and controls, matched for handedness, age, and verbal intelligence, demonstrated a neural and behavioral dissociation on verbal and visuospatial tasks in that there were no differences in either behavioral data or Broca's area activation during performance of the verbal task, but there were significant differences, both behaviorally and neurofunctionally, during the visuospatial task performance. Our findings extend the current and growing literature reporting the transferable benefits of music performance training to nonmusical cognitive abilities in children and adolescents (Costa-Giomi, 2004; Schellenberg, 2004, 2005, 2006; Schlaug et al., 2005). Indeed, these findings have important implications, by providing additional objective evidence to support the suggestion that the development and maintenance of musical performance abilities confers benefit to nonmusical cognitive domains.
