Abstract

Background The purpose of this study is to assess the epidemiology, population-specific treatment trends, and complications of distal radius fractures in the United States.

Methods The PearlDiver database (Humana [2007–2014], Medicare [2005–2014]) was used to access US inpatient and outpatient data for all patients who had undergone operative and nonoperative treatment for a distal radius fracture in the United States. Epidemiologic analysis was performed followed by age-based stratification, to assess prevalence, treatment trends, and rates of complications.

Results A total of 1,124,060 distal radius treatment claims were captured. The incidence of distal radius fractures follows a bimodal distribution with distinct peaks in the pediatric and elderly population. Fractures in the pediatric population occurred predominately in males, whereas fractures in the elderly population occurred more frequently in females. The most commonly used modality of treatment was nonoperative; however, the use of internal fixation increased significantly during the study period, from 8.75 to 20.02%, with a corresponding decrease in percutaneous fixation. The overall complication rate was 8.3%, with mechanical symptoms most frequently reported.

Conclusions The last decade has seen a significant increase in the use of internal fixation as treatment modality for distal radius fractures. The impetus for this change is likely multifactorial and partly related to recent innovations including volar locking plates and an increasingly active elderly population. The implicated financial cost must be weighed against the productivity cost of maintaining independent living to determine the true burden to the healthcare system.

Over 640,000 radius and/or ulna fractures were reported in 2001 in the United States, accounting for approximately 1.5% of all emergency department visits.^{1,2} Distal radius fractures account for 25 and 18% of all fractures in the pediatric and elderly population, respectively.^{3,4} Surgical treatment in young adults has been advocated to decrease the morbidity associated with malunion.^{5,6} However, in the aging population with lower functional demands, these fractures have traditionally been treated with cast immobilization, yielding satisfactory results despite significant secondary displacement with subsequent malunion.^{7–10} Advocates for internal

fixation in this population argue that simple fractures in the setting of osteoporosis are inherently unstable and have shown good final results with early return to function and low complication rate following internal fixation.¹¹

The distal radius practice guidelines approved by the American Academy of Orthopaedic Surgeons in 2009 recommended with moderate-strength, surgical fixation rather than cast fixation for fractures with post-reduction radial shortening > 3 mm, dorsal tilt > 10 degrees, or intra-articular displacement or step-off > 2 mm.¹² These guidelines were followed up with Appropriate Use Criteria (AUC)

based on fracture type, mechanism of injury, activity level of patient, patient health, and other injuries.¹³ Unfortunately, the initial guidelines and AUC scoring system do not provide clear indications with most recommendations graded as inconclusive. None of the 29 recommendations were graded as strong. Other indications cited in the literature include unstable fractures as defined by Lafontaine et al and Mackenney et al, open fractures, polytrauma patients, and concomitant carpal fractures.^{14–16} Although fixation-specific recommendations remain vague, the past several decades have seen an evolution in fixation options with dorsal plating in the 1990s, followed by volar plating in 2000, and the subsequent advent of fragment-specific fixation in 2014.^{14,17,18} The influence of these innovations on distal radius fracture treatment trends remains unclear.

The purpose of this study is to (1) characterize the incidence of distal radius fractures in the United States based on age and gender, (2) to examine population-specific trends in the treatment of distal radius fractures, and (3) to evaluate complications associated with each treatment modality.

Materials and Methods

Deidentified patient insurer data from the Medicare Standard Analytic File was queried using PearlDiver software (PearlDiver Inc., Colorado Springs, CO). The database stores longitudinal patient data as gathered by billing information and includes diagnoses, procedures, and patient and provider characteristics, among other information. Given Medicare's focus on the elderly, this data was supplemented with deidentified patient data from Humana, a large national private insurer covering 21 million patients, to provide a full spectrum of ages. The Humana dataset was similarly analyzed using PearlDiver.

A retrospective review was conducted on the entire database, from 2007 through 2014 for Humana, and 2005 through 2014 for Medicare. Patients with distal radius fractures were identified with the relevant International Classification of Diseases, 9th revision (ICD-9) codes. Of

this cohort, we then identified patients treated nonoperatively and those who subsequently underwent percutaneous fixation or internal fixation within 14 days by their relevant Current Procedural Terminology (CPT) codes. This timeframe was chosen as to not introduce confounding by patients requiring corrective surgery for malunion or nonunion. To examine treatment trends in different age groups, the patients in the database were stratified into four groups (0–19, 20–39, 40–64, and 65 years of age). For patient privacy protection purposes, groups with 10 patients or fewer are not reported by the database and as such were not represented in the graphical analysis. Complications were identified using ICD-9 codes and analyzed based on age and treatment modality.

Statistical analysis was performed using Microsoft Excel (Microsoft Corp, Redmond WA). Trend lines were calculated using the least squares method, with the significance being reported for the calculated *p*-value. Comparisons of complication rates were performed using a chi-squared test.

Results

Over the 10-year period from 2005 to 2014, the PearlDiver research program captured over 1 million (1,124,060) distal radius fracture treatment claims. The average annual incidence of distal radius fracture treatment claims was 112,406 claims (range, 103,273–116,793 claims). There is a bimodal distribution in which there is a peak at age 10 to 14, followed by a peak during the seventh and eighth decades of life (►Fig. 1). Males had higher incidence of fracture in the 0 to 19 age group (60.2%), while females had a higher incidence of fracture in the 40 to 64 (71.1%), and ≥ 65 (85.4%) age groups (►Fig. 2).

The most frequently used modality of treatment was closed reduction and casting treatment. In 2005, approximately 86% of distal radius fracture treatment claims were for closed treatment. This steadily declined over the 10-year period to 77.5%. The proportion of patients managed with closed reduction and percutaneous fixation also declined, from 5.43% in 2005 to 2.54% in 2014 ($r^2 = 0.97$, $p < 0.0001$).

Fig. 1 Distal radius fracture distribution by age group.

Fig. 2 Gender distribution in distal radius fractures by age group.

Fig. 3 Annual trend in the use of open reduction internal fixation (ORIF) and closed reduction percutaneous fixation (percentage). There has been a linear increase in ORIF in the timeframe of the study ($r^2 = 0.98, p < 0.0001$) with a concomitant linear decrease in percutaneous pinning ($r^2 = 0.97, p < 0.0001$).

The decreasing trend in the use of closed reduction and percutaneous fixation corresponded to an increasing trend in the use of internal fixation. Its use as the modality of treatment increased from 8.75% in 2005 to 20.02% in 2014 ($r^2 = 0.98, p < 0.0001$) (► Fig. 3).

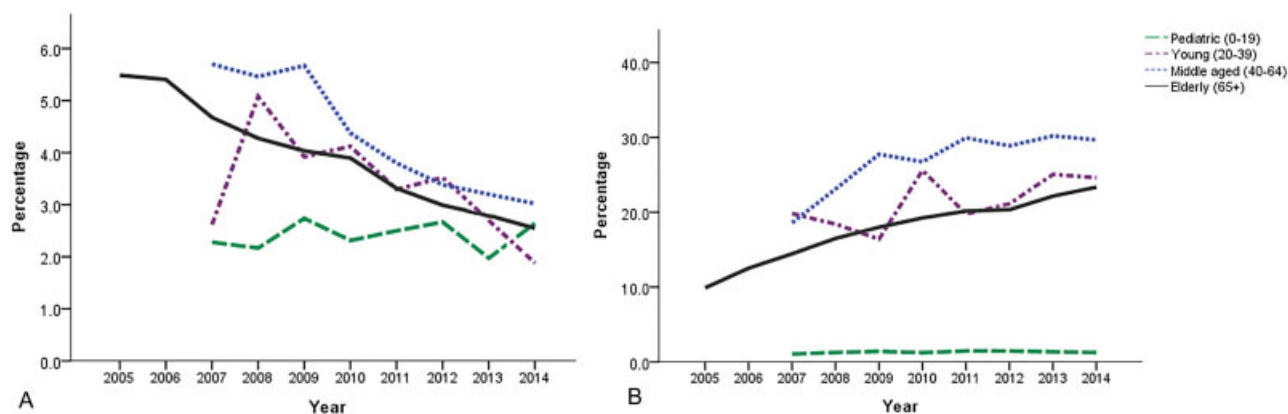

Population-specific analysis based on age group revealed the most frequent modality of treatment used overall was closed reduction for all age groups (► Table 1). This was followed in descending order by internal fixation and percutaneous pinning for all age groups except those 0 to 19 years of age, for which percutaneous pinning was the second most frequently used modality. An analysis of these groups over time revealed a decreasing trend in the use of percutaneous pinning in each group except those 0 to 19 years of age, which maintained a constant rate of approximately 2% (► Fig. 4A). The rate of internal fixation for this group also remained

constant (1.1–1.3%) over the study period, whereas the use of this modality increased for those aged between 20 and 39 (19.8–24.6%), aged between 40 and 64 (18.5–29.7%), and aged ≥ 65 (9.9–23.4%) (► Fig. 4B). The largest percentage increase in the use of internal fixation over the duration of the study was seen in those > 65 years of age.

The overall complication rate was 8.3% and includes malunion, nonunion, infection, tendon rupture, contractures, mechanical symptoms, and complex regional pain syndrome (► Table 2). The complication rate associated with nonoperative and operative modalities was 5.4 and 9.4%, respectively. Mechanical symptoms were the most commonly reported complication overall (2.06%) as well as for the operative (2.82%) and nonoperative (1.83%) subgroups. Compared to the nonoperative group, the group that received operative intervention had a statistically significant higher rate of

Table 1 Distal radius fracture treatment modality by age group

	All distal radius fractures	Percutaneous fixation	Open reduction internal fixation	Nonoperative
Pediatric (0–19)	27,564	730 (2.65%)	398 (1.44%)	26,378 (95.7%)
Young (20–39)	4,689	150 (3.2%)	1,145 (24.42%)	3,372 (71.91%)
Middle aged (40–64)	20,048	840 (4.19%)	6,366 (31.75%)	12,747 (63.58%)
Elderly (65 and above)	939,448	37,337 (3.97%)	168,978 (17.99%)	731,746 (77.89%)

**Fig. 4** Annual trend in closed reduction percutaneous fixation (A) and open reduction internal fixation (B) by age group.**Table 2** Complications after distal radius treatment by treatment group. The operative group had a higher rate of every complication examined compared to the nonoperative treatment group

	All	Operative	Nonoperative	p-Value
Malunion	13,281 (1.18%)	1,972 (0.92%)	10,489 (1.16%)	<0.0001
Nonunion	14,744 (1.31%)	3,017 (1.4%)	11,307 (1.25%)	<0.0001
Infection		5,008 (2.33%)	N/A	N/A
Tendon rupture	2,581 (0.23%)	1,038 (0.48%)	1,487 (0.16%)	<0.0001
Contractures	9,502 (0.85%)	2,075 (0.96%)	6,931 (0.76%)	<0.0001
Mechanical symptoms	23,068 (2.06%)	6,063 (2.82%)	16,637 (1.83%)	<0.0001
CRPS	3,399 (0.30%)	972 (0.45%)	2,374 (0.26%)	<0.0001

Abbreviation: CRPS, complex regional pain syndrome.

occurrence of every complication, except malunion. The rate of occurrence of specific complications in patients treated with internal fixation in descending order was mechanical symptoms (2.73%), superficial and deep infection (2.14%), nonunion (1.33%), contractures (0.96%), malunion (0.78%), and tendon rupture (0.55%). Although tendon rupture was one of the least commonly reported complication in patients treated with internal fixation, it was reported with three times greater frequency than in patients treated nonoperatively.

Discussion

The current data presents a 10-year review of distal radius fractures revealing the current epidemiology and trends in treatment as well as associated complications. The present

study reveals a bimodal distribution with peaks in the pediatric population (10–14 years) and those ≥ 65 years of age. An analysis of occurrence based on gender revealed a greater proportion of distal radius fractures in the pediatric population occurred in males. These results confirm findings by Bailey et al, which revealed a peak rate of occurrence for girls between the ages 11.5 and 12.5 years, and for boys between 13.5 and 14.5 years.¹⁹ Several studies have attributed the peak in incidence seen in the pediatric population to a combination of increased fragility of bones during peak growth velocity and increased physical activity.^{19–22} Several other authors have demonstrated similar findings based on gender.^{22–24} Landin studied fracture patterns in children and noted the accumulated risk of fracture was 27% in girls and 42% in boys.²³ A similar trend is seen in a study by Ryan et al,

which demonstrated a 64% of pediatric forearm fractures occurred in boys.²⁴

In contrast to the peak seen in the pediatric population, a majority of distal radius fractures in the elderly population occurred in females. Baron et al found a significant gender difference in the occurrence of fractures of the distal forearm.³ They noted a female:male rate ratio of 4.88, in contrast to a ratio of 3 in other upper extremity fractures. Other studies have noted similar findings with up to five times greater fracture incidence in women than in men.^{19,25} The major attributable risk factor to these findings is osteoporosis. In 2002, the National Osteoporosis Foundation estimated that there are 9.1 million women and 2.8 million men with osteoporosis.²⁶ Kanterewicz et al showed that wrist fractures were more prevalent in postmenopausal women with osteoporosis compared to those without.²⁷ Several other studies have also linked the relationship between decrease bone mineral density as a predictor for distal radius fractures as well the severity of the fractures.^{28,29}

Recent studies have focused primarily on treatment trends in the elderly population without age stratification.^{30,31} The present study provides an overall look at treatment trends in the United States with additional analysis to include age stratification and treatment-specific complication rates. The increasing trend in the use of internal fixation with corresponding decreases in the use of percutaneous and closed reduction are findings supported by multiple studies.^{30,31} Chung et al evaluated Medicare data from 1996 to 2005 showing fivefold increase in the rate of internal fixation of distal radius fractures in the elderly.³⁰ In a study of submitted case lists to the American Board of Orthopaedic Surgery from 1999 to 2007, Koval et al found a significant increase in the proportion of distal radius fractures stabilized with internal fixation.³¹ The present study provides further analysis with age stratification. The greatest change in overall practice patterns over the study period was seen in the group ≥ 65 years of age, followed by those between 40 and 64 years of age, with an increased use of internal fixation seen in both. The rate of percutaneous fixation and internal fixation remained constant in the pediatric population.

In a multicenter prospective randomized controlled trial comparing plate fixation to percutaneous and external fixation, Leung et al reported better functional scores with plate fixation.³² Other studies have looked at volar plate fixation specifically and found satisfactory outcomes in support of the internal fixation as a treatment modality.^{11,33,34} Inconclusive clinical practice guidelines in addition to advances to internal fixation including lower profile designs, proximal/distal fit plates, polyaxial capabilities, periarticular hook plates/extensions, and fragment-specific fixation could be considered to play a role in the continued increasing trend of internal fixation.^{14,17} The change toward more fracture fixation seen in the elderly population could in part be attributed to the increased risk of loss of reduction and malunion due to the inherent instability associated with osteopenia and osteoporosis.^{15,16,28} Several authors have postulated that the stability offered by internal fixation allows for an earlier ability to

perform activities of daily living and thereby preserving independence, while Koval et al eluded to an “intrinsic attraction newer technology” and pressures to offer new techniques.^{30,31} Egol et al performed a retrospective study comparing closed reduction and casting to operative treatment in patients over the age of 65 and found superior radiographic outcomes with operative intervention; however, there was no difference in functional status between the two groups at final follow-up.³⁵ A study by Arora et al comparing closed reduction and casting to internal fixation with volar locking plate found similar results with regard to radiographic and functional outcomes.³⁶ Shauver et al studied the financial impact of the increasing trend for operative treatment of distal radius fractures in the elderly population.³⁷ They found that in 2007, Medicare made \$170 million in distal radius fracture-related payments and estimated the future cost in the elderly population could reach \$240. The authors concluded that the rapid increase in treatment cost due to the more frequent use of internal fixation will result in a substantial increase in healthcare costs requiring closed evaluation and allocation of resources.³⁷

The complication rate associated with distal radius fractures treated nonoperatively and operatively was 5.4 and 9.4%, respectively, which is consistent with the current literature.^{38,39} The most frequently reported complication independent of modality of treatment was mechanical symptoms. Due to the limited patient-level data in the database, further characterizing this complication was not possible. Current literature uses the term “mechanical symptoms” to include distal radioulnar joint dysfunction/arthritis, ulnar impaction syndrome, tendonitis, among other causes of wrist pain. Malunion was the only complication that occurred more frequently in patients managed nonoperatively. This is consistent with multiple comparative studies, although their findings did not correlate to worse functional status.^{35,36}

Our study has several limitations. The analysis is dependent on accurate documentation of ICD-9 and CPT codes. The most commonly used code for internal fixation of distal radius fractures captures volar plates, dorsal plates, fragment-specific fixation, etc. Therefore, conclusions cannot be made regarding approach, construct design, or specific implant. A similar limitation is seen with percutaneous fixation. A single CPT code is used to capture Kirschner-wire fixation, standard external fixation, or even if an open reduction was performed. Some authors use a two-step approach by first determining capturing all distal radius fractures with an ICD-9 code followed by the CPT code for external fixation; however, this methodology can overestimate the use of external fixation by including patients with distal radius fractures that have had external fixation for injuries on other extremities. Lastly, there is a paucity of detailed clinical data that is inherent to database studies due to an inability to perform a chart review. Lastly, in the current study, we discussed complication trends including mechanical symptoms; however, we are unable to elaborate on the specific nature or temporality of the symptom.

In conclusion, there has been a significant change in the treatment trend of distal radius fractures in the United States

over the 10-year study period. The impetus for the increasing use of internal fixation is likely multifactorial and remains conjecture at this point in time. Possible causes include a lack of clear clinical practice guidelines, innovations to implant design, an increasingly active aging population, patient expectations including a desire for expedited recovery, and the practice of defensive medicine due to the stigma of functional malunion. Additionally, the implicated financial cost associated with the increased use of internal fixation must be weighed against the productivity cost of maintaining independent living to determine the true burden to the healthcare system.
