Supporting Information

ABSTRACT: *Mycobacterium tuberculosis* (*Mtb*) is the causative agent of tuberculosis (TB) and has evolved an incredible ability to survive latently within the human host for decades. The *Mtb* pathogen encodes for a low number of ATP-binding cassette (ABC) importers for the acquisition of carbohydrates that may reflect the nutrient poor environment within the host macrophages. *Mtb* UgpB (Rv2833c) is the substrate binding domain of the UgpABCE transporter that recognizes glycerophosphocholine (GPC), indicating that this transporter has a role in recycling glycerophospholipid metabolites. By using a combination of saturation transfer difference (STD) NMR and X-ray crystallography, we report the structural analysis of *Mtb* UgpB complexed with GPC and have identified that *Mtb* UgpB not only recognizes GPC but is also promiscuous for a broad range of glycerophosphodiester. Complementary biochemical analyses and site-directed mutagenesis precisely define the molecular basis and specificity of glycerophosphodiester recognition. Our results provide critical insights into the structural and functional role of the *Mtb* UgpB transporter and reveal that the specificity of this ABC-transporter is not limited to GPC, therefore optimizing the ability of *Mtb* to scavenge scarce nutrients and essential glycerophospholipid metabolites via a single transporter during intracellular infection.

Bacterial pathogens have evolved a wide range of strategies to survive and thrive within their host environment. The ability to assimilate nutrients is vital, and pathogens have evolved diverse strategies to uptake and scavenge the scarce energy sources that are available to them. In the context of intracellular microbial infections, there is growing evidence that in a nutrient limited environment the interplay between the host and the pathogen is important. This is manifested through the ability of bacterial pathogens to utilize discrete nutrient sources with dedicated transport machinery for import. Glycerophosphodiester metabolites that are released by the action of phospholipases on host phospholipids represent an important nutrient source for the supply of carbon and phosphate.

Mycobacterium tuberculosis (*Mtb*) is a major human pathogen and is now the leading cause of death from a single infectious agent worldwide, resulting in more deaths each year than HIV and malaria combined.¹ *Mtb* is a highly evolved pathogen that is able to persist and survive intracellularly within macrophages for decades.² However, the essential nutrients that are available to *Mtb* within the stringent environment of the human host and acquisition systems are poorly understood.^{3,4} Understanding the molecular mechanisms that enable *Mtb* to survive within this niche environment and the nutrients that are assimilated is critical to understand this major global pathogen and for the development of new therapeutic approaches.

The sugars that are available within the nutrient-limited macrophage environment are unknown; however, *Mtb* is equipped with five putative importers of carbohydrate substrates: four members of the ATP-binding cassette (ABC) transporter family and one belonging to the major facilitator superfamily.^{3,4} Until recently, the substrates for these transporters were unresolved; however, recent studies have demonstrated a role for the ABC-transporters in the recycling of components from the complex *Mtb* cell wall. Trehalose is recycled from the *Mtb* cell envelope glycolipid trehalose monomycolate and taken up by the LpqY-SugABC-transporter, which plays a critical role in the virulence of the *Mtb* pathogen.⁵ The *Mtb* UspABC-transporter has been found to recognize amino-sugars with a potential role in the uptake of *Mtb* cell wall peptidoglycan fragments.⁶

The role of the UgpABCE ABC-transporter is less clear; however, studies of its substrate binding domain *Mtb* UgpB (Rv2833c) indicate its importance for *Mtb* survival and pathogenesis, and *in vivo* *Mtb* UgpB has been found to be upregulated during infection.⁷ *Mtb* UgpB has been shown to bind the glycerophosphocholine (GPC) headgroup of the membrane phospholipid phosphatidylcholine, and metabolo-

mic profiling by NMR of intact lung tissue at various stages of *Mtb* infection has revealed that the GPC metabolite increases significantly as infection progresses, with a concomitant decrease in phosphatidylcholine.⁸ However, despite the essential role of this *Mtb* transporter, the molecular mechanisms that dictate how GPC is recognized and whether other glycerophosphodiester metabolites are substrates for this ABC-transporter are currently unknown. The only crystal structure of *Mtb* UgpB is of the protein in an open conformation without substrate bound (PDB 4MFI).⁹ Some mechanistic understanding of substrate recognition can be obtained from the crystal structure of a homologue from *E. coli* with low sequence identity (25%) in complex with glycerol-3-phosphate (G3P) (PDB 4AQ4).¹⁰ However, *Mtb* UgpB does not bind G3P. Comparison of the closed G3P-bound *E. coli* UgpB with the open *Mtb* UgpB in the absence of substrate (PDB 4MFI) reveals notable differences in the binding sites of these homologous proteins, indicating that these UgpB ABC-transporters, belonging within the same structural classification (cluster D),¹¹ have diverged to have different substrate specificities. This may reflect the nutritional requirements of the specific organism within different host environments and also the ability of bacteria to produce G3P extracellularly through the action of secreted glycerophosphodiesterases that hydrolyze glycerophosphodiesteres.¹² Other microorganisms that import GPC have evolved to use either permeases or proton symporters that belong to the major facilitator superfamily indicating that glycerophosphodiester uptake is not limited to ABC-transporters.^{13,14} It is likely that the divergence of transport systems for the import of glycerophosphodiesteres reflects the evolutionary divergence and intracellular lifestyle of the pathogen and the metabolites available within its niche environment.

In this study, we report a detailed functional and structural characterization of the *Mtb* UgpB substrate binding domain of the ABC-transporter using a combination of biochemical and biophysical approaches. We report the first crystal structure of *Mtb* UgpB in complex with GPC and identify, in both solid and solution state, the molecular determinants of binding and critical features for glycerophosphodiester recognition. Structure guided mutagenesis has revealed the crucial role of binding-site residues that underpin substrate binding and function. Moreover, we show that *Mtb* UgpB has a broad selectivity for glycerophosphodiesteres, which highlights that the *Mtb* UgpABCE transporter uptakes metabolites derived from various glycerophospholipids. Thus, *Mtb* has evolved to use a broad spectrum of nutrients via a single ABC-transporter that enables it to adapt and assimilate essential nutrients during intracellular infection.

RESULTS AND DISCUSSION

Production of *Mtb* UgpB. An N-terminal truncated *Mtb* UgpB, corresponding to removal of residues 1–34 predicted to form a trans-membrane anchor-helix, was cloned into the pYUB1062 vector with a C-terminal hexa-histidine affinity tag and expressed in *Mycobacterium smegmatis* mc²4517. Soluble *Mtb* UgpB protein was obtained and purified to apparent homogeneity using Co²⁺-affinity, anion exchange, and size-exclusion chromatography (Figure S1). The identity of the *Mtb* UgpB protein was confirmed by using in-gel trypsin digestion and analysis of the peptides by mass spectrometry.

Co-Crystal Structure of *Mtb* UgpB with GPC. Initial attempts to crystallize *Mtb* UgpB in the presence of GPC

routinely resulted in crystals of UgpB in an open conformation with no ligand bound. Therefore, to overcome this, we chemically modified the surface of *Mtb* UgpB through reductive methylation, and this resulted in crystals of UgpB in complex with GPC. The UgpB protein co-crystallized with GPC with four molecules in the asymmetric unit. Phases for the structure were determined by molecular replacement using each of the two domains from the apo-structure of *Mtb* UgpB (PDB 4MFI) as separate search models, and the structure was refined at a resolution of 2.3 Å and to a R_{work} of 20.6% and R_{free} of 25.6%; see Table S1 for the data collection and refinement statistics. Structural superposition of each molecule of *Mtb* UgpB using PDBeFOLD¹⁵ indicates that each molecule within the asymmetric unit is equivalent, aligning with a rmsd of 0.35–0.44 Å for 394–395 residues. The crystal packing and analysis of the packing interfaces using PDBePISA¹⁶ does not suggest that *Mtb* UgpB forms dimers or higher oligomers and is consistent with our analytical gel filtration studies where the protein behaves as a monomer in solution with an apparent molecular weight of 44 kDa (Figure S1D). It is therefore likely that the monomer is the biologically relevant unit, consistent with substrate binding domains of other ABC-transporters.^{17,18}

Overall Structure of the *Mtb* UgpB–GPC Complex. *Mtb* UgpB comprises two α/β domains (Figure 1). Domain I

Figure 1. Crystal structure of *Mtb* UgpB. (A) Surface representation of *Mtb* UgpB in complex with GPC. The two domains are highlighted: domain I (brown) and domain II (green). The GPC ligand is represented as spheres with dark gray carbon atoms. (B) Cartoon representation of *Mtb* UgpB in complex with GPC identifying the secondary structure elements. Domain I (brown) and domain II (green). The two hinge regions are highlighted in blue. The GPC ligand is represented as spheres with dark gray carbon atoms. (C) Superposition of domain I of GPC *Mtb* UgpB cocomplex (brown/green) with domain I of apo-*Mtb* UgpB (PDB 4MFI) (magenta/orange). (D) Surface representation of the unliganded *Mtb* UgpB (PDB 4MFI) with the two domains colored magenta (domain I) and orange (domain II).

(residues 1–154 and 307–365) consists of a five-stranded β -sheet surrounded by 11 α -helices and domain II (residues 155–306 and 366–436), of a four-stranded β -sheet enclosed by 9 α -helices. The two domains, or globular lobes, are connected via two flexible hinges that are formed between residues Arg152-Pro155 and Ala290-Ala307. Relative to the apo-crystal structure, there is a 22° rotation of domain I

relative to domain II about the interdomain screw axis with three hinge/binding regions identified from DynDom analysis¹⁹ (residues 152–153, 304–306, and 362–372 (Table S2)). This bending movement results in an almost 2-fold reduction in the volume of the cavity from 1986 to 791 Å³, as determined by CAVER,²⁰ which is in-line with the “Venus Fly-trap mechanism” for other substrate-binding proteins^{17,18} that close when the substrate is bound. Interdomain bridging and stabilization of this closed conformation of the protein is centered around Arg385, which forms interdomain hydrogen

bonds with Asp102 from domain I and Gln381 from domain II. The individual domains of *Mtb* UgpB apo- and GPC cocomplex structures align with rmsd values of 0.57 and 0.75 Å for domains I and II, respectively (over 178 atoms, domain I; over 216 atoms, domain II, PDBE/FOLD¹⁶). In comparison, superposition of *Mtb* UgpB apo- and GPC cocomplex structures align with a rmsd of 2.2 Å (over 385 residues), highlighting the importance of an interdomain conformational change mechanism for substrate recognition by *Mtb* UgpB.

(B) STD values in the red bars were obtained with a 4 s saturation time, while in the blue bars, the CORCEMA-ST calculated STD values from the 3D crystallographic structure of the *Mtb* UgpB/GPC complex obtained for the same saturation time are shown. RNOE factor, 0.25. (C) Differential epitope (DEEP)-STD factors showing the type of amino acid that the protons of the GPC ligand are orientated toward. Protons orientated toward aliphatic residues are highlighted in blue, and protons orientated toward aromatic residues are highlighted in magenta.

Ligand-Binding Site of *Mtb* UgpB. Well-defined electron density for the GPC ligand in all *Mtb* UgpB molecules within the crystal unit was observed, enabling the GPC ligand to be modeled in the *Mtb* UgpB binding site (Figure S2A). The GPC ligand is found in an identical position and orientation in each subunit (Figure S2B). Notably, the electrostatic surface shows that GPC is buried in the prominent, acidic interface that is formed between the two domains of UgpB and makes contact with both. The GPC is precisely orientated within the binding cleft such that the glycerol moiety is buried at the base of the cavity, in close proximity to the flexible-hinge region centered around Arg385, while the choline moiety extends outward towards the solvent exposed channel entrance (Figure 2).

The glycerol moiety is located between the side chains of Leu205 and Trp208 from domain II (Figure 2). The ring system of Trp208 lies approximately parallel to the C1, C2, and 2-hydroxy group of the glycerol moiety enabling π -stacking interactions, while Leu205 is orientated perpendicular to this plane and provides additional stabilization. There is an important network of hydrogen bonding interactions that anchors GPC in the binding pocket. The side chain of Asp102, from domain I, is orientated to enable direct hydrogen bonding to both the 1- and 2-hydroxy groups of the glycerol moiety. Two residues that comprise the flexible-hinge linkages are able to directly interact with GPC through the formation of additional hydrogen bond interactions between the side chain of Arg385 and the 1-hydroxy group and the backbone amide nitrogen atom of Gly306 with the 2-hydroxy group, respectively. The direct interaction of these flexible-hinge linkages with the GPC ligand may help to stabilize the UgpB–GPC complex in the closed conformation. The phosphate group of GPC is stabilized through hydrogen bond interactions with the side chains of Tyr78 and Tyr345 (domain I), Ser153 (domain I), Ser272 (domain II), and the backbone amide of Gly306. It is striking that there are no direct or charged interactions between *Mtb* UgpB and the positively charged choline moiety, though this moiety is well-defined in the electron density.

Comparison with the Binding Site of *E. coli* UgpB.

The comparison with UgpB from *E. coli*¹⁰ indicates that the overall architecture of these two periplasmic binding proteins in complex with substrate is similar, with a rmsd of 2.1 Å (PDBFold,¹⁵ 394 target residues, 25% sequence identity (Figure S3), PDB code 4AQ4), Figure 3. While *Mtb* was crystallized with GPC, the *E. coli* protein was crystallized with

G3P, which we, as well as previous studies,¹⁰ show does not bind to *Mtb* UgpB. It is interesting to note that the binding mode of the G3P core of GPC resembles the situation found in the *E. coli* UgpB–G3P complex,¹⁰ even though *Mtb* UgpB is unable to bind or recognize this smaller G3P ligand (Figure 3B). However, while the substrate binding pocket of *Mtb* UgpB resembles that of *E. coli* UgpB, there are several important differences. Notably, there are substitutions of critical residues involved in substrate binding. Leu205 is specific to *Mtb* and is replaced by a larger indole side chain from a tryptophan residue (Trp169) in *E. coli* UgpB. In addition, *Mtb* UgpB Asp102 is replaced in *E. coli* UgpB by a glutamic acid residue (Glu66) (Figure 3C). In this instance, the difference in the length of these acidic side chains may influence substrate selectivity between the different organisms. Intriguingly, while the interaction with an arginine residue is conserved between *Mtb* and *E. coli*, the arginine residues in the two proteins originate from different regions of the protein, indicating an evolutionary divergence of these substrate-binding proteins. In addition, a narrowing of the *E. coli* UgpB binding cleft results from two different loop regions. One loop region (Gly221–Asp230) in domain II of *E. coli* UgpB linking α -helices 10 and 11 narrows the substrate binding cavity as a result of a 5 Å translational shift. The difference in position of a second loop comprised of residues His8–Gly12 results in the translation of the first α -helix of *E. coli* UgpB (residues 12–30) located in domain I by approximately 6 Å toward α -helix 11 of domain II, which further narrows the *E. coli* UgpB substrate binding channel (Figure 3D,E). The comparison of the region at the entrance to the binding cleft reveals an expanded pocket for *Mtb* UgpB. It is of interest to note that in chain B of *Mtb* UgpB we observe an additional glycerol molecule located in this expanded pocket that is within 4 Å of the choline moiety of GPC (Figure S4). A glycerol molecule is also present in the *E. coli* UgpB–G3P complex, though at a different position, indicating that for both proteins the binding pockets are larger than the recognized GPC substrate.¹⁰ This may be functionally significant in substrate recognition and have an important role in the accommodation and binding of alternative phosphodiester substrates.

Solution Saturation Transfer Difference NMR of *Mtb* UgpB with Glycerophosphocholine. Given the apparent discrepancy between the lack of interactions formed between the choline moiety and its importance in binding and given that G3P lacking the choline moiety does not bind, we

Figure 5. Structure of glycerophosphodiester and derivatives probed in this study.

investigated binding in the solution state. We employed saturation transfer difference (STD) NMR to obtain quantitative maps of the ligand–protein complex in solution (Figure 4).²¹ Binding was detected for GPC, and binding epitope mapping was obtained and analyzed as described in the Methods section.²² The STD NMR signals and the GPC binding epitope and maps obtained are shown in Figure 4. From the epitope map, the glycerol moiety of GPC is identified as the main recognition element showing the highest STD normalized values. In particular, the highest STD intensity values were observed for the protons in positions 1 and 2 (H1G and H2G) of the glycerol moiety (Figure 4A), with slightly lower intensity values for the protons in position 3 (H3G). The STD values decrease from the glycerol moiety to the choline group, indicating that the ligand–protein contacts are closer to the glycerol group than to choline. Intermediate and low STD NMR intensity values were observed for the protons in positions 1 and 2 (H1C and H2C), while low intensity values were observed for the methyl groups from the choline moiety. A quantitative comparison of the NMR solution data with the X-ray structure of the complex was carried out using CORCEMA-ST calculations²³ as well as the newly developed method DEEP-STD NMR,²⁴ and the results are summarized in Figure 4. An NOE *R*-factor²⁵ of 0.25 was obtained when comparing the CORCEMA-ST calculated STD NMR intensities using the crystal structure with the experimentally obtained solution data. This indicates a very good agreement of the complex in the solution state with the crystal structure. In order to probe for additional structural information in the solution state, we then utilized differential epitope mapping by STD NMR (DEEP-STD NMR). This methodology allows us to gain information about the orientation of the ligand within the architecture of the binding site and indirectly gives us information about the type of amino acids (aromatic, polar, or apolar residues) surrounding the ligand in the bound state.²⁶ The DEEP-STD NMR factors clearly identified that the protons in position 3 of the glycerol moiety of GPC are orientated toward aliphatic amino acids, while the protons in position 1 in the choline moiety are oriented toward aromatic residues (Figure 4C). On the basis of the crystal structure of *Mtb* UgpB, these residues can be mapped to Leu205, Tyr78, and Tyr345, respectively (Figure 2). Notably, our data shows a strong correlation for the molecular determinants of GPC ligand binding to *Mtb* UgpB in both solution and the solid state.

Substrate Specificity of *Mtb* UgpB. To establish the importance of both the polar headgroup and the glycerol moiety for substrate recognition binding, we analyzed the binding interactions of *Mtb* UgpB with G3P, the preferred substrate of *E. coli* UgpB, and phosphocholine by thermal shift analysis and microscale thermophoresis. In contrast to GPC, no binding interactions were observed for these smaller derivatives. Taken together with our structural studies, these results indicate that, while the glycerol moiety is the main recognition element for *Mtb* UgpB and there are minimal interactions with the polar headgroup, the entire phosphodiester moiety is critical for substrate recognition and binding. The lack of recognition of G3P by *Mtb* UgpB is consistent with the intracellular location of two putative *Mtb* glycerophosphodiesterase enzymes (GlpQ1, Rv3842c; GlpQ2, Rv03127c) that are predicted to degrade glycerophosphodiester to produce G3P and the corresponding alcohol.^{27,28} In direct contrast, *E. coli* secretes glycerophosphodiesterase enzymes to enable the extracellular production of G3P, and this is consistent with the ability of the periplasmic *E. coli* UgpB to recognize the G3P metabolite.¹²

Our structural studies in both the solid and solution state revealed that the GPC substrate interacts predominantly with *Mtb* UgpB through interactions with the glycerol backbone. The lack of specific interactions between the protein and the polar choline headgroup located at the entrance of the substrate binding pocket led us to speculate that *Mtb* UgpB may recognize alternative glycerophosphodiester analogues. To directly investigate the substrate specificity of *Mtb* UgpB, we used microscale thermophoresis (MST) to analyze the binding interactions of other phosphodiester products formed from the lipolysis of membrane glycerophospholipids (Figure 5). From the substrates tested in each case, we were able to detect binding for GPC, glycerophosphoserine (GPS), glycerophosphoethanolamine (GPE), glycerophosphoinositol (GPI), and glycerophosphoinositol-4-phosphate (GPI4P) (Table 1, Figure 6). The measured K_d value for GPC was consistent with previous results obtained by isothermal titration calorimetry (ITC).⁹ Notably, *Mtb* UgpB also binds and recognizes GPE, GPS, GPI, and GPI4P glycerophosphodiester with binding affinities in the micromolar range (Table 1) with a preference for positively charged polar head groups. Together, this suggests that *Mtb* has evolved to have a single ABC-transporter to scavenge a range of glycerophosphodiester within its nutrient poor intracellular environment. The preference for

GPC could suggest that, as phosphatidylcholine is the main glycerophospholipid in human lung tissue,²⁹ *Mtb* UgpB has evolved to recognize the most abundant glycerophosphodiester available within the host environment with the potential to

recognize and transport a spectrum of additional glycerophosphodiester, depending on the growth conditions and nutrient availability during intracellular infection that can subsequently be catabolized by *Mtb* pathways that are involved in polar headgroup recycling.²⁷ Notably, these glycerophospholipids are also major constituents of the *Mtb* cell envelope,^{30,31} and further experiments are underway to elucidate whether the glycerophosphodiester are derived from host- or *Mtb*-lipids.

As a final evaluation for potential substrate promiscuity, we screened a panel of carbohydrates and amino acids using a thermal shift assay and assessed the binding of putative ligands that resulted in a change in the melting temperature (T_m) of *Mtb* UgpB, which can be indicative of binding. In total, 37 potential substrates were probed, including glycerol trehalose, which is known to be a substrate of the *Mtb* LpqY-SugABC ABC-transporter,⁵ and we found that none of the ligands that were screened influenced the melting temperature (Figure S5). It appears that, although *Mtb* encodes for only five putative carbohydrate importers, each transport system has a defined substrate preference. Interestingly, these data indicate that the substrate binding pocket of *Mtb* UgpB can efficiently accommodate glycerophosphodiester, but it is not able to recognize other carbohydrates or amino acids.

STD NMR of *Mtb* UgpB with GPI4P. Next, to validate some of the MST-binding data, we used STD NMR spectroscopy for a more in-depth investigation of GPI4P binding to *Mtb* UgpB. Again, the glycerol moiety of GPI4P was the main recognition element with close contacts to *Mtb* UgpB. High STD NMR intensity values were also observed for the H1 and H2 protons of the inositol ring with intermediate STD NMR values for H3 and H4 protons and low values for H5 and H6 protons (Figure 7A,B). This differs from the situation of the choline headgroup of GPC where instead low STD intensities were observed. Furthermore, the DEEP-STD NMR maps reveal a slight modification in the binding orientation of the glycerol tail of GPI4P compared to GPC as protons in position 3 orientated toward aromatic residues this time. To gain 3D structural insights about this interaction, we carried out docking calculations using Autodock Vina³² followed by validation using CORCEMA-ST calculations. An NOE R -factor of 0.31 was obtained by comparing the CORCEMA-ST calculated STD intensities from the best scored docked structure of GPI4P bound to *Mtb* UgpB and the experimental STD values. This indicates a good agreement of the proposed docking structure of the *Mtb* UgpB/GPI4P complex with the experimental STD NMR data. From Figure 7, we can observe that the protons in position 3 (H3G) are oriented toward the aromatic residues, which was also determined from DEEP-STD factor analysis. Further, also the protons of inositol-phosphate moiety are in line with the observed orientation from DEEP-STD factor analysis. In fact, protons H4I, H1G, and H2G are oriented toward aliphatic residue Leu205, while protons H1I, H3G, H6I, and H5I are oriented toward the aromatic residues Tyr78 and Tyr345, validating the proposed model structure with the experimental STD and DEEP-STD NMR data. These studies indicate that the size and charge of the glycerophosphodiester headgroup are critical in defining substrate selectivity and the binding orientation of the glycerol tail.

Activity of Sequence Variants. In order to complement our structural studies in both the solution and solid state and assess the significance of individual amino acids that were identified to be important in molecular recognition and

binding, we introduced single point mutations in eight individual residues that were suggested to interact with the glycerophosphodiester ligands. In each case, we confirmed that the substituted alanine mutation was not detrimental to the correct folding of the protein by circular dichroism spectroscopy (Figure S6). MST was used to determine the binding affinities of the *Mtb* UgpB protein with GPC, and complete abrogation of binding was observed when Tyr78, Asp102, Trp208, Ser272, Tyr345, and Arg385 were individually replaced by an alanine, confirming the significance of these residues in substrate selectivity and the importance in binding recognition. In contrast, binding of GPC was still observed when Ser153 and Leu205 were replaced by alanine, with a corresponding 85- and 45-fold reduction in the K_d values, respectively (Table 1), indicating that while these two individual residues are important for binding, they are not critical. Failure of these single-residue mutants to completely abolish binding reflects that multiple amino acids are involved in the interaction with GPC, as observed from the crystal structure. Previous studies that mutated *Mtb* UgpB Leu205 to a tryptophan residue to mimic the situation found in *E. coli* UgpB were detrimental for binding of GPC, indicating that the bulky indole side chain cannot be tolerated in *Mtb* UgpB⁹ and did not enable recognition of G3P. The distinct glycerophosphodiester recognition of *Mtb* UgpB compared with *E. coli* UgpB indicates that the mycobacterial UgpB transporter has evolved to have unique specificity and function that is distinct from other UgpB proteins.

In conclusion, to date, the nutrient requirements of *Mtb* during infection and the corresponding transport systems have not been fully elucidated. The structural and functional understanding of mycobacterial ABC-transporters that import essential nutrients is an important step to understanding the mechanisms that support intracellular survival. Importantly, we

have identified that the essential *Mtb* UgpABCE importer is linked with glycerophosphodiester uptake with wide substrate selectivity. For the first time, we have established the molecular determinants of the distinct substrate selectivity of the UgpB substrate binding protein from the *Mtb* pathogen that has important structural and functional differences with *E. coli* UgpB. We therefore propose a new role for the *Mtb* UgpABCE transporter in the uptake of glycerophosphodiesters generated from the degradation of membrane phospholipids as a route to scavenge scarce nutrients during intracellular infection.

METHODS

Procedures for cloning, protein expression, crystallization, X-ray data collection and refinement, STD NMR experiments, docking, microscale thermophoresis, thermal shift assays, and enzymatic synthesis of substrates in this study are described in the Supporting Information.

ASSOCIATED CONTENT

Supporting Information

The Supporting Information is available free of charge on the ACS Publications website at DOI: 10.1021/acscchembio.9b00204.

Detailed methods, SDS-PAGE analysis, GPC binding, sequence alignment of UgpB; location of the additional glycerol moiety in the *Mtb* UgpB binding pocket; thermal shift assay; CD spectra; crystallographic parameters; DynDom analysis; sequence of primers (PDF)

Accession Codes

Coordinates and structure factors for *Mtb* UgpB have been deposited in the Protein Data Bank under accession code 6R1B.

ACKNOWLEDGMENTS

We would like to thank M. Ahanger for assistance. We thank W. Jacobs (Albert Einstein College of Medicine, USA) for providing expression vector pYUB1062 and the *M. smegmatis* mc²4517 expression system. We acknowledge the contribution of the WPH Proteomics Facility research technology platform, University of Warwick. We thank Diamond Light Source for access to synchrotron beamlines and the staff for support during the experiments. Equipment was supported through the Warwick Integrative Synthetic Biology (WISB) research technology platform (BB/M017982/1). This work was supported by a Sir Henry Dale Fellowship to E.F. jointly funded by the Wellcome Trust and Royal Society (104193/Z/14/Z), a research grant from the Royal Society (RG120405), the MRC for a studentship to J.S.F. (MR/J003964/1), and the EPSRC for funding an Integrate Early Career fellow (J.H.; EP/M027503/1). J.A. and R.N. acknowledge support from the BBSRC through a New Investigator grant awarded to J.A. (BB/P010660/1). We are grateful for the use of the University of East Anglia (UEA) Faculty of Science NMR facility.
