Abstract

RNU4ATAC pathogenic variants to date have been associated with microcephalic osteodysplastic primordial dwarfism, type 1 and Roifman syndrome. Both conditions are clinically distinct skeletal dysplasias with microcephalic osteodysplastic primordial dwarfism, type 1 having a more severe phenotype than Roifman syndrome. Some of the overlapping features of the two conditions include developmental delay, microcephaly, and immune deficiency. The features also overlap with Lowry Wood syndrome, another rare but well-defined skeletal dysplasia for which the genetic etiology has not been identified. Characteristic features include multiple epiphyseal dysplasia and microcephaly. Here, we describe three patients with Lowry Wood syndrome with biallelic *RNU4ATAC* pathogenic variants. This report expands the phenotypic spectrum for biallelic *RNU4ATAC* disorder causing variants and is the first to establish the genetic cause for Lowry Wood syndrome.

Keywords

responsible for additional clinical disorders, often with overlapping features, creating a clinical spectrum. Based upon clinical and radiographic characteristics, by 1982, Majewski et al. were able to classify microcephalic osteodysplastic primordial dwarfism (MOPD) into types I, II, and III (Majewski & Goecke, 1982; Majewski, Ranke, & Schinzel, 1982; Majewski, Stoeckenius, & Kemperdick, 1982). Overtime, it was recognized that MOPD I and MOPD III were variants of the same disorder that had previously been described by Drs. Taybi and Linder as cephalo-skeletal dysplasia (Haan et al., 1989; Meinecke & Passarge, 1991; Meinecke, Schaefer, & Wiedemann, 1991; Taybi, 1992a, 1992b; Winter, Wigglesworth, & Harding, 1985) (OMIM #210710). In 2011, several groups identified biallelic *RNU4ATAC* mutations as causative in the classic severe MOPD I/III phenotype (Abdel-Salam et al., 2011; Edery et al., 2011; He et al., 2011; Nagy et al., 2012). Four years later, *RNU4ATAC* pathogenic variants were also shown to cause Roifman syndrome (Merico et al., 2015). Roifman Syndrome (OMIM #300258) is a rare disorder characterized by growth retardation, cognitive delay, spondyloepiphyseal dysplasia, immunodeficiency, and retinal dystrophy. While it was surprising that individuals with such varied severity of phenotype were allelic, in hindsight it is clear that there are overlapping features. Individuals with Roifman as well as MOPDI/III syndromes have growth, developmental, and immunological abnormalities, though with differing severity. They can also be differentiated on the basis of skeletal involvement: Roifman syndrome is a spondyloepiphyseal dysplasia (SED), while MOPDI/III is a spondyloe-pimetaphyseal dysplasia (SEMD).

Lowry Wood syndrome (LWS; OMIM #226969) is characterized by multiple epiphyseal dysplasia (MED) without spinal involvement and accompanied by microcephaly and intellectual disability. It has an autosomal recessive pattern of inheritance. Intrauterine growth restriction, short stature, congenital nystagmus, retinitis pigmentosa, elbow contractures, coxa vara, and joint dislocations have also been described (Brunetti-Pierri et al., 2003; Hankenson, Ozonoff, & Cassidy, 1989; Lowry & Wood, 1975; Lowry, Wood, Cox, & Hayden, 1989; Magnani et al., 2009; Nevin, Thomas, Hutchinson, Opitz, & Reynolds, 1986). After the description of *RNU4ATAC* being associated with Roifman syndrome, we asked whether LWS could be an allelic condition, based on several overlapping features between LWS and Roifman syndrome. Subsequently, *RNU4ATAC* pathogenic variants were identified as the molecular cause of LWS, and once again expanded the spectrum of phenotypes of the RNU4ATAC-opathies.

2 | CLINICAL REPORT

Patient 1 (Figures 1a and 1b) was diagnosed clinically with LWS at 3.5 years of age. She was twin born via cesarean section at 35 weeks to her then 38-year-old mother. Family history is unknown because she and her twin were adopted. At birth, her OFC was 26.5 cm (Z-score −3.36), length 37.0 cm (Z-score −3.16), and BW 1.5 kg (Z-score −2.2). Initially, an atrial septal defect was noted on echocardiogram, and over time it spontaneously closed. She had delayed speech with first words at 27 months, and delayed motor milestones, first walking at 22 months. At 10 years and 9 months, she had an OFC of 41.2 cm (Z-score −8.6), heightof 118.2 cm (Z-score −3.5), and weightof 20.5 kg (Z-score −3.6). Additional clinical features included radiographic findings of MED, mild intellectual disability, arachnoid cyst, myopia, brachydactyly with hypoplastic middle phalanges, brachyclinodactyly V, and

retinitis pigmentosa (no night vision, with peripheral vision loss and retinal pigmentary clumping). Previous research exome sequencing was not revealing. Based on the newly identified *RNU4ATAC* mutations in Roifman syndrome and the overlapping features with Lowry Wood, *RNU4ATAC* sequencing was performed. This testing identified NR_023343.1:n51G>A and NR_023343.1:n5A>C variants in trans, lying in the 5' stem loop and stem II regions of u4atac respectively, where they are likely to disrupt both internal pairing to form the loop structure and essential base-pairing with u6atac. Based on ACMG standards, 51G>A is pathogenic and 5A>C is likely pathogenic (PS3, PS4 and PM1, PM2, PM3; respectively), (Richards et al., 2015). Given the known immunologic dysfunction associated with other patients with RNU4ATAC-opathies, immunologic testing was pursued, which demonstrated low IgG and IgM levels in the absence of a clear clinical immunodeficiency.

Patients 2 and 3 (Figures 1c and 1d) were a brother, age 14 years, and sister, age 15 years, diagnosed with LWS based on microcephaly, intellectual disability, and MED. Family history was otherwise unremarkable. Both were born full-term from uncomplicated pregnancies. Growth parameters at birth were OFC 31 cm (Z-score −2.7), L 45 cm (Z-score −3.1), and BW 2.85 kg (Z-score −1.8) for the brother; and OFC 31cm (Z-score −3.9), L 46 cm (Z-score −2.6), and 2.65 kg (Z-score −2.1) for the sister. At age 8, the sister was 96 cm tall (Z-score −6.3). At age 10, her OFC was 46 cm (Z-score −5.4). The brother had similar growth but recent height measurements are not available. His OFC at age 10 was 43 cm (Z-score −7.2). Both had full lips, prominent nose, sloping forehead, brachyclinodactyly V, contractures of the elbows bilaterally, and bilateral femoral head dislocations. In addition, the brother had scoliosis and coxa vara, while the sister had mild right knee contracture and coxa valga. They appeared to have normal immune system and normal vision, but had not had formal testing. Given the shared clinical diagnosis with patient 1, *RNU4ATAC* sequencing was performed and demonstrated three variants: NR_023343.1:n.111G>A in trans with NR_023343.1:n46G>A and NR_023343.1:n123G>A. The 111G>A and 46G>A variants were both previously reported in MOPDI (He et al., 2011; Kilic et al., 2015), are in trans, are predicted to disrupt the 5' stem loop region and a region of importance for protein-binding, and are classified as pathogenic according to ACMG criteria (PS3, PS4 and PS4, PM2, PM3, PP1, PP4, respectively), (Richards et al., 2015) (Table 1).

3 | DISCUSSION

In this study, we show that biallelic pathogenic variants in *RNU4ATAC* cause LWS, expanding the phenotypic spectrum of RNU4ATAC-opathies that includes MOPDI/III and Roifman syndrome. *RNU4ATAC* is located at 2q14.2 and encodes small nuclear RNA U4atac, a component of the minor spliceosome that is required for the correct excision of the U12-dependent class of introns (He et al., 2011).

MOPDI/III, Roifman syndrome, and LWS were historically categorized as separate clinical entities based on clinical and radiographic criteria. MOPDI/III is an SEMD, Roifman syndrome is an SED, and LWS is an MED. However, all are associated with varying degrees of IUGR, poor growth, epiphyseal dysplasia, microcephaly, intellectual disability, retinal abnormalities, and autosomal recessive inheritance. Features common to at least two of the

disorders include joint dislocations, contractures, eczema, and immunodeficiency. The conditions are on a spectrum, with the short stature and overall phenotype associated with MOPDI/III being more severe than LWS and Roifman syndrome. Most MOPDI patients do not survive past the first year of life (Pierce & Morse, 2012). The mechanism through which *RNU4ATAC* variants cause different clinical phenotypes is unclear. In 2015, Merico et al. proposed that two variants which severely disrupt function cause MOPDI, while a mix of a variant severely disrupting function and a variant causing minor disruption to function causes Roifman syndrome (Merico et al., 2015). This was consistent in their cohort and for patients 2 and 3, whose variants were categorized as MOPDI variants with reduced severity and were found in an area of variable importance for splicing. However, both of the variants in patient 1 are in regions predicted by Merico et al. to be important for splicing (Supplemental Figure S1), which is inconsistent with their theory. Presently, at least three distinct clinical diagnoses are associated with *RNU4ATAC* pathogenic variants, and clinical features from all three overlap. Thus, the syndromes are less clinically distinct than previously considered and the mechanism for which the genotype causes clinical manifestations, although partially explained by their model, appears to be more complex. Promisingly, in 2012, Nagy et al., (2012) observed a possible genotype-phenotype correlation within their MOPDI/III patient cohort. They noted that patients homozygous for the 51G>A variant had a mean survival of 10.4 months compared to a mean survival of 78.75 months in patients with MOPDI/III caused by other mutations, and in compound heterozygotes for the 51G>A variant and another mutation (Nagy et al., 2012). Phenotypic analysis of a larger sample of patients with *RNU4ATAC* variants may yield more complete information for outcome predictions. Alternatively, modifying genes may be identified which may explain the phenotypic variability observed with *RNU4ATAC* variants.

This study demonstrates that *RNU4ATAC* pathogenic variants cause a spectrum of phenotypes involving multiple metaphases, epiphyses, with and without spinal involvement (MED, SED, and SEMD). This results in severe MOPDI/III to milder Roifman and LWS. Many patients are unlikely to fit perfectly into the clinically described MOPDI/III, Roifmann syndrome, or LWS; and instead may have features of all three. Since *RNU4ATAC* is not consistently targeted in standard exome capture methodologies that only target protein-coding exons, many such cases will be missed. Sanger sequencing of this locus is needed for a complete assessment. As the phenotype may continue to expand, targeted *RNU4ATAC* sequencing should be considered in undiagnosed patients who have any combination of epiphyseal dysplasia with intellectual disability, microcephaly, immunodeficiency, and/or retinal anomalies.
