Human HemK2/KMT9/N6AMT1 is an active protein methyltransferase, but does not act on DNA in vitro, in the presence of Trm112

Clayton B. Woodcock¹, Dan Yu¹, Xing Zhang¹ and Xiaodong Cheng¹

Dear Editor,

Ever since the initial discovery and characterization of *S*-adenosyl-L-methionine (SAM)¹, the ATP-activated form of methionine, SAM has become the second most commonly used enzyme cofactor after ATP. A wide variety of macromolecules, including DNA, RNA, proteins, polysaccharides, lipids, and a range of small molecules are subject to methylation by highly specific SAM-dependent methyltransferases (MTases) acting on a particular target atom. Examples of methylation targets include nucleic acids (cytosine-C5, cytosine-N4 and adenine-N6), protein residues (arginine-N, lysine-N, glutamine-N and histidine-N), and small molecules (catechol-O, histamine-N, glycine-N, and thiopurine-S).

Early sequence alignments of known SAM-dependent MTases identified a set of conserved sequence motifs among DNA cytosine-C5 MTases, DNA adenine-N6 and cytosine-N4 MTases, and protein or small molecule MTases². In essence, the two most conserved sequence motifs reflect the common functions of the MTases: motif I (FxGxG) for binding of the methyl donor SAM and motif IV for catalysis. The residues of motif IV conform in accordance with the target atom, for instance, the PC motif (proline-cysteine) is responsible for ring carbon-C5 methylation of cytosine, whereas the (D/N)PP(Y/F/W) motif for exocyclic amino methylation of adenine and cytosine. However, the apparent sequence and structural similarity do not reveal with certainty whether an enzyme acts on a particular substrate (DNA, RNA or protein). Examples include mammalian DNMT2, which shares sequence and structural similarity with DNA cytosine-C5

MTases³, but is a tRNA cytosine-C5 MTase⁴ and *Escherichia coli* (*E. coli*) HemK, which was thought to be a DNA amino MTase⁵, yet is a protein glutamine MTase^{6,7}. The conservation in an enzyme's sequence and structure merely reflects the conserved nature of catalyzing the methyl transfer onto cytosine-C5 (of DNA and RNA) or amino-group (of adenine and glutamine).

Recently, mammalian HemK2 (NCBI Reference Sequence NP_037372.4) has been documented to be a DNA adenine-N6 MTase⁸ (renamed as N6AMT1) and a histone H4 lysine-12 MTase⁹ (renamed as KMT9), in addition to its known activity of glutamine methylation of eukaryotic release factor eRF1¹⁰. The common feature of the three potential substrates is the amino group (NH₂) of glutamine, adenine, and lysine (Fig. 1a). It is rare to have a MTase (or any enzyme *per se*) capable of acting on both oligonucleotides and protein (and on two different amino acids). Because previous studies^{8,9} did not compare directly the three potential substrates, here we analyze the in vitro activities of HemK2 on the three substrates side-by-side. HemK2 forms a heterodimeric complex with Trm112¹⁰ (named after tRNA methylation protein), and we purified recombinant human HemK2-Trm112 heterodimer expressed in *E. coli* (Fig. 1b). Sequence of one of the characterized DNA substrates (GAGTC) of HemK2⁸ overlaps with the recognition sequences (GANTC) of a known bacterial DNA adenine MTase, *Caulobacter crescentus* cell cycle-regulated MTase¹¹, we thus included CcrM as a positive control. In addition, we included *E. coli* Dam (DNA adenine MTase) on GATC for comparison¹². Both bacterial enzymes were purified in house (Fig. 1b).

We designed five short DNA double-stranded oligos (#1 to #5): #1 contains no-adenine and was used as a negative control, #2, #3 and #4 oligos are thought to be substrates of HemK2⁸, #4 contains the CcrM recognition sequence

GANTC and #5 contains the *E. coli* Dam recognition sequence GATC (Fig. 1c—the letters T and B designate the top and the bottom strand respectively). Under the conditions where both CcrM and Dam completed reactions on their respective substrates (CcrM on oligo #4 and Dam on oligo #5), we observed no activities of HemK2-Trm112 on the five oligos examined (either double or single stranded) (Fig. 1d–f). However, we did observe activity of HemK2-Trm112 on peptide derived from eRF1 (residues 179–193), much-reduced activity on histone H4 (residues 1–20), and no activity on histone H3 peptide (residues 1–15) at the condition of pH 8 (Fig. 1g). Under the same condition of pH 8, mass spectrometry analysis of peptide substrates confirmed that glutamine-containing eRF1 peptides were fully methylated, whereas H4 peptides had residual methylated species and no methylation of H3 peptides (Fig. 1h).

Most (if not all) SAM-dependent MTases use the classic $\text{S}_{\text{N}}2$ reaction mechanism, which requires the target nitrogen be in a deprotonated state. Under the condition (pH 8.0) that HemK2-Trm112 demonstrated strong activity for the glutamine-containing peptide, we observed minor activity on the lysine-containing H4 peptide (Fig. 1i). We reasoned that higher pH conditions might enhance methylation of lysine substrate (with typical pK_{a} value of ~ 10), as was shown for other biochemically

characterized protein (histone) lysine MTases to have optimal *in vitro* activity at approximately pH 10¹³. After adjusting the pH to 10.5, the activity of HemK2-Trm112 is significantly increased on H4 peptide (Fig. 1i). An investigation employing peptide array libraries showed that HemK2 methylation activity on eRF1 peptide requires a glycine immediately before and an arginine positioned four-residues after the target glutamine¹⁴. H4 K12 meets this requirement with glycine (G11) and a positively charged lysine (K16) in the place of the corresponding arginine of eRF1 (see sequences shown in Fig. 1h). The short H3 peptide (residues 1–15) used in the assay does contain one glutamine and three lysine residues but is not a methylation substrate of HemK2. Finally, HemK2-Trm112 complex structure (PDB 6H1E⁹) illustrates a negatively charged substrate interface (Fig. 1j), ideal for positively charged peptides such as eRF1 and histone H4, but unsuitable for a negatively charged DNA substrate. We note that the activity on glutamine-containing eRF1 peptide is significantly reduced at the high pH (Fig. 1i), suggesting that high pH is not optimal for catalysis and/or stability of HemK2-Trm112 complex. For the lysine-containing H4 peptide, however, deprotonation of lysine by high pH is preferred for methylation to occur, but only to a much-reduced level as compared with that of glutamine methylation at pH 8.

In sum, using two established MTase assays *in vitro*, following either incorporation of tritium from $^3\text{H-SAM}$ into a substrate or formation of byproduct SAH in a bioluminescence assay, we show that human HemK2-Trm112 heterodimer is only active on protein glutamine and lysine, but not active on DNA. In light of current interests on N6-methyladenine in eukaryotic genomic DNA, our study resolves one controversy in the field. Additional data will be required to address the dual specificity of HemK2 on protein glutamine and lysine—a unique property for a MTase working on two different substrates with different target residues, one is located in the cytoplasm (eRF1, glutamine) and the other in nucleus (histone H4, lysine).

Finally, we want to clearly highlight the differences between our studies presented here and that of Xiao et al.⁸. (1) We used recombinant HemK2-Trm112 complex expressed in *E. coli* and purified using a four-column chromatography, whereas Xiao et al. used N6AMT1-Flag plasmid transfected into HEK293T cells and protein purified according to the kit instructions, presumably one-step affinity purification. (2) We used purified HemK2-Trm112 complex (Fig. 1b), whereas there was no mention whether the protein preparation used by Xiao et al. contains Trm112. In a separate study, partially purified Flag-N6AMT1 from overexpressing HEK293T cells appeared to contain a ~15-kDa protein that might be co-purified endogenous Trm112, and this protein preparation did not methylate DNA oligonucleotides *in vitro* as shown by N6mA specific antibody (see Fig. S4 of Xie et al.¹⁵). (3) Our fluorography assays on DNA (Fig. 1f) were conducted with $[\text{E}] = 2 \mu\text{M}$, $[\text{S}] = 10 \mu\text{M}$, and $[\text{}^3\text{H-SAM}] = 10 \mu\text{M}$, whereas Xiao et al. used 25 μl reaction system containing $[\text{E}] = 0.8 \mu\text{g}$ (~0.8 μM), $[\text{S}_{\text{DNA}}] = 250 \text{ pmol}$ (=10 μM), $[\text{}^3\text{H-SAM}] = 55 \mu\text{M}$ (which is puzzling as that is the concentration of the PerkinElmer NET155V $[\text{}^3\text{H-SAM}]$ stock). Both reactions were carried out at 25 °C overnight under similar buffer and salt conditions.

Acknowledgements

This work was supported by grants from NIH (GM049245) and CPRIT (RR160029). The Proteomics and Metabolomics Facilities were supported in part by CPRIT (RP130397) and NIH (1S10OD012304 and P30CA016672). We thank Dr. John R. Horton for providing purified *E. coli* Dam.

Author contributions

C.B.W. performed protein purification and enzymatic assays. D.Y. made Trm112 construct. X.Z. and X.C. organized and designed the scope of the study. All were involved in analyzing data and preparing the manuscript.

Conflict of interest

The authors declare that they have no conflict of interest.
