**Present-day African ecosystems serve as referential models for conceptualizing the environmental context of early hominin evolution, but the degree to which modern ecosystems are representative of those in the past is unclear. A growing body of evidence from eastern Africa's rich and well-dated late Cenozoic fossil record documents communities of large-bodied mammalian herbivores with ecological structures differing dramatically from those of the present day, implying that modern communities may not be suitable analogs for the ancient ecosystems of hominin evolution. To determine when and why the ecological structure of eastern Africa's herbivore faunas came to resemble those of the present, here we analyze functional trait changes in a comprehensive dataset of 305 modern and fossil herbivore communities spanning the last ~7 Myr. We show that nearly all communities prior to ~700 ka were functionally non-analog, largely due to a greater richness of non-ruminants and megaherbivores (species >1,000 kg). The emergence of functionally modern communities precedes that of taxonomically modern communities by 100,000s of years, and can be attributed to the combined influence of Plio-Pleistocene C<sub>4</sub> grassland expansion and pulses of aridity after ~1 Ma. Given the disproportionate ecological impacts of large-bodied herbivores on factors such as vegetation structure, hydrology, and fire regimes, it follows that the vast majority of early hominin evolution transpired in the context of ecosystems that functioned unlike any today. Identifying how past ecosystems differed compositionally and functionally from those today is key to conceptualizing ancient African environments and testing ecological hypotheses of hominin evolution.**

functional traits | megaherbivore | non-analog faunas | paleoanthropology | paleoecology

**A** central goal of human evolutionary studies is to understand how climatically mediated environmental changes over the last ~7 Myr shaped the anatomical, behavioral, and technological evolution of our early ancestors (1–3). Forging causal links between environmental change and hominin evolution requires detailed reconstructions of the ancient ecosystems within which our ancestors lived, including faunal community composition, the strength and direction of species interactions (e.g., predator–prey relationships), vegetation structure, and the spatial distribution of foods and other vital resources (4, 5). This research focus has fueled the generation and analysis of detailed paleoenvironmental archives across Africa, with key proxies derived from mammalian faunas (6, 7), isotopic geochemistry of fossil herbivore teeth and soil carbonates (8–10), paleobotanical remains (11–13), and multiproxy lacustrine sequences (14, 15). Though we now know considerably more about African paleoclimatic and paleoenvironmental change than we did decades ago (16), translating this knowledge to an understanding of the selective pressures that shaped hominin evolution remains an ongoing challenge (3–5).

One of the primary challenges we face is that our inferences made about the structure and functioning of ancient ecosystems are strongly shaped by those of the present (see refs. 3 and 4 for discussions of other challenges). For example, reconstructions of past climate or vegetation structure are routinely based on present-day relationships between these variables and various proxies, such as mammal species composition, the distribution of herbivore functional traits, or the isotopic composition of soil carbonates

(10, 17–20). While reliance on modern analogs is an essential component of paleoecological and paleoenvironmental reconstruction (21), it limits our ability to evaluate how ancient ecosystems might have differed from those today (22).

In conflict with hominin paleoecology's deep roots in uniformitarian approaches founded on identifying similarities between the past and present (23–25), the existence of ancient ecosystems with no modern analogs is now supported by a growing body of evidence from eastern Africa's rich and well-dated late Cenozoic fossil record. For example, recent studies have shown that many Plio-Pleistocene herbivore communities were considerably richer in megaherbivores (species >1,000 kg) (26) and were characterized by atypical dietary guild structures (8) relative to their modern counterparts. These important ecological differences may have persisted until recently, as Late Pleistocene faunas are often dominated by extinct herbivore taxa (27, 28), including some with morphologies unique among living and fossil mammals (29). Because large-bodied mammalian herbivores possess key functional traits that influence ecosystems in ways that impact a wide variety of species (30, 31), it follows that the ancient ecosystems of hominin evolution were both compositionally and functionally unlike any in Africa today.

Despite long-standing interest in the emergence of taxonomically “modern” faunas in eastern Africa (27, 32–35), we have little understanding of when or why eastern Africa's herbivore communities came to resemble those of the present in terms of their functional ecology. With this in mind, here we analyze the functional evolution of eastern African large herbivore communities (orders Artiodactyla, Perissodactyla, and Proboscidea) over the last 7 Myr using a comprehensive database of 101 fossil

## Significance

**Testing ecological hypotheses of human evolution requires an understanding of the ancient plant and animal communities within which our ancestors lived. Though present-day ecosystems provide the baseline for reconstructing the ecological context of human evolution, the extent to which modern ecosystems are representative of past ones is unknown. Through analyses of a fossil dataset spanning the last 7 Myr, we show that eastern African communities of large-bodied mammalian herbivores differed markedly from those today until ~700,000 y ago. Because large herbivores are ecosystem engineers and shape biotic communities in ways that impact a wide variety of species, this implies that the vast majority of early human evolution transpired in the context of ecosystems that functioned unlike any known today.**

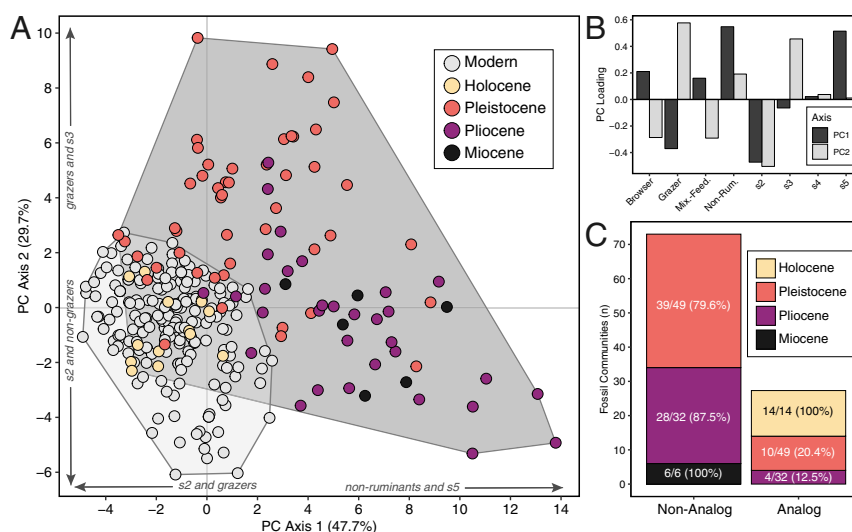

**Fig. 2.** Temporal trends in the functional trait composition of eastern African large herbivore communities over the last 7 Myr. Purple shading represents the modern range of variation for each trait. White diamonds indicate fossil communities that fall within the modern range of variation for all 8 functional traits. Orange circles indicate fossil communities that are non-analog; they fall outside the modern range of variation for one or more of the functional traits illustrated here. Dark gray lines represent LOESS regressions with a smoothing factor of 0.75; 95% confidence limits in light gray (see *SI Appendix* for further information).

**Drivers of Community Change.** One of the most substantial and well-documented changes to eastern African ecosystems since the late Miocene is the expansion of  $C_4$  grasslands (16), shown in Fig. 4A using stable carbon isotope records ( $\delta^{13}C$ ) from soil carbonates. Many of the functional changes in fossil herbivore communities, synthesized here in a plot of PC1 scores through time (Fig. 4C), track the  $\delta^{13}C$  soil record and can reasonably be interpreted as a response to grassland expansion. Turning to individual traits, prior to  $\sim 1$  Ma, dietary structure closely tracks the percentage of  $C_4$  biomass inferred from the  $\delta^{13}C$  composition of soil carbonates in eastern Africa, with grazers increasing and browsers and mixed feeders declining as grasses cover a greater

proportion of landscapes (Fig. 2). These trends are consistent with herbivore tooth enamel  $\delta^{13}C$  data spanning 4 to 1 Ma from the Turkana Basin (8). In addition, the long-term decline of megaherbivores—which our analyses show to be one of the key variables distinguishing fossil communities from modern ones (Figs. 2 and 3B)—inversely tracks the expansion of  $C_4$  grasslands. Megaherbivores favoring  $C_3$  browse were preferentially affected, strongly implying a cause–effect relationship (26).

The consequences of grassland expansion and megaherbivore decline likely translated to important shifts in the functional structure of the eastern African carnivore guild. Today, the largest

**Fig. 3.** Comparison of the functional composition of modern and fossil large herbivore communities. (A) The first 2 axes of a PCA of richness-corrected functional trait residuals for modern and fossil communities; the light gray hull encloses the modern range of community variation, and the dark gray hull encloses the fossil range of variation. (B) PC1 and PC2 loadings for all functional traits. (C) Stacked barplot of the number of non-analog versus analog fossil herbivore communities grouped by their geological epoch. Fossil communities are considered non-analog if the residual for any given trait falls outside the modern range of variation (Fig. 2).
