Introduction: In anterior cruciate ligament (ACL) reconstruction, hamstring tendon autograft is a well-accepted surgical choice as an alternative ACL graft. But the main disadvantage of autograft is its inefficient healing with host bone-tunnel which will leading to surgery failure.

Methods: A biomimetic nanofibrous membrane for tendon-bone integration is fabricated in this work, which is composed of polycaprolactone (PCL) electrospinning membrane and chitosan/hyaluronic acid (CS/HA) multilayers film.

Results: By using layer-by-layer (LbL) self-assembly this functional CS/HA multilayer films are deposited on the surface of PCL nanofiber to enable the local delivery of stromal cell-derived factor-1 α (SDF-1 α) and bone morphogenetic protein-2 (BMP-2) in tendon-bone interface. This membrane can promote cell proliferation and recruitment, as well as inducing the osteogenic differentiation and recruitment of BMSCs.

Conclusion: Further in vivo studies demonstrate that to wrap the tendon autograft using the membrane may afford superior tendon-bone integration and inhibit scar tissue formation in a rabbit ACL reconstruction model. More importantly, the biomechanical properties of the tendon-bone interface have been improved. This study shows that this biomimetic nanofibrous membrane is effective for improving tendon-bone healing after ACL reconstruction surgery.

Keywords: anterior cruciate ligament reconstruction, tendon-bone healing, layer-by-layer self-assembly, nanofibrous membrane, stromal derived factor-1 α

Introduction

The clinical treatment of knee anterior cruciate ligament (ACL) injury caused by high-risk sports, over-exercise or accidents is still a great challenge.^{1,2} As ACL plays an important role in the stability of the knee joint, ACL injury can lead to knee instability and a high risk of osteoarthritis (OA).^{3,4} Due to the limited regenerative capacity of the ACL, pursuing suitable grafts for its reconstruction has always been a goal of sport medicine. In ACL reconstruction surgery, hamstring tendon autografts are widely chosen as alternative ACL grafts due to advantages such as low risks of arthropathy and donor-site lesions.^{5,6} However, the main disadvantage of an autograft is its inefficient integration with the host bone tunnel, which will result in long postoperative healing time, graft sliding and bone loss in the bone tunnel during movement and will finally lead to surgery failure.^{7,8} The poor integration process of autografts and bone tunnels is ascribed to the rapid cell proliferation of fibroblasts compared to that of osteoblasts, which results in the formation of scar tissue with poor biomechanical properties at the tendon-bone interface, eventually leading to inefficient integration.⁹

Therefore, investigation into novel scaffolds to promote bone tissue formation and tendon-bone interface integration in the tunnel is necessary for the improvement of biomechanical function and postoperative recovery.

The tissue engineering approach provides new ideas for solving this problem. Previous studies have confirmed that some bioactive scaffolds, such as decellularized scaffolds,^{10,11} electrospun scaffolds^{12,13} and collagen sponges,^{14,15} promote tendon-bone healing. Among them, the preparation of electrospinning scaffolds is simple and the cost is low. These scaffolds can simulate the extracellular matrix and constituted a 3D-culture environment of cells, which made it widely used for repairing the injuries of connective tissues.^{12,16,17} In our previous study, we designed a polycaprolactone nanofibrous scaffold doped with nanohydroxyapatite to wrap autologous tendon for ACL reconstruction in a rabbit model.¹² The results confirmed that this scaffold can effectively promote the proliferation and mineralization of osteoblasts, reduction of fibrous scar tissue at the tendon-bone interface, and improvement in biomechanical properties. However, this scaffold has limited effects on the early healing of the tendon-bone interface, and further improvements are needed. In recent years, researchers have paid increasing attention to the synergistic effect of stem cell recruitment

derived from chemotactic factors and growth factors. For example, some studies confirmed that the synergistic interaction of stromal cell-derived factor-1 α (SDF-1 α) with bone morphogenetic protein-2 (BMP-2) can promote bone marrow stromal cell (BMSC) homing and new bone formation.^{18–20} Therefore, the strategy of locally delivering SDF-1 α can overcome many of the shortcomings of clinical applications of exogenous stem cell transplantation.

In this work, a dual-growth-factor delivery system consisting of SDF-1 α - and BMP-2-loaded chitosan/hyaluronic acid (CS/HA) multilayer coatings was manufactured using layer-by-layer (LbL) self-assembly (Figure 1). LbL self-assembly system has recently been explored as a convenient and green drug controlled release system.²¹ Functional, polyelectrolyte multilayer films were deposited on the surface of nanofibers to render the latter more biomimetic and enable the local delivery of growth factors. A polyelectrolyte multilayer film is a LbL build-up of oppositely charged polyelectrolytes to form a nano/micro-scale film that acts as a reservoir to retain the bioactivity of electrostatically adsorbed molecules. As Chitosan (CS) and hyaluronic acid (HA) are biocompatible materials which were widely used in bone tissue engineering,^{22,23} in this work, we selected CS and HA as the polyelectrolytes for LbL self-assembly. The primary objective of this

Figure 1 Schematic illustration of the fabrication of nanofibrous membrane, and the implantation of the membrane-wrapped autograft tendon into femur and tibia bone in ACL reconstruction surgery.

Abbreviations: SDF-1 α , stromal derived factor-1 α ; BMP-2, bone morphogenetic protein-2; ACL, anterior cruciate ligament.

study was to investigate whether a delivery system of SDF-1 α and BMP-2 could be fabricated using LbL self-assembly and could thus have the potential to induce osteogenic differentiation and recruitment of BMSCs. The secondary objective was to investigate whether this scaffold could enhance tendon-bone interface integration and inhibit scar tissue formation. Therefore, the effects of the scaffold on the bio-activities of BMSCs in terms of their recruitment, proliferation and osteogenic differentiation were evaluated *in vitro*. Moreover, a rabbit ACL injury model was employed in this study for *in vivo* ACL reconstruction, and biomechanical and histological analyses were applied for a comprehensive follow-up evaluation *in vivo*.

Materials and Methods

Materials

The reagents for electrospinning, PCL (Mw =80 kDa), dichloromethane and dimethyl sulfoxide (DMSO), were purchased from Sigma-Aldrich (USA). The reagents for LbL self-assembly, polyallylamine hydrochloride (PAH), CS (Mw=50-190 kDa) and HA (Mw=1500-1800 kDa) were also obtained from Sigma-Aldrich (USA). Dulbecco's modified Eagle's medium (DMEM), PBS, Fetal bovine serum (FBS), penicillin-streptomycin and trypsin were purchased from Gibco (USA). Recombinant human BMP-2 (rhBMP-2) and recombinant human SDF-1 α /CXCL12 were purchased from Peprotech (USA).

Fabrication of Nanofibrous Polycaprolactone (PCL) Membrane

Using a conventional electrospinning method, random nanofibrous PCL scaffolds were manufactured. Briefly, a polymer solution was prepared by dissolving PCL in a mixture of dichloromethane/DMSO (3:1, w/w) at a concentration of 6% (w/w). The PCL solution was placed into a 10-mL glass syringe, and then the syringe was fixed to a pump (LSP01-1A, Longer Pump Inc., People's Republic of China) to control the flow speed at a constant rate (0.5 mL/h). A high voltage (15 kV) was applied to the needle tip, and the distance between the tip and the nanofiber collector was 20 cm. The collector for the PCL nanofibers was an aluminum foil-covered cylinder rotating at 100 rpm. The PCL nanofiber membranes were collected from the aluminum foil and sterilized with ethanol overnight before they were ready for further use. The PCL nanofibrous scaffolds utilized in this study were of similar thickness.

Preparation of the Growth Factor-Loaded Membrane

The CS/HA multilayer film-coated PCL scaffold was prepared using an LbL self-assembly method. Briefly, solutions of polyallylamine hydrochloride (PAH, 1 mg/mL), CS (1 mg/mL, with 1 mM acetic acid), and HA (1 mg/mL, pH 4.7) were prepared. LbL was used to coat the nanofibrous scaffold with a CS/HA multilayer film loaded with positively negatively charged SDF-1 α and positively charged rhBMP-2 at pH 4.7. Briefly, the PCL membrane was initially immersed in the PAH solution for 1 hr to form a positively charged precursor layer, which then initiated the LbL assembly process. Then, the PCL membrane was soaked in a solution of SDF-1 α (1 μ g/mL) and HA for 5 mins, and the membrane was subsequently soaked in a solution of rhBMP-2 (1 μ g/mL) and CS. This process was repeated 10 times to coat the PCL nanofibers with the SDF-1 α /BMP-2-loaded CS/HA multilayer film. This scaffold loaded with BMP-2 and SDF-1 α was denoted as S+B@P. In addition, as the BMP-2-loaded scaffold is a widely studied classic scaffold for bone repair, we fabricated a BMP-2-loaded PCL scaffold as a positive control (denoted as a B@P) to illustrate the advantages and clinical applicability of S+B@P. Briefly, after the PAH-derived positively charged precursor layer formed, the PCL membrane was soaked in the HA solution without SDF-1 α for 5 mins, and then the membrane was soaked in a solution of rhBMP-2 (1 μ g/mL) and CS. This process was repeated 10 times, and a CS/HA multilayer film loaded with a single growth factor (BMP-2) was fabricated. The abbreviations of the scaffolds used in this work are summarized in Table 1.

Characterization of Scaffolds

The S+B@P and B@P specimens, as well as the untreated PCL membranes, were sputter-coated with gold. Then, their micromorphology was visualized under scanning electron microscopy (SEM) (S3000N, Hitachi, Japan) at

Table 1 Sample Abbreviations Used in This Work

Name of Sample	Description of Sample
PCL	Nanofibrous PCL scaffold
B@P	BMP-2-loaded CS/HA multilayer-modified PCL scaffold
S+B@P	SDF-1 α - and BMP-2-loaded CS/HA multilayer-modified PCL scaffold

an accelerating voltage of 15 kV. The average fiber diameter of each specimen was measured using ImageJ software after the micrographs were obtained ($n=3$). An average of 100 fibers were counted for each specimen. In addition, a thin piece was removed from each sample and placed on copper meshes. Then, the structure of each group was observed under a transmission electron microscope (TEM) (JEM-2100F, JEOL, Japan)

The deposition of polyelectrolytes (CS/HA) on the nanofibers of S+B@P and B@P after the LbL self-assembly was evaluated using an attenuated total reflection-Fourier transform infrared (ATR-FTIR) spectrometer (Tensor 27, Bruker, Woodlands, TX, USA) and a UV-vis spectrophotometer (Cary 50, Varian).

The hydrophilicity of each group was detected by water contact angle (WCA) analysis based on a Model 200 video. Briefly, the PCL, S+B@P and B@P membranes were cut into a size of 5 cm x 5 cm and flattened. Then, a 1 μ l water droplet was placed on the surface of the sample, and the instrument's video recorder was used to observe the interaction between the water droplet and the material interface within one minute. The WCA was calculated using the VCA Optima software.

The scaffolds of each group were cut into a size of 1 cm \times 1 cm and soaked in 1 mL of phosphate-buffered saline (PBS) at 37°C. The PBS samples were collected and replaced with fresh PBS daily, such samples were immediately frozen at -80. The amount of SDF-1 α and rhBMP-2 released in PBS was measured by an ELISA kit (Peprotech, USA) for 50 days ($n=3$). PBS samples from the release studies were thawed and returned to room temperature immediately prior to their use. ELISA was performed in accordance with the instructions provided with the development kit. Color monitoring of the ELISA plates was performed using a PerkinElmer Victor3 multilabel reader with a 405 nm filter and 650 nm correction filter.

In Vitro Studies

Cell Proliferation and Migration

SD rat BMSCs were purchased from the Cell Bank of the Chinese Academy of Sciences (Shanghai, People's Republic of China). The scaffolds of each group were cut into circular films with a diameter of 1.6 cm and then pasted on the bottom of a 24-well plate. The BMSCs (1×10^5 cells/well) were seeded in each well and cultured in Dulbecco's modified Eagle's medium (DMEM) containing 10% foetal bovine serum (FBS) and 1% penicillin/streptomycin. BMSC proliferation was evaluated using the Cell Counting Kit-8 assay (CCK-8,

Dojindo Molecular Technologies, Inc., Kumamoto, Japan) after 1, 3 and 5 days of culture according to the manufacturer's protocol. Briefly, the cells were washed twice by PBS, and then treated with 500 μ L CCK-8 working solution (500 μ L DMEM containing 10% WST-8 solution(v/v)). After the plates incubated at 37°C for 2 h, 200 μ L of resulting solution in each well was transferred to a 96-well plate. Optical density (OD) value at 540 nm was recorded with a micro-plate reader (Victor X, PerkinElmer).

Additionally, the morphology of BMSCs cultured on the scaffold was observed by SEM. Briefly, the BMSCs were cultured on the scaffolds for 24 hrs. Then, the cells were washed twice with PBS and immersed in PBS containing 1% glutaraldehyde for 4 hrs. They were then dehydrated in ethanol solutions at concentrations of 20%, 40%, 60%, 80%, and 100% and finally dried at 25°C. The sample was gold sputtered under vacuum and visualised under SEM (S3000N, Hitachi, Japan).

An in vitro BMSC migration model based on Transwell (Corning) was established. Briefly, 100 μ l cell suspensions of BMSCs with a density of 50,000/mL were added to the upper chamber of each Transwell insert. After 24 and 48 hrs of culture, the polycarbonate membrane was removed, and the unmigrated cells on the membrane were gently removed. Then, the membrane was immersed in a 2.5% glutaraldehyde solution for 2 hrs, and the migrating cells were subsequently stained using 0.5% crystal violet solution for 10 mins. The migrating cells were observed using a microscope, and 6 fields per well were randomly selected and photographed. Subsequently, the number of cells was counted using ImageJ software.

Alkaline Phosphatase (ALP) and Alizarin Red Staining (ARS) Analysis

The capability of PCL, B@P and S+B@P to induce the osteogenic differentiation of BMSCs was assessed by ALP and ARS analysis. Briefly, the membranes of each group were cut into circular films with a diameter of 1.6 cm and then pasted on the bottom of a 24-well plate. The BMSCs (1×10^5 cells/well) were seeded in each well and cultured in osteogenic induction medium (OIM: β -glycerol phosphate, dexamethasone and ascorbic acid supplemented in full DMEM). After 7 days of culture, the level of ALP secretion was evaluated by an ALP staining kit and ALP quantification kit (Beyotime Biotechnology Inc., Shanghai, People's Republic of China). After 30 days of culture, the level of mineralised deposition of the BMSCs was evaluated by ARS staining. The cells were fixed in 70% ethanol for 1 hr. After washing twice with

double-distilled H₂O (ddH₂O), the BMSCs were stained with an ARS solution (pH=4.8) for 30 mins. After staining, the cells were washed using ddH₂O and then air dried at room temperature. After 30 days of culture, the level of mineral deposition was evaluated by an ARS staining kit (Solarbio, Beijing, People's republic of China). The ALP- and ARS-stained cells were observed using a microscope, and 6 fields per well were randomly selected and photographed. After the photographs were taken, the ARS-stained mineral deposition was desorbed with 10% cetylpyridinium chloride (Sigma-Aldrich). The solution was collected, and optical density was recorded at 540 nm with a spectrophotometer (Multiskan MK3, Thermo Fisher).

In Vitro Real-Time Polymerase Chain Reaction (PCR) Analysis

To clarify the influence of different scaffolds on osteogenic differentiation in vitro, the gene expression levels of runt-related transcription factor 2 (Runx2), collagen I (Col I), osteopontin (OPN) and osteocalcin (OCN) were detected in the PCL, B@P and S+B@P groups after 7 and 14 days after BMSCs seeded on the scaffolds, respectively. Total tissue RNA was extracted with the TRIzol reagent (Invitrogen Inc., Carlsbad, CA, USA) according to the instructions for phenol chloroform-isoamyl alcohol extraction. RNA (1000 ng) was placed into a 20 μ L reaction system for reverse transcription with the PrimeScript RT reagent kit (Takara) according to the manufacturer's instructions. Real-time PCR was performed using the SYBR Green PCR Master Mix (Takara) on a real-time PCR System (Applied Biosystems 7500). The primer sequences used in this study were designed as follows: Runx2 forward 5'-TCTTCCCAAAGCCAGAGCG-3' and reverse 5'-TGCCATTCGAGGTGGTCG-3'; Col I forward 5'-TGGATGGCTGCACGAGT-3' and reverse 5'-TTGGGATG GAGGGAGTTTA-3'; OPN forward 5'-GAGGAGAAGGC GCATTACAG-3' and reverse 5'-AAACGTCTGCTTGTCT GCTG-3'; OCN forward 5'-CATGAAGGCTTTGTCAGA CT-3' and reverse 5'-CTCTCTCTGCTCACTCTGCT-3'; GAPDH forward 5'-GGCAAGTTCAACGGCACAGT-3' and reverse 5'-GCCAGTAGACTCCACGACAT-3'. Each quantitative PCR run was performed with at least three experimental replicates, and the relative expression level of each gene was calculated using the $2^{-\Delta\Delta Ct}$ method.

In Vivo Studies

ACL Reconstruction Animal Models

The animal study was approved by The University of Fudan Institutional Animal Care and Use Committee and

conducted according to the Guide for the Care and Use of Laboratory Animals of Fudan University. The procedure of the ACL reconstruction surgery is illustrated in Figure 2. Briefly, 48 skeletally mature female New Zealand white rabbits (12 weeks old, 2.4 \pm 0.3 kg) were used and divided into three groups (PCL, B@P and S+B@P) with six rabbits in each group. Under general anaesthesia, the bilateral limbs were shaved and disinfected. Then, skin incisions were made to expose the right knee joint of the rabbit, and lateral parapatellar arthrotomy was subsequently used. As shown in Figure 2, the native ACL was exposed after removing the soft tissue surrounding the ACL. Then, the native ACL was removed from the insertion sites by sharp dissection. A bone tunnel 2.5 mm in diameter was created with a drill in the femur and tibia insertion sites of the native ACL. The contralateral semitendinosus tendon was harvested and wrapped with the membrane. The semitendinosus tendon wrapped with the PCL membrane was used as the control group. The prepared graft was passed through the bone tunnel and joint cavity. Both ends of the graft were attached to the adjacent periosteum and soft tissue with two 4–0 Ethibond sutures (Johnson & Johnson, New Brunswick, NJ, USA), and the wound was then closed. After the surgical procedure, the rabbits were kept in large cages without influencing their movement to prevent joint stiffness. After 4 and 8 weeks post-surgery, the rabbits were sacrificed to harvest tissue samples for histological and biomechanical analysis. The interface healing between the engineered tendon and host tissue was also examined.

Histological Analysis

After the rabbits were sacrificed, the knee joint samples were removed and fixed in 10% neutral buffered formalin for 3 days and were then dehydrated through an alcohol gradient (30%–100%) and embedded in paraffin wax. The specimens were cut to a thickness of 5 μ m along the longitudinal axis of the tendon. These sections were treated with haematoxylin and eosin (H&E) and Masson's trichrome stain (Masson's) for histological evaluation. The sections stained with H&E and Masson's were observed using a light microscope (Eclipse 80i, Nikon), and the images were captured using a camera (DS-5M, Nikon). For immunohistochemistry staining, endogenous peroxidase was blocked by incubation with 3% (v/v) hydrogen peroxide in methanol for 10 mins. Then, the sections were blocked for 20 mins with a blocking reagent containing goat serum in PBS after washing three times with PBS. After overnight incubation at 4°C with a primary antibody, the sections

Figure 2 A diagrammatic representation of the procedure of ACL injury modeling and reconstruction surgery.

Notes: (A) Both ends of the autograft (Partial Achilles tendon) were wrapped using the membrane for ACL reconstruction; The procedure of modeling and reconstruction: (B) The ACL tendon was exposed; (C) The ACL tendon tissue was damaged to formatted an ACL injury; (D) & (E) ACL reconstruction using the membrane wrapped autograft.

were washed and then incubated with a secondary antibody (MaxVision kit; Maixin Biotechnology) for 15 mins at room temperature. Dimethyl aminoazobenzene (DAB) (Simple Stain DAB Solution, Maixin Biotechnology) was used for colour development. Hematoxylin staining was used to reveal the nuclei. The results were evaluated by three individuals who were blinded to the treatments.

Biomechanical Testing

After sacrifice, the knee joint specimens ($n=4$) were harvested, and single pull-to-failure analysis was carried out in this experiment. Except for the grafts and tendon, all soft tissue surrounding the ACL was carefully removed from each sample. Care was taken not to damage the connective tissue between the humeral head and tendon. All mechanical testing was conducted using an electronic universal material testing system (AGS-X, Shimadzu, Co., Japan). To reduce slippage, the femur and the tibia were wrapped in saline-moistened gauze, followed by fixation with a restraining jig. Before the tensile test, the samples were preloaded with a static preload of 1 N for 5 mins. After preconditioning, the ultimate failure load was measured immediately with an elongation rate of 5 mm/min. After applying a preload of 1 N with a test speed of 5 mm/min, the femur-graft-tibia complex underwent preconditioning for

a total of 20 cycles. The load–deformation curve was recorded from which the ultimate failure load (N) was measured. Stiffness (N/mm) was calculated from the slope of the linear region of the load–deformation curve at the maximal load-to-failure point. For each sample, the test was completed when the graft was ruptured.

Statistical Analysis

The data are expressed as the mean \pm standard deviation from three to four samples. Student's *t*-test was performed to assess statistically significant differences in the results of different experimental groups. Statistical analysis was carried out with the SPSS Statistics 18.0 statistical software package (SPSS Inc., Chicago, IL, USA), and $P<0.05$ was considered to be statistically significant.

Results

Characterization

The random nanofibrous PCL membrane was fabricated by electrospinning technology, followed by coating of the nanofibers with the CS/HA multilayer complex using LbL self-assembly. To determine the effect of the coated CS/HA multilayers on the nanofiber structure, the microscopic morphology of all samples was observed by SEM and TEM. As Figure 3A shows, as the CS/HA were assembled

on the nanofibers, all samples maintained a 3D nanofibrous structure. The morphology of the nanofibers in the B@P and S+B@P groups was similar to that of the PCL group, but there seemed to be a coating on the surface of the fibers in the B@P and S+B@P groups. According to the distribution of fiber diameter, the diameter of nanofibers in the B@P and S+B@P groups increased significantly (from 476.5 ± 174.1 to $571.3 \pm 139.6/539.6 \pm 209.7$ nm), and there was no significant difference between the two groups. The reason for the increase in the fiber diameter of the B@P and S+B@P groups is that the CS/HA coating was assembled on the surface of the nanofibers, which is confirmed by the TEM images (Figure 3B). Obviously, a core-shell structure was fabricated in the B@P and S+B@P groups due to the CS/HA complex deposition.

Through the electrostatic interaction between the amine groups (CS) and the carboxyl group (HA), a CS/HA polyelectrolyte layer was formed. We recorded the changes in the composition of the CS/HA multilayer coating-modified PCL scaffold by ATR-FTIR and UV-vis spectroscopy. As shown in Figure 3C, the ATR-FTIR spectrum of the B@P group demonstrates a distinct absorption at 1605 cm^{-1} , which belongs to the antisymmetric stretching vibration in the carbonyl group of HA. Because CS in the CS/HA multilayers contains an amide II group, this spectrum also shows an absorption at 1556 cm^{-1} , similar to the results of a previous CS/HA complex study.²⁴ As shown in the UV-vis spectroscopy data (Figure 3D), due to the -COOH group of HA in the CS/HA multilayers, a distinct absorption peak appeared at 210 nm after CS/HA was coated on PCL. In addition, the ATR-FTIR and UV spectra of S+B@P are almost the same as those of B@P. These data illustrated that the “shell” coated on the surface of PCL nanofibers was formed by the deposition of CS and HA, which confirmed that we successfully established the CS/HA multilayers on PCL nanofibers.

The hydrophobicity and hydrophilicity of a scaffold can be detected by a WCA test. The moment at which the water droplets contacted the surface of the scaffold was set to 0 s, and the time from 0 s to when the droplets were completely absorbed by the scaffold (the WCA was reduced to 0) was recorded. As shown in Figure 3E and F, at 0 s, the WCA of the B@P group was 41.7° , and that of the S+B@P group was 48.7° . The water droplets of both groups were completely absorbed within 1 min, while that of the PCL group was maintained at 111° for a long time. This result indicates that the hydrophilicity of the PCL scaffold was significantly

improved after being coated with CS/HA, which means that the high hydrophilicity of B@P and S+B@P may be beneficial for cell attachment and growth. The reason for the improvement in hydrophilicity is due to the presence of hydrophilic groups (amine, carboxyl and hydroxyl groups) of the CS/HA multilayer coating. The improvement of hydrophilicity is due to the hydrophilic groups (amine, carboxyl and hydroxyl groups) of the CS/HA multilayer coating. In addition, B@P and S+B@P show similar characteristics, which means that changing the loaded growth factor seems to have little effect on the properties of the scaffolds.

The release profiles of SDF-1 α and BMP-2 from the scaffolds were investigated using ELISA kits. As presented in Figure 3H, in the B@P group, there was an initial burst release (48.3%) in the first three days. On day 10, 79.5% of BMP-2 was released from the scaffold, and a subsequent stable release of BMP-2 up to 30 days was detected, indicating that the B@P scaffold is capable of maintaining a long-term release of BMP-2. In the S+B@P group (Figure 3G), SDF-1 α and BMP-2 exhibited nearly the same release behavior with initial bursts of 47.3% and 54.6%, respectively. After 10 days, 81.7% of total SDF-1 α and 79.4% of total BMP-2 were released from the scaffold. Therefore, these data demonstrated that the long-term release of single/dual growth factors can be achieved by adding the growth factor into the components via LbL assembly.

Morphology, Osteogenic Differentiation and Migration of BMSCs

Cell viability and proliferation were evaluated using the CCK-8 kit. As shown in Figure 4D, after the BMSCs were cultured for 7 days on the scaffolds, there was no significant difference in cell viability between the B@P and S+B@P groups, while the viability of the PCL groups was significantly lower than that of the other groups. After 9 days, the cell viability of the S+B@P group was significantly higher than that of the B@P group. SEM was utilized to observe the morphology of the BMSCs cultured in the scaffold. In Figure 4A, the pseudopods of BMSCs fused with the nanofibers of each group, and these cells showed an extended morphology, while no collapsed morphology or dead cells were observed. As demonstrated in Figure 4E, quantitative analysis of the migrated cells based on Transwell indicated that the levels of cell migration were significantly higher for the S+B@P group than for the B@P and PCL groups. Subsequently, we evaluated the potential of each group to

induce the osteogenic differentiation of BMSCs *in vitro*. ALP is considered an important marker of osteogenesis, and a higher ALP secretion indicates a higher mineralization level of BMSCs. The results of ALP staining showed that extensive blue-violet deposition appeared in the B@P and S+B@P groups (Figure 4B), while the results of the

quantitative detection of ALP demonstrated that the content of ALP in the S+B@P group was significantly higher than that in the PCL group (Figure 4F). Furthermore, the results of ARS indicated that after 30 days of osteogenesis induction *in vitro*, a high level of calcium deposition (red deposition) was found in the B@P and S+B@P groups

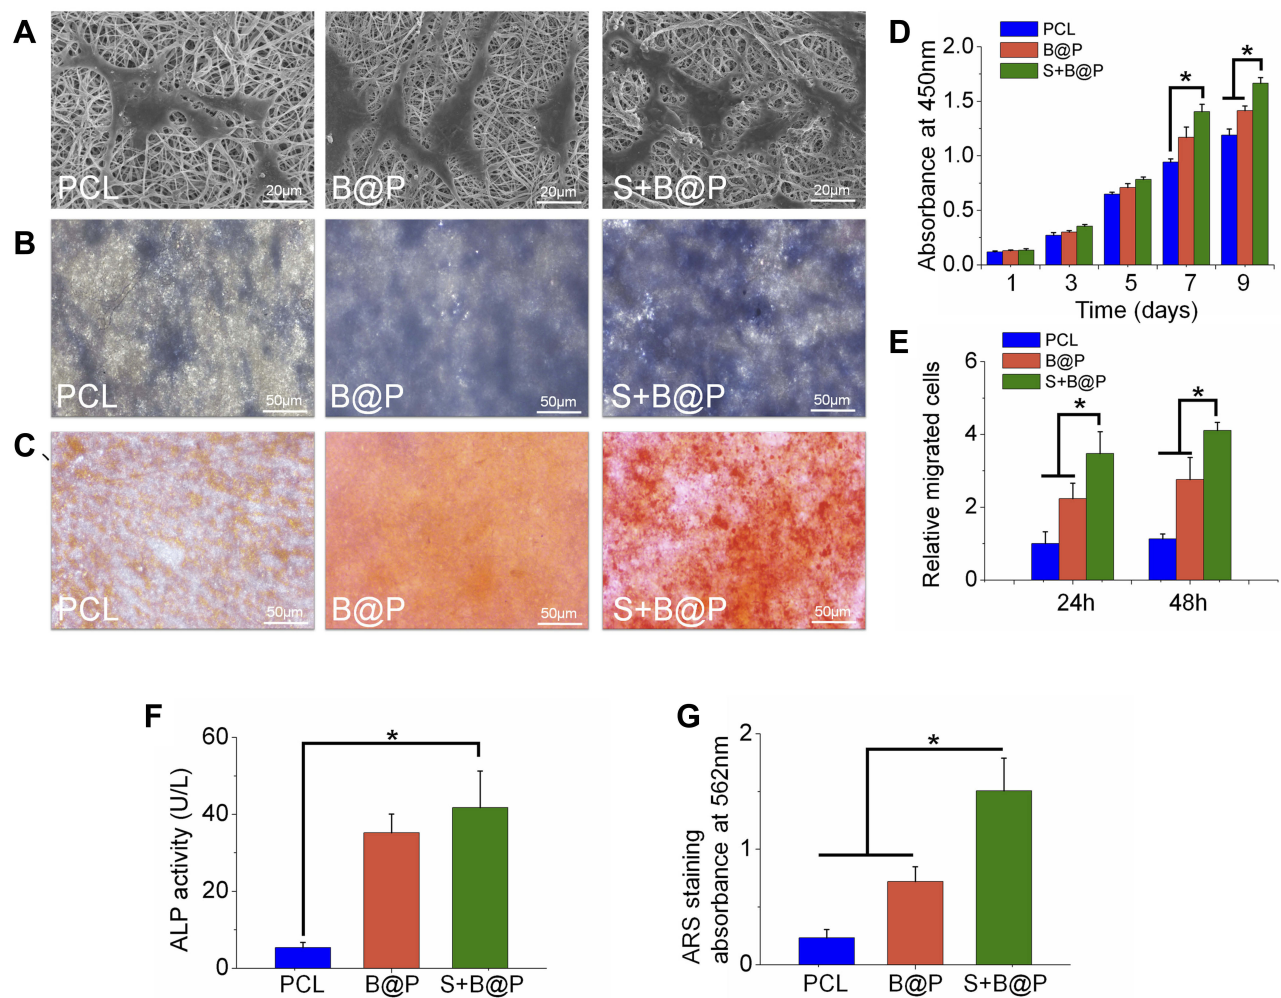

Figure 4 In vitro testing of BMSCs after cultured on each membrane (PCL, B@P and S+B@P).

(Figure 4C). However, whereas many mineralized nodules were observed in the S+B@P group, few mineralized nodules were found in the B@P group. Quantitative analysis of ARS confirmed that there were more mineralized deposits in the S+B@P group (Figure 4G). In addition, the local delivery of SDF-1 α and BMP-2 in S+B@P could regulate key genes of osteogenic differentiation in BMSCs in vitro (Figure 5). According to the results, the expression level of the Runx2 gene was significantly higher in the S+B@P group than in the other groups after the BMSCs were seeded on the scaffold for 7 days (Figure 5A). Additionally, after 14 days of culture, the gene expression levels of OCN, OPN, and COL I were higher in the S+B@P group than in the other groups (Figure 5B–D). In general, the S+B@P group

is clearly the most capable of promoting the osteogenic differentiation of BMSCs.

Histological Analysis

To confirm the feasibility of the S+B@P scaffold for promoting the healing of autologous grafts and bone, both ends of an autologous Achilles tendon were wrapped with the S+B@P membrane and then implanted into the bone tunnel of a femur and tibia by ACL reconstruction surgery in a rabbit model. At 4 and 8 weeks after surgery, the interface between the autograft and the host bone tunnel was observed by H&E staining as well as Masson's staining (Figure 6A and B). Obviously, some inflammatory cells infiltrated into the interface 4 weeks

after the ACL reconstruction surgery, which was a normal healing phenomenon, and these cells almost disappeared after 8 weeks. Additionally, thin fibrous scar tissue was formed in the tendon-bone interface in the S+B@P group. Notably, at 8 weeks after surgery, in the S+B@P group, a large amount of new bone formed inside the autograft, which demonstrated that the bone tunnel was healing and the tendon-bone integration was good. In the B@P group, although the fibrous scar tissue was thin, the autograft attached to the bone tightly, and there was less new bone formation at the interface, which indicates poor tendon-bone integration. However, in the PCL group, there was still more fibrous scar tissue at the interface, no significant mineralization was observed, and many membranes remained. In addition, immunohistochemical staining was utilized in this work for labelling

osteogenic markers (including OCN and OPN) in the tissue samples, and the results are shown in Figure 6C and D. More brown precipitates indicated that more markers were stained. In the S+B@P group, at 4 and 8 weeks, the secretion of OCN and OPN in the bone tunnel always remained at a high level. The secretion of OPN in the B@P group was high at 4 weeks but dropped significantly at 8 weeks, which means that the level of new bone formation was relatively higher in the S+B@P group. In general, these results of the histological experiments demonstrated that the local delivery of SDF-1 α and BMP-2 from the membrane was capable of promoting bone tunnel healing and tendon-bone interface integration. More importantly, the membrane modified by the growth-factor-loaded coating can accelerate the fusion of the membrane to the autologous tendon as well as the

degradation of the membrane, while the unmodified PCL membrane was not completely degraded after 8 weeks in vivo.

Biomechanical Testing

The biomechanical properties of the regenerative autograft-bone interface in each group were evaluated using an Instron tension/compression system. Based on this system, the maximum failure force and stiffness of the graft can be detected, and the degree of interface integration between the autograft and bone can be inferred. At 8 weeks after surgery, the S+B@P group exhibited superior mechanical properties compared to those the B@P and PCL groups and had a failure force that was 25.8% higher than that of the B@P group and 87.1% of that of the PCL group (S+B@P vs B@P vs PCL: 79.9 vs vs 63.5 N,

$p < 0.05$) (Figure 6E). Additionally, the stiffness of the S+B@P group was 80.5% higher than that of the PCL group, and 40.3% higher than that of the B@P group (S+B@P vs B@P vs PCL: 19.5 vs 13.9 vs 10.8 N/mm, $p < 0.05$) (Figure 6F). These results confirmed that the local delivery of SDF-1 α and BMP-2 effectively improved the biomechanical properties of the interface.

Discussion

Histologically, “enthesis” refers to a special transitional series of tissues in the ligament-to-bone interface, which is characterised by a structure consisting of three regions, including the ligament/tendon, fibrocartilage/calcified fibrocartilage, and bone.²⁵ This distinct structure is critical for stress transfer between connective tissue and bone tissue.²⁶ However, regenerating the native enthesis between the allograft and host bone

tunnel after ACL reconstruction is difficult. Several studies have unveiled that the allograft and bone tunnel possess poor spontaneous healing ability and that the regenerative tissue in the tendon-bone interface mostly consists of poorly organized Sharpey-like fibers.²⁷ Unfortunately, this regenerative tissue has inferior biochemical properties and is inefficient for maintaining the stability of the autograft in bone tunnels. Eventually, poor tendon-to-bone healing could increase the risk of graft slippage and reinjury.²⁸ Another reason for hampered tendon-to-bone healing is peri-tunnel bone loss, which may result in bone tunnel widening, graft laxity, and infiltration of the joint fluid into the bone tunnel and even osteoarthritis.^{7,8,29} Therefore, a successful graft-bone healing process requires timely tendon-bone interface integration to reduce the risk of surgical failure and enable the patients to quickly resume physical activity.

SDF-1 α , which belongs to the chemokine CXC family, is a functional homeostatic chemokine that is secreted by immune cells in the early stage of the bone regeneration process and promotes the migration of circulating stem cells, such as BMSCs, to injured sites.^{30,31} In addition, due to its excellent capability of promoting the osteogenic differentiation of stem cells, BMP-2 has been widely applied for promoting bone defect healing and regeneration. Although the results of some studies show that BMP-2-loaded scaffolds for bone regeneration are satisfactory, BMP-2 acts primarily in the late stage of the bone regeneration process. Until recent years, researchers have focused on the initial steps of bone regeneration and homeostatic chemokine-induced BMSC recruitment in injured sites.^{31,32} Studies have demonstrated that scaffolds loaded with dual growth factors (SDF-1 α and BMP-2) have excellent therapeutic effects on bone repair.^{20,33–35} In particular, although the release of SDF-1 α alone has a limited effect on promoting bone regeneration, the release of SDF-1 α and BMP-2 can synergistically promote the osteogenic differentiation and bone regeneration induced by BMP-2.²⁰ Therefore, the objective of this study is to design a flexible multilayered scaffold loaded with SDF-1 α /BMP-2 that is suitable for assisting allograft grafting into the bone tunnel. We hypothesized that this membrane can accommodate the narrow space of the tendon-bone interface and locally release SDF-1 α /BMP-2. Due to the synergism of the released dual growth factors, the membrane has the capability of enhancing robust tendon-bone healing and integration and inhibiting fibrous scar tissue growth at the interface.

Based on our previous studies,^{36,37} a nanofibrous PCL membrane loaded with SDF-1 α and BMP-2 was fabricated (S+B@P). By using LbL, the CS/HA multilayer coating was successfully established on the surface of the nanofiber, and the growth factor was tightly bound to the coating by electrostatic force. SEM was utilized to analyze the morphology of the nanofibers. After coating with CS/HA polyelectrolyte multilayers, the diameter of the nanofibers increased, forming a core-shell structure. In addition, the WCA data show that the hydrophilicity of the membrane was improved. This improvement occurred because with the progress of LbL self-assembly, a large amount of CS and HA with hydrophilic groups (amine, carboxyl and hydroxyl groups) adsorbed on the fiber, enhancing the hydrophilicity of the membrane. Our study investigated the effect of the local delivery of SDF-1 α and BMP-2 from the S+B@P scaffold on the migration and osteogenic differentiation of BMSCs, as well as on allograft-bone tunnel healing in vivo. Compared with the B@P group with only BMP-2 loaded into the scaffold, the S+B@P group showed good BMSC migration efficiency and activity in vitro. According to the results of ALP & ARS analysis, we surprisingly discovered that the S+B@P scaffold could enhance the osteogenic differentiation of BMSCs via the synergism of SDF-1 α and BMP-2. Additionally, as the real-time PCR results showed, the expression of the transcription factor Runx2 was enhanced and prolonged in the S+B@P group, leading to the enhanced expression of Col I, which marks osteogenesis-related extracellular matrix (ECM) maturation; eventually, the expression of the bone mineralization marker OCN was dramatically enhanced. These results demonstrated that S+B@P can promote the migration of circulating BMSCs to the tendon-bone interface via the release of SDF-1 α . Subsequently, the recruited BMSCs were exposed to BMP-2 released by S+B@P and efficiently initiated BMP signaling and transduction in downstream pathways.

To test the capability of this membrane for promoting tendon-bone healing in vivo, we established a rabbit ACL injury model and wrapped both ends of an autogenous tendon graft using the membrane for ACL reconstruction. According to the results of the histological experiments, at 4 weeks after surgery, the S+B@P group showed little fibrous tissue formation, and the autograft attached to the bone tunnel tightly; however, the boundary line between the allograft and bone was very obvious, which means that the tendon-bone interface was not integrated. In the PCL

and B@P groups, more fibrous scar tissue formation and remaining scaffolds were observed at the interface. At 8 weeks postoperatively, in the S+B@P group, there was a large amount of new bone formation in the interface and in the autograft, which means that the interface had begun to be integrated. This finding means that bone tissue, rather than fibrous scar tissue, grows extensively in the interface and into the autologous tendon, firmly “holding” the tendon and improving the biomechanical properties of the interface, as evidenced by the results of biomechanical testing. These data are of clinical significance for the treatment of ACL injury.

Conclusion

Generally, these data are of clinical significance for the treatment of ACL injury. Due to the synergism of the released dual growth factors, the membrane has the capability of enhancing robust tendon-bone healing and integration and inhibiting fibrous scar tissue growth at the interface. Furthermore, the biomechanics of the reconstructed ACL were improved. Therefore, this biomimetic nanofibrous membrane is applicable in clinical practice. Some researchers believe that the spatiotemporal release of SDF-1 α and BMP-2 can achieve better results than a mixed release. Therefore, in our future research, we will develop a biomimetic membrane based on S+B@P that can spatiotemporally release dual growth factors for ACL reconstruction.

International Journal of Nanomedicine

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
