

# Antidiabetic Drugs and Statins in Nonalcoholic Fatty Liver Disease

Sneha Kothari \*, Hiteshi Dhama-Shah †, Samir R. Shah †

\*Global Hospitals Mumbai, India and †Department of Hepatology, Global Hospitals, Mumbai, India

**Nonalcoholic fatty liver disease (NAFLD) has become the most prevalent liver disease worldwide. Despite its high prevalence and rising incidence, there are currently no specific targeted pharmacotherapies approved by the Food and Drug Administration (FDA) for nonalcoholic steatohepatitis (NASH). Current therapies for patients with NAFLD include lifestyle modification. Vitamin E and pioglitazone are recommended for those confirmed to have NASH. However, there are concerns about the long-term safety of both pioglitazone and vitamin E in higher doses. Metformin is essential for managing the abnormal metabolic parameters in patients with NAFLD. Glucagon-like peptide-1 analogue, sodium-dependent glucose cotransporter inhibitors, and peroxisome proliferator-activated receptor agonists have shown benefits in improving metabolic parameters and reducing hepatic lipid accumulation and inflammation. However, the role of these antidiabetic agents in specifically reversing NASH needs to be established. Indeed, statins have been underprescribed in patients with NASH owing to fear of hepatotoxicity despite coronary artery disease being a common cause of death in patients with NAFLD. Statins reduce the risk of cardiovascular morbidity and mortality in patients with NASH and dyslipidemia. However, their use specifically for treatment of NASH needs further evaluation. Optimizing the control of risk factors remains the main strategy for treatment until targeted pharmacotherapies for NASH are available. (J CLIN EXP HEPATOL 2019;9:723–730)**

Over the years, a strong correlation has been established between metabolic syndrome (MetS) and nonalcoholic fatty liver disease (NAFLD), identifying NAFLD as a hepatic manifestation of MetS.<sup>1,2</sup> The prevalence of NAFLD is found to be two and a half times more in patients with MetS (27%) than without MetS (11%).<sup>3</sup> Studies have also reported an increased risk of type 2 diabetes (T2D) and cardiovascular disease (CVD) in patients with NAFLD.<sup>4</sup> In patients with T2D and CVD, the prevalence of NAFLD is 75% and 28%, respectively.<sup>5,6</sup> Besides, 28% of patients with NAFLD have hyperlipidemia.<sup>7</sup> The pathogenesis of NAFLD is a result

of a series of liver insults, known as the ‘multiple-hit’ hypothesis. These include insulin resistance, dietary substrates (carbohydrates and fats), endocrine hormones, gut microflora, and genetic factors.<sup>8</sup> In view of the multiple hits responsible for progression of NAFLD to nonalcoholic steatohepatitis (NASH) and NASH-related fibrosis, prevention and management pose a challenge to drug discovery and development. One of the initial measures, which helps modulate the metabolic parameters in NAFLD, is lifestyle modification with diet and exercise.<sup>9</sup> A weight reduction of 7–9% has shown to reduce inflammation, and a 10% weight reduction has shown to reduce fibrosis in patients with NASH. However, the lack of success in its implementation and challenge with sustaining weight loss has led to the need for effective pharmacological agents. In the present review, we have discussed the role of antidiabetic agents and statins in the management of NASH.

## METFORMIN

Originally derived from *Galega officinalis*, metformin has been the first choice of treatment in patients with T2D.<sup>10</sup> As an insulin sensitizer, metformin lowers blood glucose levels by inhibiting hepatic gluconeogenesis, stimulating muscle glucose uptake and decreasing intestinal glucose absorption.<sup>11</sup> Metformin induced AMPK (5' adenosine monophosphate activated protein kinase), activation decreases fatty acid synthesis and increases fatty acid oxidation. This contributes to reduction in hepatic fat and improved insulin sensitivity in patients with NAFLD.<sup>12</sup>

**Figure 1** Direct and Indirect effects of GLP-1RA/DPP-4i on NAFLD (Adapted and modified from Dhir *et al.*, 2018<sup>23</sup>). GLP-1, glucagon-like peptide-1; DPP-4, dipeptidyl peptidase-4; NAFLD, nonalcoholic fatty liver disease.

In addition, metformin supplementation has shown to reduce hypertension and hyperlipidemia in patients with NAFLD, thereby reducing cardiovascular morbidity.<sup>13</sup>

Along with regulation of impaired fasting glucose, hypertension, and dyslipidemia, patients with NAFLD need weight management. Metformin aids in weight loss by decreasing the appetite and sensitizing insulin. A study on the *ob/ob* mice model of hepatic steatosis showed the role of metformin in normalizing alanine aminotransferase (ALT) levels by decreasing the expression of tumor necrosis factor  $\alpha$ .<sup>14</sup> In nondiabetic patients with NASH, metformin supplementation significantly improved the body mass index (BMI), insulin sensitivity, ALT levels, and liver volume determined with ultrasonography. However, metformin plus lifestyle intervention did not improve liver histology or aminotransferases, compared with lifestyle intervention alone, independent of dose, treatment duration, or diabetic state.<sup>15,16</sup> Furthermore, in the TONIC trial, involving 173 nondiabetic patients with NASH diagnosed by liver biopsy, metformin supplementation failed to reduce ALT levels and improve liver histology compared with placebo.<sup>17</sup> Some studies have also demonstrated that long-term supplementation of metformin may reduce the risk of liver cancer by 62% in patients with T2D.<sup>18,19</sup>

Despite improvement in the metabolic parameters, namely, insulin resistance, hypertension, dyslipidemia, and BMI, European Association for the Study of the Liver (EASL) guidelines do not recommend metformin for treatment of NASH in view of lack of histological benefit.<sup>20</sup>

### INCRETIN-BASED THERAPIES: GLUCAGON-LIKE PEPTIDE-1 RECEPTOR AGONISTS AND DIPEPTIDYL PEPTIDASE-4 INHIBITORS

Incretins account for up to 70% of insulin response after oral intake of glucose. It is mediated by glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) released from enteroendocrine cells in the gastrointestinal tract after food ingestion. They have a very short half-life as they are degraded by dipeptidyl peptidase-4 (DPP-4). The half-life is prolonged using the DPP-4 inhibitor (DPP-4i), or the levels are increased by using GLP-1 receptor agonists (GLP-1RAs).<sup>21</sup>

Evidence from studies in mice suggests the presence of hepatic GLP-1 resistance at the GLP-1 receptor level or downstream. Reduced GLP-1R expression and DPP-4 up-regulation have been reported in liver tissue of patients with NAFLD. Bernsmeier *et al*<sup>22</sup> showed that GLP-1 secretion is deficient in patients with NAFLD and NASH. GIP secretion is contrarily preserved. Insulin resistance accompanied by hyperglucagonemia is found to be more severe in patients with NASH. It therefore remains unclear whether deficiency in GLP-1 secretion, hepatic GLP-1 resistance, or both the components is involved. These pathophysiologic findings provide evidence for the use of the GLP-1R agonist for the treatment of NAFLD. Incretins have shown to have beneficial effect indirectly by improvement in glycemic control and by inducing weight loss. In addition, they bind to the GLP-1R on hepatocytes to reduce insulin

resistance, lipotoxicity, and oxidative stress, as summarized in Figure 1.<sup>23</sup>

## GLUCAGON-LIKE PEPTIDE-1 RECEPTOR AGONIST

Several studies have hinted at a potential benefit of GLP-1RA in NAFLD, but until recently evidence is inconclusive. A meta-analysis of six, phase III, randomized controlled trials encompassing the LEAD program was performed by Armstrong *et al*<sup>24</sup> to evaluate the effect of liraglutide on liver parameters compared with active placebo in patients with T2D. Of the 4442 patients analyzed, 50.8% had baseline ALT abnormality. Liraglutide 1.8 mg/day led to significant reductions in ALT ( $p = 0.003$ ) and hepatic steatosis on CT imaging compared with placebo. However, both effects were lost after adjusting for weight reduction and glycosylated hemoglobin (HbA1c); thus, effects were attributable to changes in weight and glycemic control. In the LEAN study, overweight patients with NASH and diabetes and those with NASH and without diabetes were treated with liraglutide 1.8 mg/day for 48 weeks or placebo. A total of 39% patients in the liraglutide group achieved resolution of steatohepatitis without worsening of fibrosis as against 9% in the placebo group ( $p = 0.019$ ). In addition, fibrosis progressed in only 9% of patients in the liraglutide group as compared with 36% of patients in the placebo group ( $p = 0.04$ ).<sup>25</sup> In a prospective, single-center study (LIRA-NAFLD), patients with uncontrolled T2D (HbA1C > 7%) were treated with subcutaneous liraglutide 1.2 mg daily on background oral antidiabetic drugs/insulin for 6 months. There was significant reduction in liver fat content in patients treated with liraglutide, and the effect was mainly driven by body weight reduction.<sup>26</sup> Eguchi *et al* reported a reduction in the BMI, visceral fat accumulation, aminotransferases, and hyperglycemia in 19 patients with biopsy-proven NASH treated with liraglutide for 24 weeks. There was also improvement in liver histology in 6 of 10 patients who repeated liver biopsy after 96 weeks of liraglutide treatment.<sup>27</sup>

In a randomized trial, 30 obese adults with NAFLD were randomized to a supervised program of energy restriction plus moderate-intensity exercise to induce  $\geq 5\%$  weight loss or liraglutide 3 mg daily for 26 weeks, followed by 26 weeks with only advice to prevent weight regain. In the liraglutide group, the participants were only advised to stop eating if they developed satiety, but no specific dietary advice was given. The participants in both groups had significant ( $p < 0.01$ ) and similar reductions in weight, liver fat fraction, serum ALT, and caspase-cleaved cytokeratin 18 at 26 weeks. Six months after stopping both interventions, these benefits were not sustained in the liraglutide group despite advice on weight maintenance in contrast with the preserved benefits of supervised lifestyle modification.

The use of liraglutide for the treatment of NAFLD in overweight and obese adults should be combined with diet and exercise, underscoring the importance of lifestyle modification for the management of NAFLD.<sup>28</sup>

GLP-1RAs are usually well tolerated, except for a modest increase in gastrointestinal symptoms of nausea and diarrhea. Current evidence does not support the concern of an increased risk of pancreatitis. A meta-analysis showed that the prevalence of pancreatitis and pancreatic cancer in patients on GLP-1RA was not significantly different from that observed in comparator arms.<sup>29,30</sup> The GLP-1RA has been studied in patients with NASH who are obese with/without T2D. Benefits of GLP-1RAs outweigh the risks in patients with NAFLD/NASH and diabetes or those with NAFLD/NASH and without diabetes. Whether the beneficial effects are just related to weight loss or they have direct effects needs further elucidation.<sup>31</sup> Although liraglutide has not been further evaluated in phase 3 development, semaglutide, another GLP-1 analogue is under phase 2B trial evaluating its efficacy versus placebo in 372 participants with stage F2–F3 fibrosis and NAFLD activity score (NAS)  $\geq 4$  with a score of at least 1 for each of the components (steatosis, ballooning, and lobular inflammation).<sup>32</sup>

## DIPEPTIDYL PEPTIDASE-4 INHIBITOR

The DPP-4i increases incretin effect by delaying quick inactivation of GLP-1 in plasma. The hepatic expression of DPP-4 is increased significantly in patients with NAFLD. Most of the studies evaluating the DPP-4i in NAFLD have used sitagliptin as it was the earliest molecule widely used in the group. Iwasaki *et al*<sup>33</sup> found that 4 months of treatment with sitagliptin 50 mg/day in 30 patients with NAFLD was associated with significant decrease in aspartate transaminase (AST), ALT, and  $\gamma$ -gamma glutamyl transferase (GGT) levels, in addition to improvement in the glycemic parameters. A study by Yilmaz *et al*<sup>34</sup> showed that treatment with sitagliptin for 1 year was associated with significant reduction in NASH scores and a trend towards improved hepatic steatosis. In contrast, in a study conducted by Fukuhara *et al*<sup>35</sup> in 44 patients with biopsy-proven NAFLD, sitagliptin treatment showed no significant change in liver transaminases despite a reduction in HbA1C levels.

In a study by Cui *et al*, 50 patients with NAFLD and prediabetes or early stages of diabetes were randomized to sitagliptin 100 mg/day versus placebo and followed up for 24 weeks. Liver fat reduction was not statistically significant as measured by the magnetic resonance imaging (MRI)-based biomarker of proton density fat fraction (PDFF) in several liver segments ( $p = 0.4$ ).<sup>36</sup>

The DPP-4i is well tolerated and improves glycemic control; however, current evidence does not support its use in NASH.

### SODIUM-DEPENDENT GLUCOSE COTRANSPORTER INHIBITORS

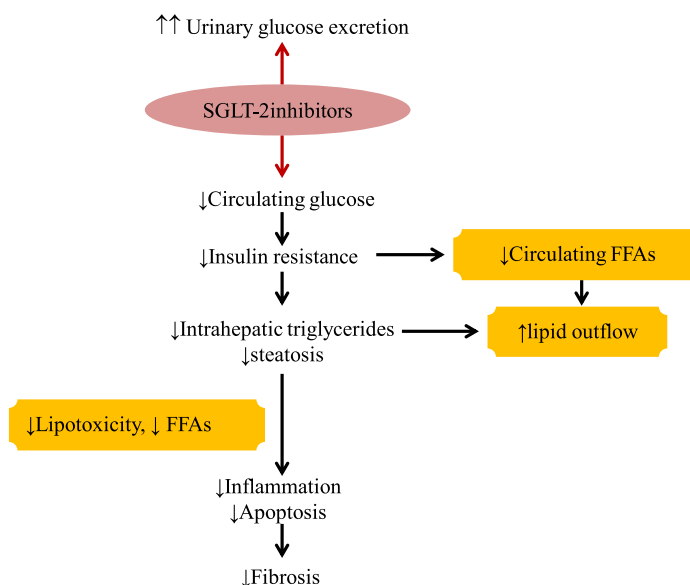

Sodium-dependent glucose cotransporter-2 (SGLT2) is expressed in proximal renal tubules. They are responsible for a majority of glucose reabsorption from the tubular lumen. The sodium-dependent glucose cotransporter-2 inhibitor (SGLT-2i) (gliflozins) inhibits SGLT2 and improves glycaemic control by promoting urinary glucose excretion. In addition, it leads to weight loss and blood pressure reduction with a minimal risk of hypoglycemia.<sup>37</sup>

The adipose tissue serves as energy storage reservoirs against calorie overload. Beyond its capacity, the excess calorie accumulates in ectopic nonadipose tissues, such as the liver, skeletal muscle, and pancreas. In these organs, lipotoxicity leads to their metabolic dysfunctions and histopathologic changes. The SGLT-2i reduces *de novo* lipogenesis by attenuating hyperglycemia and hyperinsulinemia. It promotes fat accumulation in epididymal fat and prevents ectopic fat accumulation in the liver by improving insulin sensitivity in adipose tissue. The fibrosis of white adipose tissue limits its lipid storage capacity via inhibiting adipocyte hypertrophy, which leads to ectopic lipid accumulation in the liver. SGLT-2i lead to the adipose expansion without an increase in inflammation or fibrosis referred to as “healthy adipose expansion.” In mice models of fatty liver, canagliflozin has shown to alter glutathione metabolism favorably to reduce oxidative stress in adipose tissue. The postulated mechanism of action of the SGLT-2i in NAFLD is summarized in Figure 2.<sup>38,39</sup>

The benefits of the SGLT-2i in the prevention of NAFLD have been demonstrated in animals.<sup>38</sup> Seko *et al* conducted a retrospective study comparing 24 weeks of treatment with ipragliflozin 50 mg or canagliflozin 300 mg with sitagliptin in patients with T2D and biopsy-proven NAFLD. Both groups had significant improvements in serum AST and ALT levels from baseline; however, weight loss was significant in the SGLT-2i group.<sup>39</sup> A retrospective review was conducted by Ohki *et al* in Japanese patients with NAFLD and T2D who had abnormal ALT levels despite treatment with the GLP-1RA or DPP-4i. Addition of the SGLT-2i as a second-line treatment resulted in significant decrease in ALT (62–38 IU/L;  $p < 0.01$ ), with 58.3% of patients achieving normalization of ALT levels. It also improved the fibrosis-4 index, from 1.75 to 1.39 ( $p = 0.04$ ).<sup>40</sup>

The E-LIFT trial with empagliflozin, a study from India, enrolled 50 patients with T2D and NAFLD who were randomly assigned into two groups for 20 weeks, the empagliflozin group (standard treatment for T2D plus empagliflozin 10 mg daily) and control group (standard treatment without empagliflozin). Change in liver fat was measured by MRI-PDFF. Patients on empagliflozin had significant reduction in liver fat (mean MRI-PDFF difference, 4.0%;  $p < 0.0001$ ) compared with the control group.<sup>41</sup>

Two investigator-initiated single-arm open-label studies have used paired liver biopsies to evaluate the effect of the SGLT-2i for the treatment of NASH in patients with T2D. These pilot studies have shown improvement in scores of steatosis, lobular inflammation, ballooning, and fibrosis

Note: FFAs, free fatty acids

**Figure 2** Adapted and modified. Mechanism of action of SGLT-2 inhibitors in NAFLD. SGLT2, sodium-dependent glucose cotransporter-2; NAFLD, nonalcoholic fatty liver disease; FFA, free fatty acids.

stage, thus serving as the impetus for larger, randomized, double-blind, placebo-controlled studies on the SGLT-2i for the treatment of NASH.<sup>42,43</sup> In addition, the SGLT-2i improves cardiometabolic parameters such as systolic blood pressure, diastolic blood pressure, fasting blood glucose, and high density lipoprotein (HDL) cholesterol. Improvement in cardiac and renal outcomes is important because CVD is the leading cause of mortality in patients with NAFLD.<sup>44,45</sup> Data evaluating the long-term safety and tolerability of the SGLT-2i are lacking owing to their recent introduction on the market. In 2015, the FDA released warning cautioning prescribers to screen for urinary tract infections in patients on SGLT-2i. In addition, Fournier's gangrene (FG) is a newly identified safety concern in patients receiving SGLT-2i. FG is a newly identified safety concern in patients receiving SGLT-2i.<sup>46</sup>

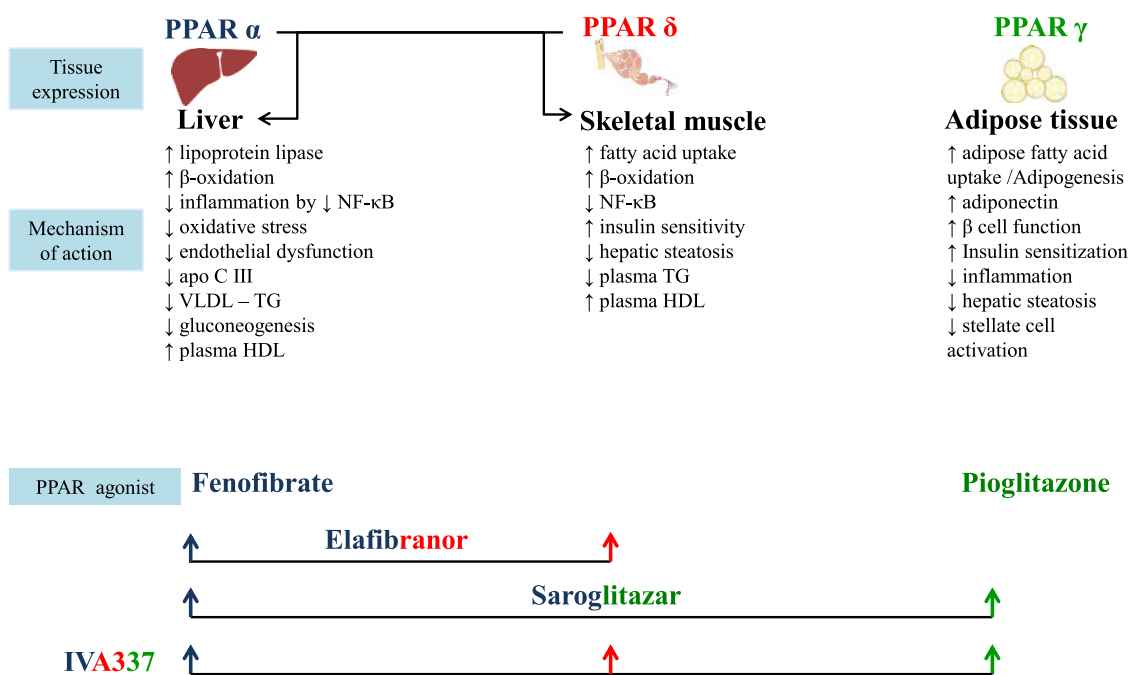

### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR AGONIST

Peroxisome proliferator-activated receptor (PPAR) agonists are ligand-activated nuclear receptors consisting of three isoforms: PPAR $\alpha$ , PPAR $\delta$ , and PPAR $\gamma$ . Each of these isoforms differs from each other with respect to their action (Figure 3). The PPAR $\alpha$  agonist fenofibrate has beneficial effects in reducing triglycerides and decreasing synthesis of apolipoproteins. In addition, its anti-inflammatory and antioxidant actions help reduce necroinflammation, apoptosis, and fibrosis. However, data regarding the effect of fenofibrate in NASH are inconclusive.<sup>47</sup>

Pioglitazone, a PPAR $\gamma$  agonist, is recommended for patients with T2D. Pioglitazone improves insulin and glucose parameters, increases lipid storage in subcutaneous adipose tissue, increases adiponectin, and reduces lipotoxicity in the liver.<sup>48</sup> In the PIVENS trial, nondiabetic patients with NASH were treated with 30 mg pioglitazone. Compared with placebo, pioglitazone reduced liver inflammation but not fibrosis.<sup>48</sup> Owing to probability of relapse of NASH after discontinuation, pioglitazone needs to be continued for a longer period. Treatment with pioglitazone for >24 months and at a cumulative dose of >28,000 mg (average daily dose of pioglitazone about 40 mg/day) has been linked to bladder cancer.<sup>49</sup> The efficacy of low-dose pioglitazone (7.5–15 mg) in NASH needs further elucidation. In addition to risk of malignancy, pioglitazone has side effects such as weight gain, bone loss, and peripheral edema.<sup>50</sup>

The coexistence of T2D and dyslipidemia has also led to the development of dual PPAR agonists. The PPAR $\alpha$ / $\gamma$  agonist, saroglitazar, has shown to improve liver histopathology and biochemistry in experimental NASH models.<sup>51</sup> Currently, phase 3 randomized controlled trial (RCT) is ongoing in India to assess the effect of saroglitazar versus placebo for 52 weeks in biopsy-proven noncirrhotic NASH. Saroglitazar, unlike pioglitazone, does not lead to weight gain and peripheral edema.<sup>52</sup>

PPAR $\delta$  decreases hepatic gluconeogenesis and fatty acid oxidation, improves insulin sensitivity, and inhibits activation of macrophages and Kupffer cells. The dual PPAR $\alpha$ / $\delta$  agonist, elafibranor, has been shown to improve liver,

**Figure 3** Mechanism of action of the PPAR agonist in NAFLD. **Table 1 Summary of recommendations for statin treatment in patients with NAFLD (Adapted and modified from Pastori et al., 2015<sup>56</sup>).**

Long-term statin treatment and liver toxicity
<ol style="list-style-type: none"> <li>As per the national lipid association (NLA), the risk for serious liver injury from statins is quite rare.</li> <li>LFT monitoring in asymptomatic individuals is not recommended.</li> </ol>
Statin for the treatment of dyslipidemia in patients with nonalcoholic fatty liver disease
<ol style="list-style-type: none"> <li>Patients with NAFLD are at high risk of cardiovascular morbidity and mortality.</li> <li>Treatment of dyslipidemia plays a critical role in the overall management of NAFLD.</li> <li>Patients with NAFLD and dyslipidemia are not at increased risk of statin hepatotoxicity.</li> <li>Statin reduce CVD morbidity and mortality in patients with NAFLD/NASH by two-third times as compared with untreated patients not on statins.</li> </ol>
Statin for the treatment of nonalcoholic fatty liver disease and nonalcoholic steatohepatitis
<ol style="list-style-type: none"> <li>Preliminary studies have shown that statins may possibly improve hepatic histology in patients with underlying NAFLD; however, no convincing histological data are available.</li> <li>At present, statins are not recommended for treatment of NASH.</li> </ol>

LFT, liver function test; NAFLD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis; CVD, cardiovascular disease.

adipose tissue, and peripheral tissue insulin sensitivity and reduce ALT levels in patients with MetS.<sup>53</sup> In a phase 2b randomized double-blind placebo-controlled trial in patients with biopsy-proven noncirrhotic NASH, 19% of study participants with NAS>4 on elafibranor 120 mg/day showed resolution of NASH as compared with 12%

on placebo ( $p = 0.045$ ). Currently, elafibranor 120 mg/day is being evaluated in a phase 3 randomized clinical trial for its effect on liver histology and mortality in patients with NAS >4. Recently, a new-generation pan-PPAR agonist, IVA 337, is found to activate all the three isoforms of PPAR $\alpha$ , PPAR $\delta$ , and PPAR $\gamma$ . In addition to encouraging results in preclinical and clinical studies, its safety profile makes it a promising drug for NASH.<sup>54</sup>

**STATINS**

Statins reduce cholesterol biosynthesis by inhibiting 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase. In addition, owing to their anti-inflammatory, antioxidant, and antifibrotic effects, they may be beneficial for the treatment of NASH.<sup>55</sup> The subclasses of statins function differently with respect to oral absorption, bioavailability, liver extraction, protein binding, and HMG-CoA reductase activity. Atorvastatin, lovastatin, simvastatin, and fluvastatin are lipophilic in nature and are metabolized by the cytochrome P450 system. On the other hand, pravastatin and pitavastatin are hydrophilic and thus are minimally metabolized in the liver, whereas rosuvastatin has an intermediate behavior. Studies have shown that the hydrophobic statins, lovastatin and simvastatin, reach a higher concentration in the liver compared with hydrophilic pravastatin. However, the exact clinical relevance of these differences is uncertain.<sup>56</sup>

Despite patients with T2D and NAFLD being at a higher risk of CVD compared with patients with diabetes alone, statins are underprescribed in NASH. This is mainly because of the concern regarding their safety in patients with deranged liver function tests (LFTs).<sup>56,57</sup> A

<sup>a</sup>Dual PPAR agonists are currently in phase 3 clinical trials.

<sup>b</sup>The pan-PPAR agonist is currently in phase 2b clinical trials.

comprehensive review of the safety and efficacy of statins in patients with chronic liver disease, including patients with NAFLD, concluded that statins were safe for the management of dyslipidemia in patients with NASH.<sup>58</sup>

Statins have shown considerable improvement in liver histology in *in vivo* NASH models. In 3 *post hoc* analyses of RCT (n = 1,600, n = 1,123, and n = 8864) the use of atorvastatin had beneficial effect in NAFLD/NASH, in terms of reduction in liver enzymes and normalization of liver echogenicity. In the study, the atorvastatin dose of up to 80 mg/day was deemed to be safe.<sup>56,57</sup> In a 1-year pilot study (n = 20), rosuvastatin monotherapy (10 mg/day) lead to complete NASH resolution in biopsy-proven NASH in patients with MetS. In addition, the LFT normalized, and ultrasonography showed absence of steatosis at the end of the study. The beneficial effect of rosuvastatin was attributed to the reduction in systemic inflammation.<sup>57,58</sup> In a multicenter, prospective study involving 107 European individuals, statins had a protective effect on NAS ( $p < 0.001$ ) and the fibrosis stage F2–F4 ( $p = 0.017$ ). The amelioration of NASH and histological lesions correlated strongly with the dose of statins.<sup>56,57</sup>

The recommendations for use of statins in patients with NAFLD are summarized in Table 1.<sup>56</sup> The EASL/European Association for the Study of Diabetes/European Association for the Study of Obesity guidelines do not suggest statin administration for the treatment of NAFLD/NASH; however, they suggest statins can be safely prescribed in NAFLD/NASH with dyslipidemia. Further statin therapy is contraindicated for patients with decompensated cirrhosis and acute liver failure.<sup>9,20</sup>

Apart from control of diabetes, antidiabetes drugs may have variable effects on the resolution of NASH (Table 2).<sup>59</sup> Optimal control of risk factors with lifestyle modification, antidiabetic drugs, and statins will form an integral part of the management of patients with NAFLD until specific targeted therapies are available to prevent progression of NASH and fibrosis.
