Background: Fragmented QRS reflects disturbances in the myocardium predisposing the heart to ventricular tachyarrhythmias. Recent studies suggest that fragmented QRS (fQRS) is associated with worse major arrhythmic events in hypertrophic cardiomyopathy (HCM). However, a systematic review and meta-analysis of the literature has not been done. We assessed the association between fQRS and major arrhythmic events in hypertrophic cardiomyopathy by a systematic review of the literature and a meta-analysis.

Methods: We comprehensively searched the databases of MEDLINE and EMBASE from inception to May 2017. Included studies were published prospective or retrospective cohort studies that compared major arrhythmic events (sustained ventricular tachycardia, sudden cardiac arrest, or sudden cardiac death) in HCM with fQRS versus non-fQRS. Data from each study were combined using the random-effects, generic inverse variance method of DerSimonian and Laird to calculate risk ratios and 95% confidence intervals.

Results: Five studies from January 2013 to May 2017 were included in this meta-analysis involving 673 subjects with HCM (205 fQRS and 468 non-fQRS). Fragmented QRS was associated with major arrhythmic events (pooled risk ratio = 7.29, 95% confidence interval: 4.00–13.29, $p < .01$, $I^2 = 0\%$).

Conclusion: Baseline fQRS increased major arrhythmic events up to sevenfold. Our study suggests that fQRS could be an important tool for risk assessment in patients with HCM.

KEYWORDS

fragmented QRS, hypertrophic cardiomyopathy, major arrhythmic events

1 | INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a common inherited disease of the heart muscle. The prevalence of the disease in the general

population is approximately 1 in 500 (Maron et al., 2014). Some patients may remain asymptomatic throughout life but others may experience heart failure symptoms or sudden cardiac arrest. Symptomatic HCM is a now much more manageable condition with improved options for SCA prevention (e.g., subcutaneous implantable defibrillator) and invasive treatments of outflow tract obstruction (Maron et al.,

Data from this paper will be presented at the 2017 American Heart Association Scientific Sessions.

2014). Nonetheless, identification of patients at high risk of SCA or sudden cardiac death remains challenging.

The twelve-lead ECG is one of the most common, useful and cost-effective investigations performed in clinical settings. Fragmented QRS (fQRS) is a marker of myocardial scar and identifies high-risk patients in various cardiac conditions, including acute coronary syndrome, cardiac sarcoidosis, Brugada syndrome, acquired long QT syndrome, or idiopathic dilated cardiomyopathy (Das, Khan, Jacob, Kumar, & Mahenthiran, 2006; Sha et al., 2011; Take & Morita, 2012). Recent studies suggest that fQRS is associated with increased major arrhythmic events in patients with HCM (Debonnaire et al., 2015; Femenia et al., 2013; Kang et al., 2014; Nomura et al., 2015; Ozyilmaz et al., 2017). However, no systematic review or meta-analysis of literature has been done to address the association in this group of patients. Therefore, we performed a systematic meta-analysis to establish the association between fQRS and major arrhythmic events in HCM.

2 | METHOD

2.1 | Search strategy

Two investigators (CK and PC) independently searched for published studies indexed in MEDLINE and EMBASE databases from inception to January 2017 using a search strategy that included the terms “fragmented QRS”, “QRS fragmentation” and “hypertrophic cardiomyopathy” (described in Data S1). Only English language publications were included. A manual search for additional pertinent studies and review articles using references from retrieved articles was also completed.

2.2 | Inclusion criteria

The eligibility criteria included the following:

1. Cohort studies (prospective or retrospective) reporting incidence of major arrhythmic events (MAE) including sustained ventricular tachycardia, sudden cardiac arrest, or sudden cardiac death) in HCM patients with and without fQRS.
2. Relative risk, hazard ratio, odds ratio, incidence ratio, or standardized incidence ratio with 95% confidence intervals or sufficient raw data for these calculations had to be provided.
3. HCM participants without fQRS were used as controls.

Study eligibility was independently determined by two investigators (TR and NK) and differences were resolved by mutual consensus. Newcastle–Ottawa quality assessment scale was used to evaluate each study in three domains: recruitment and selection of the participants, similarity and comparability between the groups, and ascertainment of the outcome of interest among cohort studies (Stang, 2010).

2.3 | Data extraction

A standardized data collection form was used to obtain the following information from each study: title of study, name of first author, year

of study, year of publication, country of origin, number of participants, demographic data of participants, method used to identify cases and controls, method used to diagnose the outcomes of interest (fQRS and major arrhythmic events), and average duration of follow-up. Confounders were also assessed and adjusted effect estimates with 95% confidence interval 95% confidence intervals and covariates were included in the multivariable analysis.

To ensure accuracy, all investigators independently performed this data extraction process. Any data discrepancy was resolved by referring back to the original articles.

2.4 | Statistical analysis

We performed a meta-analysis of the included cohort studies using a random-effects model. The extracted studies were excluded from the analysis if they did not present an outcome in each intervention group or did not have enough information required for continuous data comparison. We pooled the point estimates from each study using the generic inverse-variance method of DerSimonian and Laird (1986). The heterogeneity of effect size estimates across these studies was quantified using the I^2 statistic and Q statistic. For the Q statistic, substantial heterogeneity was defined as $p < .10$. The I^2 statistic ranges in value from 0% to 100% ($I^2 < 25%$, low heterogeneity; $I^2 = 25\%–50%$, moderate heterogeneity; and $I^2 > 50%$, substantial heterogeneity; Higgins, Thompson, Deeks, & Altman, 2003). A sensitivity analysis was performed to assess the influence of the individual studies on the overall results by omitting one study at a time. Publication bias was assessed using funnel plot and Egger's regression test (Sterne & Egger, 2001; $p < .05$ was considered significant). All data analyses were performed using the Stata SE 14.1 software from StataCorp LP.

3 | RESULT

3.1 | Description of included studies

Our search strategy yielded 15 potentially relevant articles (eight articles from EMBASE and seven articles from MEDLINE). After exclusion of three duplicate articles, 12 articles underwent title and abstract review. One article was excluded because it was an abstract presentation. Six articles were excluded at this stage since they were not cohort studies, did not report the outcome of interest (MAE) or were not conducted in patients with HCM, leaving five articles for full-length article review. Therefore, three retrospective and two prospective cohort studies of HCM patients (205 fQRS and 468 non-fQRS controls) were included in this meta-analysis. Figure 1 outlines the search and literature review process. The clinical characteristics and summary of included studies are described in Table 1.

3.2 | Quality assessment of included studies

Newcastle–Ottawa scales of the included studies are described in the Table S1. The Newcastle–Ottawa scale uses a star system (0–9)

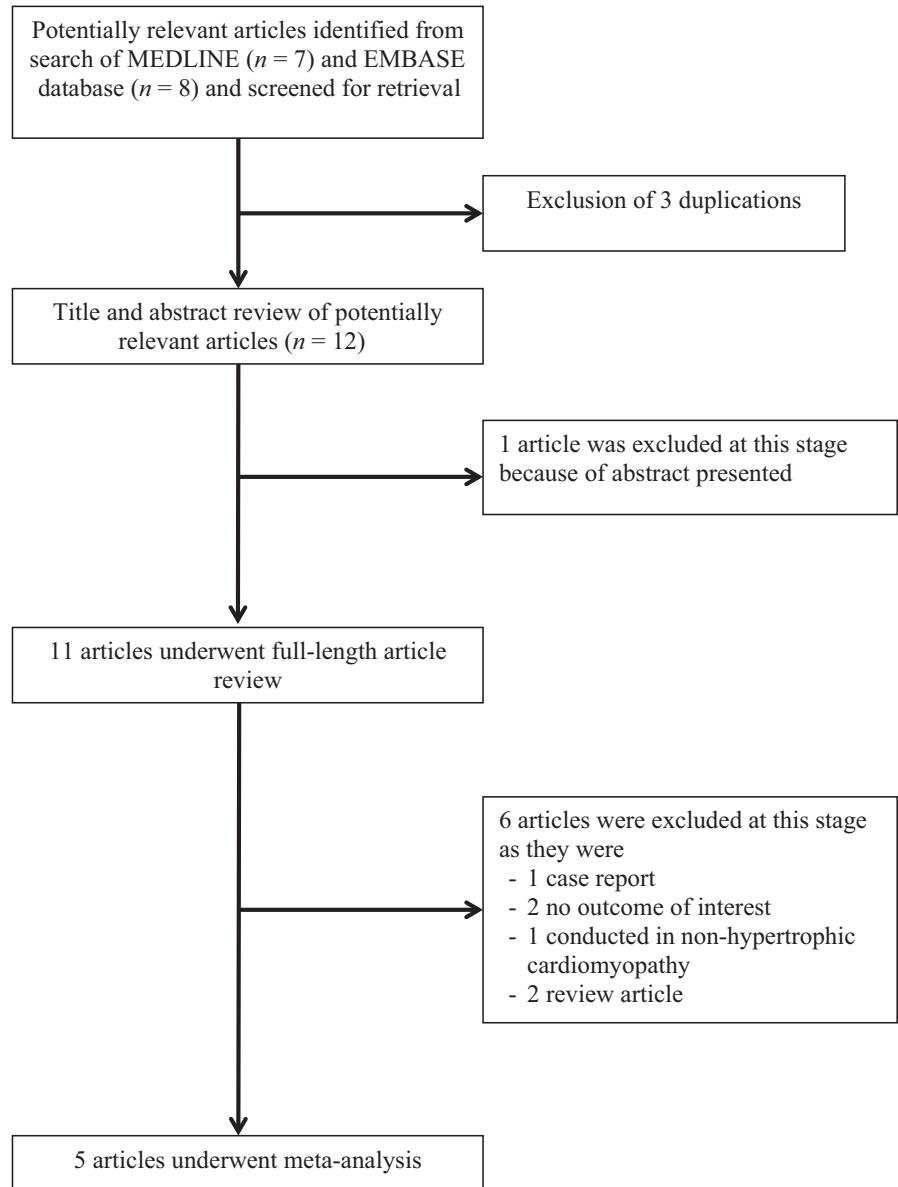

FIGURE 1 Search methodology and selection process

to evaluate included studies on three domains: selection, comparability, and outcomes. Higher scores represent higher study quality. Intra-study risks of bias of included studies are also described in Table S2.

3.3 | Meta-analysis results

Five studies from January 2013 to May 2017 were included in this meta-analysis. All of five studies did reveal an increased MAE among HCM patients with fQRS with four of the five studies achieving statistical significance. The pooled analysis demonstrated a statistically significant increased risk of MAE in HCM patients with fQRS compared to non-fQRS HCM patients with the pooled risk ratio of 7.29 (95% confidence interval: 4.00–13.29, $p < .001$, $I^2 = 0\%$). There was no statistical heterogeneity observed. Forest plot of our meta-analysis is shown in Figure 2.

3.4 | Sensitivity analysis

To assess the stability of the results of the meta-analysis, we conducted a sensitivity analysis by excluding one study at a time. The results were not significantly altered indicating that our findings were robust.

3.5 | Publication bias

To investigate potential publication bias, we examined the contour-enhanced funnel plot of the included studies in assessing change in log OR of death or composite outcome (Figure 3). The vertical axis represents study size (standard error) while the horizontal axis represents effect size (log odds ratio). From this plot, distribution of studies on both sides of the mean was symmetrical. The Egger's test was significant ($p = .568$) and confirmed no small study bias.

Study	Debonnaire et al. (2015)	Femenia et al. (2013)	Kang et al. (2014)	Nomura et al. (2015)	Ozyilmaz et al. (2017)
Prior personal history of SVT/VF/SCD	13	43	N/A	7	N/A
Abnormal BP during exercise	N/A	13	N/A	N/A	N/A
ICD implantation at baseline	58	102	N/A	7	11
fQRS definition criteria	Presence of various RSR' patterns, notching in the R or S wave or presence of >1 additional R in ≥ 2 beats of a non-aVR lead.	Presence of various RSR' patterns, which included an additional R' or notching of the R-wave, notching of the down- or upstroke of the S-wave, or the presence of >1R' in two contiguous leads.	Presence of an additional R', notching in the nadir of the R or S wave, or the presence of >1 R' in 2 contiguous leads that corresponded to a single myocardial territory.	QRS duration <120 ms R', notching in nadir of the S wave, notching of R wave, or >1 R' in 2 contiguous leads In patients with right or left bundle branch block (QRS duration ≥ 120 ms) RsR' pattern with or without a Q wave, >2 notches in the R wave, >2 notches in the downstroke or upstroke of the S wave, in two contiguous leads Patients with mechanical pacing (QRS duration ≥ 120 ms) >2 R' or >2 notches in the S waves in two contiguous leads	Presence of R' with or without a Q wave on 12-lead ECG, the presence of notching on an R wave, the presence of notching on an S wave, or the presence of more than one R' wave in two adjacent derivations corresponding to the feeding area of one of the major coronary arteries
Endpoints	Occurrence of malignant sustained VT, VF, or SCD	Appropriate ICD therapies (sustained VT or VF)	Major arrhythmic events (sustained VT and SCD)	Major arrhythmic event (sudden cardiac death, sustained VT and VF)	Sudden cardiac death
Mean follow-up	Median 5.7 years (IQR 2.7–9.1)	47.9 \pm 39.3 months	6.3 years	4 years	5 years
Conclusion	Extensive fQRS is associated with sustained VT/VF and or SCD in HCM patients.	fQRS is associated with a significant increase in arrhythmic events in HCM patients with ICD implant.	The presence of an fQRS, in particular in the inferior leads, was significantly associated with a higher risk of fetal ventricular arrhythmia events in HCM patients	fQRS is significantly associated with heart failure with hospitalization and lower heart failure-free survival in HCM patient	fQRS significantly increase risk of ventricular arrhythmias and SCD in HCM patients. fQRS is an independent high-risk indicator of SCD in HCM

Bold terms indicate subgroup definition. ECG, electrocardiogram; fQRS, fragmented QRS; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter defibrillator; IQR, Interquartile range; N/A, not applicable; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia.

4 | DISCUSSION

Hypertrophic cardiomyopathy is a complex inherited heart disease and one of the most common causes of sudden cardiac death (SCD) in young adults. Multiple approaches to management of the patient

should be taken into consideration. Prevention of SCD is a critical part of caring for the HCM patient. The overall risk of SCD in HCM patients is about 1% per year (Gersh et al., 2011). Recommended prevention strategies include exercise restriction, anti-arrhythmic drugs, and ICD. Identifying those who would benefit from an ICD is challenging but

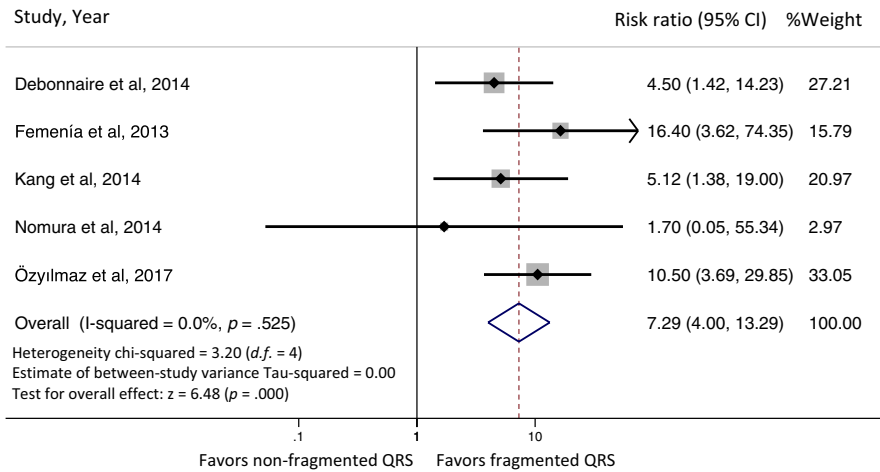

FIGURE 2 Forest plot of the included studies assessing the association between fragmented QRS and major arrhythmic events

FIGURE 3 Funnel plot of fragmented QRS and major arrhythmic events. Circles represent observed published studies

an essential part of clinical decision-making. Recommendations are based on cohort studies that identify relationships between clinical characteristics and prognostic outcomes.

Our meta-analysis summarized all available evidence of MAE in HCM from five studies, a total of 779 patients. Fragmented QRS was present in 46% of the studied population. Our study revealed that HCM patients with fQRS have a statistically significant increased risk of MAE compared to those without fQRS (pooled risk ratio of 7.29, 95% CI 4.00–13.29, $p < .001$, $I^2 = 0\%$). This result stresses the importance of integrating fQRS into risk stratification of HCM for SCD in clinical practice.

The importance of fQRS, which is suggestive of myocardial scarring and fibrosis, has been increasingly supported by recent studies of MAE in various cardiac diseases (Das et al., 2006; Konno et al., 2015; Lu et al., 2017; Sha et al., 2011; Take & Morita, 2012), including HCM (Debonnaire et al., 2015; Konno et al., 2015; Lu et al., 2017). Fibrosis or tissue heterogeneity increases susceptibility to reentry and arrhythmias. The presence of fQRS is more common in patients with high-risk characteristics, such as family history of SCD, history of syncope, and HCM patients with a calculated HCM Risk-SCD score $>6\%$ (Ozyilmaz

et al., 2017). The strength of the association of fQRS with MAE may depend on observed territory of distribution (Femenia et al., 2013; Kang et al., 2014). A previous study of HCM patients found that the presence of fQRS in more than two territories has a positive predictive value of 33% and negative predictive value of 88% of MAE or sudden cardiac death (Debonnaire et al., 2015).

Recently, HCM Risk-SCD, a tool developed to estimate the 5-year risk of SCD in HCM patients, was introduced to guide ICD placement for primary prevention of SCD (Authors/Task Force Members, 2014). ICDs may be considered in patients with HCM Risk-SCD score of $\geq 4\%$ to 6% 5-year risk and should be considered if 5-year risk $\geq 6\%$. Variables currently used in HCM Risk-SCD are age, family history of sudden cardiac death, unexplained syncope, left ventricular outflow gradient, maximum LV wall thickness, LA diameter, nonsustained ventricular tachycardia (Authors/Task Force Members, 2014). fQRS could provide important additional risk assessment and in fact fQRS has been shown to increase the positive predictive value from 8% to 20% and specificity from 72% to 92% in patients with one risk factor (NEED REF). Specificity was increased from 88% to 94% in patients with at least two risk factors (Kang et al., 2014). Addition of fQRS to traditional markers significantly improved the specificity and positive predictive value of future MAEs in “low risk” patients as well (Kang et al., 2014).

4.1 | Limitation

In our meta-analysis, there were some limitations that could limit its generalizability. First, all of the studies included were cohorts which are observational in nature. Three out of five studies were retrospective. Secondly, our meta-analysis was only focused on MAE. Given the published outcomes available for study, we did not take overall mortality or total cardiovascular mortality into account. However, the recent study from Lu et al. (2017) shows that fQRS is associated with increased all-cause mortality, cardiovascular disease mortality, and heart failure related death. In addition, our data is not sufficient to determine the relationship between fQRS and other ECG parameters such as prolonged QTc

or territory of fQRS to the outcome of interest. According to Debonnaire et al. (2015), prolonged QTc is an independent predictor of ventricular arrhythmias and sudden cardiac death. Finally, there was some heterogeneity amongst the studies. However, we used sensitivity analysis methods in the random-effects model and found no difference between the imputed risk ratio and its 95% confidence interval.

5 | CONCLUSION

In conclusion, we found that baseline fQRS significantly increased the risk of MAE in HCM patients. fQRS should be considered as an important factor when considering primary prevention ICD implantation in HCM patients. Further study is needed to establish the role of fQRS in risk stratification for SCD in patients with HCM.
