ABSTRACT

INTRODUCTION The diagnostic performance of ultrasound-fine needle aspiration to identify thyroid nodules harbouring malignancy remains variable. The aim of this study was to determine thyroid nodule size and cytological classification as predictors of malignancy risk.

MATERIALS AND METHODS We conducted a retrospective cohort analysis at an academic hospital involving 499 consecutive patients who underwent thyroid surgery between 2004 and 2015.

RESULTS A total of 503 thyroid nodules (499 patients, 84% female; mean age 50.8 years, standard deviation, SD, 15.4 years) were analysed. Of these, 19.5% were malignant. The mean (\pm SD) nodule size was 3.28 ± 1.63 cm and 3.27 ± 1.54 cm for benign and malignant nodules, respectively. The odds of malignancy for thyroid nodules less than 3.0 cm was similar to those for nodules of 3.0 cm or greater (0.26 compared with 0.29; $p=0.77$). Overall, the sensitivity and specificity of fine-needle aspiration in this cohort were 71.4% and 100%, respectively. The overall false negative rate was 5.4%. When the cut-off of 3.0 cm was used, the false negative rate in thyroid nodules less than 3.0 cm was 0% compared with 7.0% in nodules of 3.0 cm or greater. Thus, class ($p<0.01$) but not nodule size ($p=0.49$), was associated with higher malignancy risk.

CONCLUSIONS Our results suggest that thyroid nodule size did not accurately predict the risk of thyroid malignancy irrespective of fine-needle aspiration cytology. Routine diagnostic thyroid lobectomy solely owing to thyroid nodule size of 3.0 cm or greater is currently not justified.

Introduction

Thyroid cancer is the most common form of endocrine malignancy and recent data indicate that it is currently the fifth most common cancer worldwide.^{1,2} Although most thyroid nodules are benign,³ approximately 5–15% turn out to be malignant on final histopathology.⁴ Furthermore, most thyroid cancer manifests as thyroid nodules with or without any associated symptoms.⁵ Unlike other cancers that show stable or declining trends, the incidence of thyroid cancer has continued to surge globally over the past few decades.⁶ The incidence in the United States, for example, has increased dramatically to 4.5%, while in Great Britain the incidence has risen at 3.4% in both genders.^{2,7}

Ultrasound-guided fine needle aspiration is an important preoperative diagnostic tool to identify thyroid nodules harbouring malignancy.⁸ Data indicate that the false-negative rate of fine-needle aspiration in detecting thyroid cancer is 0–5%.⁹ However, when the false negative rate is stratified according to nodular size, conflicting results emerge. Many studies reported that large nodule size (≥ 3.0 cm) carries a higher false negative rate, ranging from 10.4% to as high as 25%.^{10–15} Consequently, many clinicians advocated that diagnostic thyroid lobectomy be performed based solely on nodule size.^{15,14,16} In contrast, other studies have found that nodule size did not adversely affect the false negative rates of fine-needle aspiration.^{17–24} In this study, we sought to determine and evaluate the diagnostic accuracy and predictive values of ultrasound-guided fine-needle

aspiration in our institution, specifically looking at the nodule size and cytology.

Materials and methods

Data collection

Approval was obtained from the Clinical Research Ethics Committee of the Cork Teaching Hospitals prior to the commencement of this study. Data were retrospectively collected from prospectively maintained theatre logbooks on patients who underwent thyroid surgery in Cork University Hospital by a single endocrine surgeon between January 2004 and December 2015. The inclusion criteria were: (a) patients who underwent first time thyroid surgery for thyroid nodules; (b) patients with complete preoperative investigations performed; and (c) patients with complete final histopathology reports after the surgery. Patients were excluded if: (a) the surgery was a repeat surgery (eg completion thyroidectomy); (b) there were incomplete preoperative investigation reports; and (c) incomplete final histopathology surgery after the surgery.

In our institution, all thyroid nodules subjected to ultrasound-guided fine-needle aspiration and cytology evaluation are discussed in a multidisciplinary meeting between the radiologists, pathologists, endocrine surgeons/physicians and oncologists/radiotherapists. The criteria for surgery includes cytology report of malignancy (Thy 5); suspected malignancy (Thy 4); concern for follicular neoplasm (Thy 3f), undetermined with atypia (Thy 3a) in at least two biopsies performed at different times; benign cytology (Thy 2) but large-sized nodules ($\geq 2.0\text{--}3.0$ cm); benign cytology result but with high suspicions of malignancy in ultrasonographic and clinical examinations; concurrent thyroidectomy made during excision of parathyroid adenoma; and patient's concern.

The following data were collected: patient's initials and medical chart number, sex, date of birth, age, date and type of surgery, preoperative investigations and final histopathology reports. For preoperative investigations, information such as cytology classification based on the British Thyroid Association classification was collected and includes the primary side and size of the dominant nodules, and the corresponding final histopathology diagnosis.⁹ In cases of repeated fine-needle aspiration cytology for a single thyroid nodule, the highest cytology classification was taken. Only the dominant thyroid nodule was recorded based on the ultrasound report of the largest dimension in centimetres. Following surgery, the corresponding histopathology reports of the nodules were recorded. Because our institution only adopted the standardised fine-needle aspiration reporting system from year 2011 onwards, only data from this period was used to calculate false negative rate, sensitivity and specificity.

Statistical analyses

The main outcome parameters were the probability of thyroid malignancy as a function of nodule size and cytology classification. Fine-needle aspiration sensitivity,

specificity and positive likelihood ratio were calculated according to cytology classification with the corresponding 95% confidence interval (CI). To calculate these, Thy 2 (Bethesda II) cytological finding was considered as a negative result while Thy 4 to Thy 5 (Bethesda V-VI) were considered as positive test results for malignancy. Thy 1, Thy 3a and Thy 3f (Bethesda I, III and IV) were included in the summary tables but excluded in calculations involving fine-needle aspiration false-negative rate, sensitivity and specificity. The false negative rate was defined as thyroid nodules being reported as benign under fine-needle aspiration cytology but malignant on final histopathological examination after surgery. Surgical histopathology results represent the gold standard in determining malignancy in any given thyroid nodule. Diagnostic odds ratio was also calculated as a single indicator measure of the diagnostic test accuracy.

The probability of malignancy as a function of nodule size and fine-needle aspiration cytology was modelled using two models of binomial logistic regression analysis. The first model evaluated the probability of malignancy as a function of nodule size alone ($n=503$). The second model evaluated the probability of malignancy as a function of both nodule size and fine-needle aspiration cytology ($n=187$). Results of the binomial logistic regression models were reported using predicted probabilities. A two-sided p -value of less than 0.05 was considered as statistically significant. Statistical analysis was performed using IBM SPSS version 23 and Graphpad Prism version 6.

Results

Patient demographics

During the period from January 2004 to December 2015, 754 patients underwent thyroid surgery for various reasons. Of these, 499 patients involving 503 thyroid nodules were included in the study because they met our inclusion criteria. Our study sample comprised 419 (84%) women and 80 (16%) men. The mean age of the overall sample was 50.74 years (SD 15.41) (95% CI 49.39–52.09) and ages ranged between 14 years and 99 years (Table 1). There was no significant difference in mean age between female and male patients (50.44 vs 52.84).

Histopathology and fine-needle aspiration test characteristics

The mean size of thyroid nodule (\pm SD) was 3.275 cm (\pm 1.61 cm) with a 95% confidence interval of 3.13–3.42. Cytological breakdown of the thyroid nodules and mean nodule size are summarised in Table 1 and Figure 1. When a reproducible classification of fine-needle aspiration cytology reporting was adopted into our institution in 2011, only thyroid nodules from this period was analysed for cytology and fine-needle aspiration test characteristics ($n=187$). In this cohort, 30 of 187 (16%) of the nodules were malignant on final surgical histopathology. The rates of malignant disease according to fine-needle aspiration cytological classification were 0%, 5.4%, 15.4%, 22.8%, 100% and 100% for patients in British

^a Cytological classification available for 187 nodules.

Thyroid Association classes Thy 1 to Thy 5 (corresponding Bethesda classes I to VI). Histologically, classic papillary thyroid carcinoma was the most common type of malignancy in this cohort (56.7%) followed by follicular variant of papillary thyroid carcinoma at 23.3% and follicular thyroid carcinoma at 13.3% (Table 2). After excluding for Thy1, Thy3a and Thy3f (Bethesda I, III and IV), a total of 84 nodules were evaluated. Overall, the sensitivity and specificity of fine-needle aspiration in this cohort were 71.4% (95% CI 41–92%) and 100% (95% CI 95–100%), respectively. The overall false negative rate was 5.4%. When the cut-off of 3.0 cm was used, the false negative rate in nodules less than 3.0 cm was 0% compared with 7.0% in nodules of 3.0 cm or greater.

Nodule size and the rate of malignancy

For the purpose of this study, the rates of malignancy were compared based on the nodule size. Overall, there was no significant difference in the rate of malignancy on subgroup analysis based on nodule sizes. The rates of malignancy according to every 1.0 cm increase in nodule size are summarised in Table 3. When the 3.0 cm cut-off point was used, the rates of malignancy between nodules less than 3.0 cm compared with nodules of 3.0 cm or greater was not statistically different (18.1% vs 20.6%, $p=0.5$) and the odds of malignancy were similar for nodules less than 3.0 cm compared with nodules of 3.0 cm or greater (0.264, 95% CI 0.205–0.341 vs 0.288, 95% CI 0.168–0.494; $p=0.77$).

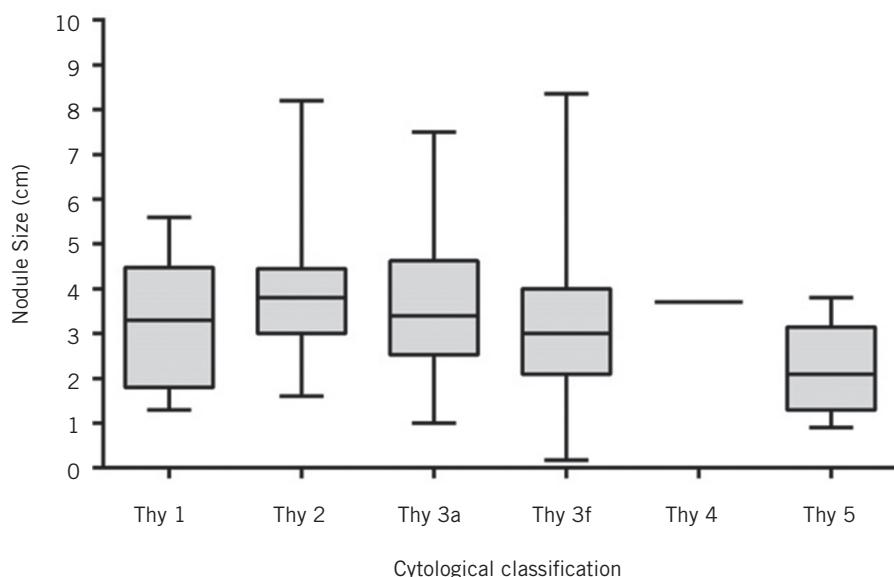

Figure 1 Box plot of thyroid nodule size distributions according to cytology classification. The solid line within each box represents the median. The box comprises the 25th to 75th percentiles of nodule size in each cytology class. The whiskers represent the most extreme data point (minimum–maximum) for each cytology class.

Table 2 Summary of cytological classification based on fine-needle aspiration and rates of malignancy.

Characteristic	Thy classification					
	1	2	3a	3f	4	5
Thyroid nodules, n (malignant, n)	16 (0)	74 (4)	52 (8)	35 (8)	1 (1)	9 (9)
Rate of malignant neoplasm (%)	0	5.4	15.4	22.8	100	100
Pathology of malignant nodules, (n):						
Papillary thyroid cancer (PTC)	0	3	3	2	0	9
PTC follicular variant	0	1	2	3	1	0
Follicular thyroid cancer (FTC)	0	0	2	2	0	0
FTC, Hürte cell variant	0	0	0	1	0	0
Medullary thyroid cancer	0	0	1	0	0	0

Table 3 Rate of thyroid nodule malignancy according to size (every 1 cm increment).

TN size (cm)	Nodules (n)	Malignant, n (%)
1.0–1.9	90	17 (18.9)
2.0–2.9	131	23 (17.6)
3.0–3.9	136	27 (19.9)
4.0–4.9	73	15 (20.5)
≥ 5.0	73	16 (21.9)
All nodules	503	98 (19.5)

Binomial logistical regression determining the probability of malignancy was performed based on two models: nodule size alone, and nodule size and FNA cytology. In the first model, nodule size ($n=503$) was used in the logistic regression model. Actual nodule size was not predictive of thyroid malignancy in this model (OR 0.99, $p=0.99$) with a Hosmer and Lemeshow test p -value of 0.25. Similarly, not every 1 cm increase in nodule size (Table 3) was predictive of malignancy (OR 1.06, $p=0.49$), nor was the 3.0 cm cut-off point (OR 0.85, $p=0.49$). In the second model, both nodule size and fine-needle aspiration cytology were evaluated as potential predictors of malignancy ($n=187$). As expected, fine-needle aspiration cytology was predictive of malignancy (OR 3.57, $p<0.001$) but not the actual nodule size (OR 1.06, $p=0.67$).

Discussion

This study examines the association between thyroid nodule size and malignancy rate at a single institution. Evaluation of nodule size and the probability of malignancy remains an interesting area of research because, to date, there is no consensus as to whether nodule size does in fact predict thyroid malignancy. Our study aimed to add to the large body of information pertaining to the relationship

between nodule size and the rate of malignancy and to elucidate whether or not there is a cut-off size for nodule resection. Some studies showed that large nodule size (≥ 3.0 –4.0 cm) is associated with an increased probability of malignancy and have advocated surgical excision of these nodules.^{10,13,15,25} On the other hand, other studies have reported that the rate of malignancy does not increase substantially when comparing large and small nodules, and have advocated that surgery should not be performed on the basis of large nodule size alone.^{25,26–28} Another group reported that small nodule size is associated with a higher rate of malignancy up to a threshold of about 2.0–3.0 cm.^{22,24,29,30} Kamran *et al*, for example, reported that in small nodules (1.0–2.0 cm) the risk of malignancy rises proportionally up to a threshold of 2.0 cm, beyond which there is no graded increase in malignancy.²⁴ Additionally, Cavallo *et al* reported that the highest malignancy risk was observed in nodules of less than 2.0 cm, with no graded decrease beyond the 2.0-cm threshold.³¹

There are currently no clear guidelines as to what size warrants surgical excision, so the indications for surgery differ between institutions. Compared with previous studies,^{10,13,15,25} our data show that nodule size was not predictive of thyroid malignancy for every 1.0-cm increment (Table 3) or when grouped into nodules of less than 3.0 cm compared with those of 3.0 cm or greater (malignancy rates of 18.1% vs 20.6%). The results were similar when fine-needle aspiration cytology was factored into the analysis using a binomial logistic regression. Although large nodule size has been suggested as a possible risk factor for malignancy, there is very little evidence supporting this suggestion at the moment.

One of the major obstacles in studying the relationship between nodular size and the incidence of malignancy is that the final histopathological diagnoses are only available in nodules subjected to surgery. For the majority of nodules not subjected to surgery, the final histopathology is simply not available for analysis. The apparent difference in malignancy rates between the different nodule size groups as reported by previous studies may be explained

by several factors. First, smaller nodules are usually selected for surgery only if there is a suspicion of malignancy either cytologically, radiologically or clinically. Therefore, only those with strong possibility of malignancy are undergoing surgery in this group. Second, compared with smaller nodules, large nodules ($\geq 3.0\text{--}4.0$ cm) are more likely to undergo surgery even if the cytology is benign.¹⁵ This is largely because of concerns of high malignancy rate, as reported by some earlier studies,^{10,15} and higher false negative rates.^{10,11,15,31} Finally, large nodules are more likely to cause clinical complaints of compression and cosmetic issues to the patients and are more likely to be excised, regardless of cytology or radiological appearances.

Another way of elucidating whether larger nodule size warrants surgery or not is to evaluate and compare the false negative rates between the different sizes. A number of studies have examined this question and the results have been variable. Several studies showed that a nodule size of 3.0 cm or greater is associated with higher false negative rates compared with a nodule size of less than 3.0 cm, ranging between 5.8% to 17%.^{10,12,14–16,23,31} Other studies have identified that large nodules (≥ 3.0 cm) are not associated with any significant increase in false negative rate, while yet other studies have shown an even lower false negative rate compared with a nodule size of less than 3.0 cm.^{18,21,29,50,52} In addition, a few studies have examined 4.0 cm as a cut-off point and have shown similar equivocal results between the two groups.^{11,15,14,20} In our study, the overall false negative rate was 5.4%. When a cut-off point of 3.0 cm was used, the false negative rate in nodules less than 3.0 cm was 0% compared with 7.0% in those of 3.0 cm or greater. The cut-off size of 3 cm was chosen in this study because the majority of nodules of 3.0 cm or greater are subjected to thyroid surgery in our institution. This stems from earlier study by Meko *et al* indicating a high prevalence of malignancy in large nodules (defined as ≥ 3.0 cm), which carry significantly higher false negative rates (16.6% vs 0% in the study).¹⁰ The results are criticised, however, because the authors did not use ultrasound guidance in their fine-needle aspiration biopsy, which is a standard of care today.

There are several potential explanations why larger nodules are associated with higher false negative rates. First, by virtue of their size, a complete sampling of large nodules is more difficult than in small nodules because of cytological heterogeneity within the nodules.^{13,15} This means that an island of cancer cells may coexist with a larger proportion of benign cells within the nodule. This risk may be reduced by taking multiple samples from different parts of the nodule, depending on its size, to obtain more representative results. Second, sampling error may contribute to the perceived higher false negative rates in large nodules. This might occur when cells taken for the sampling are not from the index nodule. Ultrasound guidance and on-site processing of the biopsy specimen are among the recommendations to improve sampling error.¹⁹ Although the rates of malignancies between nodules less than 3.0 cm and those of 3.0 cm or greater are

comparable, the false negative rate was higher in the 3.0 cm or greater group (7.0%). It is therefore appropriate to repeat the fine-needle aspiration in this nodule size group, despite benign cytology, to improve diagnostic accuracy.

There were four false negative nodules (three papillary thyroid carcinoma and one follicular variant papillary thyroid carcinoma) in the 3.0 cm or greater group. The follicular variant of papillary thyroid carcinoma case was reviewed by a pathologist and met all the criteria for non-invasive follicular thyroid neoplasm with papillary-like nuclear feature.³³ If this nodule was not considered definitely malignant, the corrected false negative rate was 4.0%. When the cut-off of 3.0 cm was used, the false negative rate in nodules less than 3.0 cm remained 0% compared with 5.2% in those of 3.0 cm or greater.

We also evaluated the diagnostic accuracy and predictive value of ultrasound-guided fine-needle aspiration of thyroid nodules at a single institution. Our data demonstrate an overall sensitivity and specificity of 71.4% and 100%, respectively. This is consistent with the reported sensitivity and specificity of fine-needle aspiration by Cross *et al*.⁹ The rate of non-diagnostic nodules (Thy1, Bethesda I) in our study was 8.5%, within the recommended rate of less than 10%.³⁴ The overall malignancy rate in nodules with benign cytology ($n=74$) was 5.4%.

Taken together, it remains challenging to interpret these conflicting results in the context of clinical application. A meta-analysis by Hammad *et al* involving 10,817 thyroid nodules reported that a nodule size of 3.0–5.9 cm had a greater risk of malignancy compared with a size of 3.0 cm or greater (OR 1.26).³⁵ Interestingly, the author also reported that an even larger group of nodules (size ≥ 6.0 cm) is associated with a much lower risk of malignancy compared with a size of less than 3.0 cm (OR 0.84). However, this meta-analysis involved only four studies in each comparison, with one of the studies contributing more than 50% in weight to the overall data and therefore is a potential bias. Certainly, a larger meta-analysis involving all known studies done on this topic is warranted to elucidate current conflicting results.

Conclusion

Our data indicate that nodule size did not accurately predict the risk of thyroid malignancy irrespective of fine-needle aspiration cytology. Only fine-needle aspiration cytology was consistently reliable in determining whether or not a particular nodule was likely to be malignant or not. It remains difficult, therefore, to objectively justify routine diagnostic thyroid lobectomy solely because of a nodule size of 3.0 cm or greater.
