ABSTRACT

Background

Umbilical arterial catheters (UACs) are among the most commonly used monitoring methodologies in neonatal intensive care. There seems to be significant variance between neonatal intensive care units in exactly how these catheters are used. This variance involves heparin dosing, catheter materials and catheter design and positioning of the catheter.

Objectives

To determine whether the use of heparin in fluids infused through an umbilical arterial catheter in newborn infants influences the frequency of clinical ischemic events, catheter occlusion, aortic thrombosis, intraventricular hemorrhage, hypertension, death, or the duration of catheter usability.

Search methods

Randomized and quasi-randomized controlled trials of umbilical catheterization use were obtained using the search methods of the Cochrane Neonatal Review Group. *The Cochrane Library*, MEDLINE (search via PubMed), CINAHL and EMBASE were searched from 1999 to 2009.

Selection criteria

Randomized trials in newborn infants of any birthweight or gestation.

Comparison of heparinised to non heparinised infusion fluids, including comparison of heparin in the infusate to heparin just in the flush solution.

Clinically important end points such as catheter occlusion or aortic thrombosis.

Data collection and analysis

There were five randomized controlled trials retrieved. All gave details of the incidence of catheter occlusion. Two also reported the incidence of aortic thrombosis. The intervention was reasonably consistent: heparin in the infusate at a concentration of 1 unit/mL was investigated in all trials except one which used a concentration of 0.25 units/mL. Studies generally included both term and preterm infants.

Main results

Heparinization of the infusate decreases the incidence of catheter occlusion but does not affect the frequency of aortic thrombosis. Heparinization of the flush solution is not an adequate alternative.

There does not appear to be an effect on frequency of intraventricular hemorrhage, death or clinical ischemic phenomena.

Authors' conclusions

Heparinization of the fluid infused through an umbilical arterial catheter decreases the likelihood of umbilical arterial catheters occluding. The lowest concentration tested so far (0.25 units/mL) has been shown to be effective. Heparinization of flushes without heparinizing the infusate is ineffective. The frequency of aortic thrombosis has not been shown to be affected; however, the confidence intervals for this effect are very wide. The frequency of intraventricular hemorrhage has not been shown to be affected by heparinization of the infusate, but again the confidence intervals are very wide and even a major increase in the incidence of grade 3 and 4 intraventricular hemorrhage would not have been detected.

PLAIN LANGUAGE SUMMARY**Umbilical artery catheters in the newborn: effects of heparin**

The umbilical artery catheters (tubes) (UACs) commonly used in neonatal intensive care to monitor babies can sometimes cause them problems. They can be placed in high or low positions, and come in different materials and designs. The blood anticoagulant, heparin, theoretically helps prevent blood clots forming (thromboses), but high doses could lead to haemorrhage (bleeding). This review found that low heparin doses are effective in preventing catheters becoming blocked and needing to be re-inserted. There is not enough evidence to rule out the possibility of adverse effects. Heparin does not seem to lower the rate of blood clots in the major artery.

BACKGROUND

Description of the condition

Umbilical arterial catheters (UACs) are among the most commonly used monitoring methodologies in neonatal intensive care. There seems to be significant variance between neonatal intensive care units in exactly how these catheters are used. This variance involves heparin dosing, catheter materials and catheter design and positioning of the catheter. Immediately after insertion of a UAC, local vascular compromise is frequently evident, usually in the form of blue or white toes, but occasionally with more severe and extensive ischemic manifestations. Aortic thrombi and renal ischemia have also been described. Some epidemiologic and case control studies have also shown that use of umbilical artery catheterisation is statistically associated with the later development of necrotizing enterocolitis. In order to minimize these morbidities some aspects of the use of UACs have been subjected to a small number of randomized control trials.

Description of the intervention

Most NICUs now add heparin to the fluid being infused through the UAC.

How the intervention might work

Several studies have examined whether this practice affects catheter occlusions or aortic thrombosis, and whether adding heparin to fluids used to intermittently flush the UAC, in place of adding heparin to the infusate, is adequate.

Heparin exposure at high dosage may be associated epidemiologically with an increased risk of intraventricular hemorrhage (Lesko 1986; Malloy 1995). It is therefore necessary to ensure that heparinization of fluids does indeed have a benefit as well as to determine whether clinically important adverse effects have been reliably assessed in newborn infants.

Why it is important to do this review

This review updates the existing review "Umbilical artery catheters in the newborn: effects of heparin" published in the Cochrane Database of Systematic Reviews (Barrington 1999).

OBJECTIVES

To determine whether the use of heparin in fluids infused through an umbilical arterial catheter in newborn infants influences the frequency of clinical ischemic events, catheter occlusion, aortic thrombosis, intraventricular hemorrhage, hypertension, death, or the duration of catheter usability.

METHODS

Criteria for considering studies for this review

Types of studies

Randomized and quasi randomized clinical studies were selected. Clinically relevant outcomes were collated with survival and long term disability being given the greatest weight. Both term and preterm infants were included.

Types of participants

Newborn infants, both preterm and term. Entry criterion was usually simply the 'need' for an umbilical artery catheter, as defined by the attending medical staff.

Types of interventions

Random assignment to administration of heparin in the infusate or control without heparin.

Random assignment to a group which received heparin in intermittent flush solution only was considered separately.

Types of outcome measures

1. Catheter occlusion;
2. Aortic thrombosis;
3. Death;
4. Intraventricular hemorrhage;
5. Hypertension;
6. Clinical ischemic events.

Search methods for identification of studies

The standard search method of the Cochrane Neonatal Review Group was used.

Electronic searches

Randomized and quasi randomized controlled trials of umbilical catheterization use were obtained from the following sources: 1. MEDLINE Search using Melvyl Medline Plus and the keyword headings 'Umbilic#', 'Catheter#' and subject heading 'Infant, Newborn'.

The bibliography cited in each publication obtained was searched in order to identify additional relevant articles.

The original search was completed in November 1997. The search was updated in November 1998.

The search was updated in April 2009:

The Cochrane Library, MEDLINE (search via PubMed), CINAHL and EMBASE were searched from 1999 to 2009.

Search terms: umbilic* AND catheter. Limits: human, newborn infant and clinical trial. No language restrictions were applied.

Searching other resources

Randomized and quasi randomized controlled trials of umbilical catheterization use were obtained from searching the following other resources:

1. Effective Care of the Newborn Infant, edited by JC Sinclair and MB Bracken
2. Search of personal data files

Clinical trials registries were also searched for ongoing or recently completed trials (clinicaltrials.gov; controlled-trials.com; and who.int/ictrp)

Data collection and analysis

The standard methods of the Cochrane Neonatal Review Group Guidelines were employed.

Selection of studies

Reports were first reviewed to determine whether there was a concurrent control group, and discarded if not. The method of assignment to control and intervention groups was then determined and if not random or quasi random, then the trial was discarded.

Data extraction and management

The review author extracted, assessed and coded all data for each study using a form that was designed specifically for this review. For each study, final data was entered into RevMan by the review author (KB).

Assessment of risk of bias in included studies

The standard method of the Cochrane Neonatal Review Group were employed. Each identified trial was assessed for methodological quality with respect to a) masking of allocation b) masking of intervention c) completeness of follow-up d) masking of outcome assessment. This information is included in the Characteristics of Included Studies Table.

For the update in 2009, the risk of bias table was completed in order to address the following questions:

1. Sequence generation: Was the allocation sequence adequately generated?
2. Allocation concealment: Was allocation adequately concealed?
3. Blinding of participants, personnel and outcome assessors: Was knowledge of the allocated intervention adequately prevented during the study? At study entry? At the time of outcome assessment?
4. Incomplete outcome data: Were incomplete outcome data adequately addressed?
5. Selective outcome reporting: Are reports of the study free of suggestion of selective outcome reporting?
6. Other sources of bias: Was the study apparently free of other problems that could put it at a high risk of bias?

Measures of treatment effect

Statistical analyses was performed using Review Manager software. For categorical outcomes, estimates for relative risk and risk difference were calculated. For outcomes measured on a continuous scale, estimates for weighted mean difference were calculated. 95% confidence intervals were used.

Assessment of heterogeneity

Heterogeneity between trials was evaluated by inspecting the forest plots and quantifying the impact of heterogeneity using the I^2 statistic. A fixed effects model for meta-analysis.

Data synthesis

If multiple trials were found and meta-analysis was judged to be appropriate, the analysis would be done using Review Manager software (RevMan 5). All meta-analyses were to be done using the fixed effect model.

Subgroup analysis and investigation of heterogeneity

If data was available, subgroup analysis based on gestational age or birth weight were planned.

RESULTS

Description of studies

The original search strategy retrieved 849 articles. These were further reduced by restricting the search by use of the terms prospective, random#, control#, comparative or clinical. When studies of animal subjects and of epidural catheterisation were also removed, 233 reports remained. The abstract of each was read individually to determine if there was a possibility that the papers were reporting randomized prospective controlled trials. This final examination revealed six trials investigating heparin use, one of which was a trial published only as an abstract and reporting a study comparing heparinization of the infusate to full systemic heparinization (McDonald 1984). This trial was excluded from further analysis. All five remaining trials included both term and preterm infants. Several of these trials do not give information regarding the total dose of heparin administered to the infants. This would, of course, be highly relevant to the occurrence of hemorrhagic complications. Where such information is given it is noted below. At the time of the updated search in 1999 one further randomized controlled trial was added (Chang 1997).

Ankola 1993 performed a non-masked study in 30 infants who required catheter placement for clinical indications. Heparin was administered at a lower dose than any of the other studies at 0.25 units/mL. Total heparin dose received was 25 to 50 units per kg per day. Maximum heparin infusion rate was 38 (SD 7) U/kg/d. Major outcome variables were duration of catheter usability, catheter occlusion, intraventricular hemorrhage, necrotizing enterocolitis, clinical ischemic phenomena (blue discoloration of toes) and sepsis.

Bosque 1986 randomised 47 infants to receive either heparin at a dose of 1 unit/mL added to the infusate and no heparin in the solution used to flush the catheter, or no heparin in the infusate and 1 unit/mL added to the flush solution. Infants were stratified by birth weight. The group with heparin in the infusate received 80 to 220 U/kg/d of heparin, with a mean of 120 U/kg/d. The group with heparin in the flush received 0.8 to 9.8 U/kg/d with a mean of 3.9 U/kg/d. The major outcome variables were catheter occlusion, ischemic complications, prothrombin time and partial thromboplastin time.

David 1981 studied 50 infants (one later removed from analysis) randomly assigned to either 1 unit heparin/mL, in both the infusate and the flush, to no heparin in either fluid. Total heparin doses were not clearly stated but the highest dosage ranged from 125 to 200 U/kg/d. The major outcome variable of the study was the occurrence of aortic thrombi detected by single shot aortogram performed at the time of catheter removal, if the catheter had been in place for more than 24 to 72 hours. Autopsies, if available, were also used to determine aortic clots. Clotting studies were also performed

Horgan 1987 performed a trial in 111 term and preterm infants. Infants were randomly allocated to one of four nurseries. In two nurseries heparinized fluids were used, in the other two heparin was not used. The text also states that allocation to a particular nursery was based on the availability of bed space. This study

may therefore have had 'haphazard' rather than truly random allocation, and allocation was certainly not masked. Both high and low catheters were allowed according to physician preference. Total heparin doses ranged from 0.46 to 3.4 U/kg/hr, with a mean of 0.9 U/kg/hr. Outcome variables reported were aortic thrombi determined by ultrasound, catheter occlusion, intraventricular hemorrhage of grade 3 or 4, sustained hypertension, (systolic pressure above 100 mm Hg or mean >85 mm Hg in term infants and > 70 mm Hg in premature infants).

Rajani 1979 performed a well masked randomized study with the randomization code maintained by pharmacy until the end of the study. 62 infants, term and preterm, were randomized to either heparin or placebo added at 1 unit/ml to the catheter infusate. Fluids ran at a minimum of 5 mL/hr in all but one infant, giving a total heparin dose in excess of 5 units/hr for all except one infant in the treatment group. It was noted in the discussion that patients received between 100 and 200 U/kg/d. Outcome variables were duration of catheter 'life-span', incidence of occlusion, clotting studies, and clinical ischemic phenomena defined as blue toes lasting for more than 8 hours.

Chang 1997 reported a prospective masked trial of heparin usage in umbilical catheters. This study assessed the effects of the use of heparin in both umbilical arterial and venous catheters, at a concentration of 1 unit/mL. The study only included preterm infants at risk for development of intraventricular hemorrhage by reason of a gestational age of less than 31 completed weeks gestational age. The study period was from birth to the fifth day of life, and heparin doses received by the infant averaged 4.3 U/kg/hr (no standard deviation given). The primary outcome variable was the occurrence of intraventricular hemorrhage, of any grade. Hemostatic variables were also determined and compared between groups. Mortality rates and severe intraventricular hemorrhage rates were reported and are included in the meta-analysis.

Risk of bias in included studies

Ankola 1993

Masking of allocation: No method for masking allocation is described, no details of the randomization process are given.

Masking of intervention: Not attempted

Completeness of follow up: All patients are accounted for

Masking of Outcome: Not attempted

Bosque 1986

Masking of allocation: Allocation was determined by a table of random numbers and "a separate pad of paper was used for each weight group". There does not appear to have been adequate allocation concealment.

Masking of intervention: Not attempted.

Completeness of follow up: All infants appear to have been accounted for.

Masking of outcome: Not attempted.

Other Comments: Hypothesis not described. Study was stopped when it was found that all of the occlusions were in the flush only group, and that the difference was statistically significant.

David 1981

Masking of allocation: Allocation clearly described: A pad containing randomly ordered group designations was used, the top page torn off for each patient, assignments not visible until torn off.

Masking of intervention: Not attempted.

Completeness of follow up: Yes.

Masking of outcome: Not attempted for most outcomes, aortograms were read by a radiologist unaware of group assignment.

Horgan 1987

Masking of allocation: Not attempted.

Masking of intervention: Not attempted.

Completeness of follow up: All infants appear to have been accounted for. The numbers of infants who actually had ultrasounds is not stated, even though two infants had aortic thrombosis diagnosed by clinical symptoms alone.

Masking of outcome: Not attempted.

Other comments: Hypotheses stated, authors do not describe how they arrived at a sample size.

Rajani 1979

Masking of allocation: This appears to have been adequate.

Masking of intervention: This was placebo controlled fully masked study.

Completeness of follow up: All infants accounted for.

Masking of outcome: Yes.

Other comments: Hypothesis stated, No sample size determination is described. Life table analysis of catheters with and without heparin was performed.

Chang 1997

Masking of allocation: Randomization was revealed only to the pharmacist involved and therefore this appears to have been adequate.

Masking of intervention: This was a placebo controlled masked study.

Completeness of follow up: Outcomes are described for all except 5 infants deleted from analysis as they contravened exclusion criteria.

Masking of outcome: It appears that the interpretation of the ultrasounds was performed by a single masked radiologist, and this was therefore adequate.

Other comments: Both venous and arterial lines were studied in this trial.

Effects of interventions

Heparin in infusate compared to no heparin (Comparison 1):

Heparin in the infusate clearly decreases the incidence of catheter occlusion; (four trials 252 infants) typical Relative Risk 0.20; (95% CI 0.11, 0.35) (Outcome 1.1.1). This result was remarkably consistent between studies.

Using heparin solely in the flush solution and not in the infusate does not appear to be effective in preventing catheter occlusion (**Bosque 1986**).

A concentration of 0.25 units/mL, in comparison to no heparin, was effective in one trial (**Ankola 1993**), and appears to have a similar efficacy to higher concentrations but has not been directly compared to a higher concentration.

The duration of catheter usability was reported by several of the studies by the use of life table analysis. (**David 1981**; **Rajani 1979**; **Ankola 1993**). All showed a significant prolongation of the life of the catheter with heparinization.

Aortic thrombosis incidence, however, does not appear to be affected by heparin use. Neither of the two studies that examined this showed an effect (David 1981; Horgan 1987). The overall relative risk was 0.71; 95% CI 0.42, 1.22 (Outcome 1.2).

Coagulation studies were described in several reports (David 1981; Horgan 1987, Bosque 1985, Rajani 1979; Chang 1997). The timing of performance of the studies, methodologic details and detail of reporting of the results varied so greatly that a meta-analysis was not performed. However, in general terms none of the studies showed a significant prolongation of prothrombin or partial thromboplastin times. Horgan 1987 and Chang 1997 did not show an effect on fibrinogen concentrations; David 1981 did not show an effect on thrombin or reptilase times; and Rajani 1979 did not show an effect on antithrombin 3 concentrations, whereas Chang 1997 showed a decrease in antithrombin 3 concentrations at the end of the study in the heparin group.

Hypertension was reported by only one of the studies (Horgan 1987) and was significantly reduced by the addition of heparin, relative risk 0.05; 95% CI 0.00, 0.78 (Outcome 1.3).

Grade 3 and 4 Intraventricular hemorrhage was not affected (Ankola 1993; Horgan 1987; Chang 1997), relative risk 1.07; 95% CI 0.58, 1.99 (3 trials, 254 infants) (Outcome 1.4).

Clinical ischemic phenomena were reported by three of the studies; none reported a significant effect of heparinization. The overall RR was 1.28; 95% CI 0.66, 2.48 (3 trials, 139 infants) (Outcome 1.5).

Mortality was reported in four studies (Ankola 1993; Horgan 1987; Rajani 1979; Chang 1997). Each failed to show a significant difference between heparinized and non-heparinized fluids. The overall relative risk was 0.87; 95% CI 0.50, 1.49 (Outcome 1.6). David 1981 mentioned that mortality was not significantly different between groups, but did not give figures. (Ankola 1993 mentioned that one control patient died "during the period of this data collection").

DISCUSSION

The one excluded study (McDonald 1984) compared full systemic heparinization using 20 - 25 U/kg/hr of heparin to heparinization of the infusate (1 - 2 U/mL). The first 19 infants in the study were reported in an abstract. The incidence of aortic thrombosis, determined by aortography, was reported as 1/11 with full heparinization vs. 4/8 with heparinized infusate. These proportions are not statistically significant by Fisher exact test. The abstract stated that the intervention was "without complications including ICH". We will attempt to obtain further information regarding this study. In particular, the incidence of intracranial hemorrhage will be sought.

Heparinization of the infusate appears to be effective in reducing the incidence of catheter occlusion. This leads to an increase in the usable lifespan of the catheter. There is not a statistically significant effect of heparinization on the frequency of aortic thrombi. However, the confidence intervals for this effect are wide, as only 134 infants have been evaluated for this common and important outcome. Thus it remains possible that a decrease in aortic thrombosis of as much as 50% could have been missed in the studies published to date. The lack of documented effect of heparin on aortic thrombosis, if confirmed in further studies, may suggest

that mechanical factors may be more important, or that systemic anticoagulation may be necessary to prevent this complication. Clinically apparent ischemic phenomena were also unaffected by heparinization, again suggesting that mechanical factors may be most important in determining the frequency of blue or white toes.

There was no effect of routine use of heparin on mean values of coagulation tests or on analyses of clotting factors. The decrease in AT3 demonstrated by Chang 1997 is of questionable significance, in general heparin administration has been associated with an increase in AT3 levels, so a slight decrease, which remained within the accepted normal range is of uncertain significance. The wide range of administered heparin doses means that there remains a possibility of an effect of heparin on coagulation in that group of infants who receive greater volumes of heparinized fluids.

Adverse effects were not noted. The incidence of intraventricular hemorrhage was not different between groups, but it must be remembered that almost all of these studies included infants of all gestational ages, many of whom would be at very low risk for this complication. A relatively small number of infants have been evaluated for extensive intracranial hemorrhage (n = 254). The confidence intervals for effect on intracranial hemorrhage are very wide and still include the possibility that routine addition of heparin to umbilical artery catheters doubles the incidence of grade 3 and 4 hemorrhages! The actual total dose of heparin differed widely because of varying infusion rates, and was not standardized between groups. Infants who receive the highest doses of heparin may be at increased risk for intraventricular hemorrhage as suggested by two epidemiologic studies (Lesko 1986; Malloy 1995).

Mortality was also not significantly affected by heparinization (n evaluated = 316), but again the confidence intervals are very wide. There are no clear data on the frequency of necrotising enterocolitis which was an outcome variable in only one study (the incidence in both groups was zero, Ankola 1993).

AUTHORS' CONCLUSIONS

Implications for practice

Heparinization of fluids administered via umbilical arterial catheter appears to decrease the incidence of catheter occlusion, so prolonging the life of the catheter. The effective concentration may be as low as 0.25 units/mL. Until further data are available it appears to be reasonable to use the lowest effective concentration of heparin to maintain catheter patency.

Implications for research

Further research should evaluate the efficacy of using even lower concentrations of heparin. Other methods for reducing catheter occlusions or preventing aortic thrombosis, such as the use of heparin bonded catheters, should be compared to heparinization. Because of the imprecision of our estimates of the risk of heparinization of infusates on hemorrhagic complications and the effects on major thrombotic complications, further research must adequately assess the incidence of aortic thrombosis and of major intraventricular hemorrhage.

CHARACTERISTICS OF STUDIES

Characteristics of included studies [ordered by study ID]

Ankola 1993

Methods	Single center randomized study. Masking of allocation; not described. Masking of intervention; No. Completeness of follow up; Yes. Masking of outcome; No.	
Participants	30 term and preterm infants.	
Interventions	Heparin at 0.25 units/mL, or no heparin, in the infusate. Flush solutions did not contain heparin.	
Outcomes	Catheter occlusion, intraventricular hemorrhage, PT, PTT were only measured in the heparin group. Blue toes.	
Notes		
Risk of bias		
Bias	Authors' judgement	Support for judgement
Adequate sequence generation?	Unclear risk	No details of the randomization process are given.

Umbilical artery catheters in the newborn: effects of heparin (Review)

Ankola 1993 (Continued)

Allocation concealment?	Unclear risk	No method for masking allocation is described, no details of the randomization process are given.
Blinding? All outcomes	High risk	Masking of intervention: Not attempted. Masking of Outcome: Not attempted.
Incomplete outcome data addressed? All outcomes	Low risk	Completeness of follow-up: All patients are accounted for.

Bosque 1986

Methods	Randomised single center study. Masking of allocation; appears not to have been done. Masking of intervention; No. Completeness of follow up; Yes. masking of outcome; No.	
Participants	47 preterm and term infants stratified by birth weight.	
Interventions	Infants received either heparin at a dose of 1 unit/mL added to the infusate and no heparin in the solution used to flush the catheter, or no heparin in the infusate and 1 unit/mL to the flush solution.	
Outcomes	Clotting studies (PT and PTT), incidence of catheter occlusion, duration of catheter usability.	
Notes		

Risk of bias

Bias	Authors' judgement	Support for judgement
Adequate sequence generation?	Low risk	Allocation was determined by a table of random numbers and "a separate pad of paper was used for each weight group".
Allocation concealment?	High risk	There does not appear to have been adequate allocation concealment.
Blinding? All outcomes	High risk	Masking of Intervention: Not attempted. Masking of outcome: Not attempted.
Incomplete outcome data addressed? All outcomes	Low risk	Completeness of follow-up: All infants appear to have been accounted for.
Free of other bias?	Unclear risk	Other Comments: Hypothesis not described. Study was stopped when it was found that all of the occlusions were in the flush only group, and that the difference was statistically significant.

Chang 1997

Methods	Single center masked prospective controlled trial. Masking of allocation; yes. Masking of intervention; yes. Completeness of follow up; yes. Masking of outcome; yes.	
Participants	Preterm infants, <31 weeks gestational age, who had umbilical catheters placed. Either arterial or venous catheters or both were acceptable.	
Interventions	Addition of heparin 1 unit/mL to the infusate, compared to placebo. No heparin in the flush solution.	

Umbilical artery catheters in the newborn: effects of heparin (Review)

Chang 1997 (Continued)

Outcomes Intraventricular hemorrhage diagnosed by a head ultrasound at 1 week of age was the primary outcome variable. Secondary outcomes included clotting times (PT, PTT) and coagulation factor assays (fibrinogen, AT3).

Notes

Risk of bias

Bias	Authors' judgement	Support for judgement
Allocation concealment?	Low risk	Masking of allocation: Randomization was revealed only to the pharmacist involved and therefore this appears to have been adequate.
Blinding? All outcomes	Low risk	Masking of intervention: This was a placebo controlled masked study. Masking of outcome: It appears that the interpretation of the ultrasounds was performed by a single masked radiologist, and this was therefore adequate.
Incomplete outcome data addressed? All outcomes	Unclear risk	Completeness of follow-up: Outcomes are described for all except 5 infants deleted from analysis as they contravened exclusion criteria.
Free of other bias?	Unclear risk	Other comments: Both venous and arterial lines were studied in this trial.

David 1981

Methods Single center randomized study. Masking of allocation; Yes. Masking of intervention; No. Completeness of follow up; Yes. Masking of outcome; No.

Participants 50 term and preterm infants requiring umbilical arterial catheterisation for clinical care.

Interventions Heparin at 1 unit/mL in the infusate and the flush compared to no heparin in either the infusate or the flush.

Outcomes Clinical ischemic phenomena, hematuria, clotting studies, Aortic thrombi on aortograms performed after 24 to 72 hours or at autopsy.

Notes

Risk of bias

Bias	Authors' judgement	Support for judgement
Adequate sequence generation?	Low risk	Allocation clearly described: A pad containing randomly ordered group designations was used, the top page torn off for each patient, assignments not visible until torn off.
Allocation concealment?	Low risk	Masking of allocation: As noted above. A pad containing randomly ordered group designations was used, the top page torn off for each patient, assignments not visible until torn off.
Blinding? All outcomes	High risk	Masking of intervention: Not attempted. Masking of outcome: Not attempted for most outcomes, aortograms were read by a radiologist unaware of group assignment.

David 1981 (Continued)

Incomplete outcome data addressed? All outcomes	Low risk	Completeness of follow-up: Yes.
--	----------	---------------------------------

Horgan 1987

Methods	Single center randomized study. Masking of allocation; No. Masking of intervention; No. Completeness of follow up; Yes. Masking of Outcome; No.
Participants	111 infants "randomly" allocated to one of four nurseries, two of which used heparin and two of which didn't.
Interventions	Heparin at 1 unit/mL in the infusate, running at 2 mL/hr. The flush solutions did not contain heparin.
Outcomes	Frequency of catheter occlusion. Aortic thrombosis by ultrasound within 12 to 24 hours after catheter removal, PT and PTT.

Notes

Risk of bias

Bias	Authors' judgement	Support for judgement
Allocation concealment?	High risk	Masking of Allocation: Not attempted.
Blinding? All outcomes	High risk	Masking of Intervention: Not attempted. Masking of outcome: Not attempted.
Incomplete outcome data addressed? All outcomes	Unclear risk	Completeness of follow-up: All infants appear to have been accounted for. The numbers of infants who actually had ultrasounds is not stated, even though two infants had aortic thrombosis diagnosed by clinical symptoms alone.
Free of other bias?	Unclear risk	Other comments: Hypotheses stated, authors do not describe how they arrived at a sample size.

Rajani 1979

Methods	Single center randomized study. Masking of allocation; yes. Masking of intervention; Yes. Completeness of followup; Yes. Masking of outcome; Yes.
Participants	62 term and preterm infants requiring umbilical arterial catheterisation for clinical therapy.
Interventions	Heparin at 1 unit/mL or placebo (5% dextrose) added to UAC fluid. No heparin was added to the flush solution.
Outcomes	Clinical ischemic phenomena, catheter occlusion, PT and PTT.

Notes

Risk of bias

Bias	Authors' judgement	Support for judgement
-------------	---------------------------	------------------------------

Rajani 1979 (Continued)

Allocation concealment?	Low risk	Masking of allocation: This appears to have been adequate.
Blinding? All outcomes	Low risk	Masking of intervention: This was placebo controlled fully masked study. Masking of outcome: Yes.
Incomplete outcome data addressed? All outcomes	Low risk	Completeness of follow-up: All infants accounted for.
Free of other bias?	Unclear risk	Other comments: Hypothesis stated, No sample size determination is described. Life table analysis of catheters with and without heparin was performed.

Characteristics of excluded studies [ordered by study ID]

Study	Reason for exclusion
McDonald 1984	Abstract only published; data not given in sufficient detail to analyze. This was a comparison of heparinization of the infusate to complete systemic heparinization of the infant. Reported as a "trial in progress".

DATA AND ANALYSES
Comparison 1. Heparin in infusate compared to no heparin

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 Catheter occlusion prior to removal	5	299	Risk Ratio (M-H, Fixed, 95% CI)	0.19 [0.10, 0.33]
1.1 Studies comparing heparin in the infusate to no heparin	4	252	Risk Ratio (M-H, Fixed, 95% CI)	0.20 [0.11, 0.35]
1.2 Studies comparing heparin in the infusate to heparin only in the flush	1	47	Risk Ratio (M-H, Fixed, 95% CI)	0.09 [0.01, 1.52]
2 Aortic thrombosis	2	134	Risk Ratio (M-H, Fixed, 95% CI)	0.71 [0.42, 1.22]
3 Hypertension	1	111	Risk Ratio (M-H, Fixed, 95% CI)	0.05 [0.00, 0.78]
4 Intraventricular hemorrhage, grade 3 and 4	3	254	Risk Ratio (M-H, Fixed, 95% CI)	1.07 [0.58, 1.99]
5 Clinical ischemic phenomena	3	139	Risk Ratio (M-H, Fixed, 95% CI)	1.28 [0.66, 2.48]
6 Death	4	316	Risk Ratio (M-H, Fixed, 95% CI)	0.87 [0.50, 1.49]

Analysis 1.1. Comparison 1 Heparin in infusate compared to no heparin, Outcome 1 Catheter occlusion prior to removal.

Analysis 1.2. Comparison 1 Heparin in infusate compared to no heparin, Outcome 2 Aortic thrombosis.

Analysis 1.3. Comparison 1 Heparin in infusate compared to no heparin, Outcome 3 Hypertension.

Analysis 1.4. Comparison 1 Heparin in infusate compared to no heparin, Outcome 4 Intraventricular hemorrhage, grade 3 and 4.

Analysis 1.5. Comparison 1 Heparin in infusate compared to no heparin, Outcome 5 Clinical ischemic phenomena.

Analysis 1.6. Comparison 1 Heparin in infusate compared to no heparin, Outcome 6 Death.

WHAT'S NEW

Date	Event	Description
4 August 2009	New search has been performed	This review updates the existing review "Umbilical artery catheters in the newborn: effects of heparin" published in the Cochrane Database of Systematic Reviews (Barrington 1999). Updated search found no new trials. No changes to conclusions.

HISTORY

Protocol first published: Issue 1, 1999

Review first published: Issue 1, 1999

Date	Event	Description
22 October 2008	Amended	Converted to new review format.

CONTRIBUTIONS OF AUTHORS

Keith Barrington (KB) wrote the original review and updated the review in 1999.

The 2009 update was conducted centrally by the Cochrane Neonatal Review Group staff (Yolanda Montagne, Roger Soll, Diane Haughton) and reviewed and approved by KB.
