Abstract

Background—Researchers have documented that child maltreatment is associated with adverse long-term consequences for mental health, including increased risk for depression. Attempts to conduct meta-analyses of the association between different forms of child maltreatment and depressive symptomatology in adulthood, however, have been limited by the wide range of definitions of child maltreatment in the literature.

Objective—We sought to meta-analyze a single, widely-used dimensional measure of child maltreatment, the Childhood Trauma Questionnaire, with respect to depression diagnosis and symptom scores. Participants and Setting: 192 unique samples consisting of 68,830 individuals.

Methods—We explored the association between total scores and scores from specific forms of child maltreatment (i.e., emotional abuse, physical abuse, sexual abuse, emotional neglect, and physical neglect) and depression using a random-effects meta-analysis.

Results—We found that higher child maltreatment scores were associated with a diagnosis of depression ($g=1.07$; 95% CI, 0.95–1.19) and with higher depression symptom scores ($Z=-.35$; 95% CI, .32–.38). Moreover, although each type of child maltreatment was positively associated with depression diagnosis and scores, there was variability in the size of the effects, with emotional abuse and emotional neglect demonstrating the strongest associations.

Conclusions—These analyses provide important evidence of the link between child maltreatment and depression, and highlight the particularly larger association with emotional maltreatment in childhood.

Keywords

child maltreatment; depression; abuse; neglect; meta-analysis

Depression is a significant public health concern; indeed, major depressive disorder (MDD) is the leading cause of disability worldwide (World Health Organization, 2017). Understanding the etiology of depression, and in particular mutable factors that may play a causal role, is critical for reducing risk for this recurrent and debilitating disorder (Liu, 2017). Prospective studies have documented that greater adversity in childhood is associated with more chronic depression (Klein & Kotov, 2016), more severe depression (Rhebergen et al., 2012), and a longer time to remission (Fuller-Thomson, Battiston, Gadalla, & Brennenstuhl, 2014). The role of early adversity in increasing risk for the subsequent development of depression is substantial; in fact, Kessler et al. (2010) estimated that almost 25 percent of population-attributable risk is due to early adversity.

Among early adverse experiences, child maltreatment is a particularly potent risk factor for depression. Previous meta-analyses examining child maltreatment and depression have found that experiencing any form of maltreatment (treated statistically as the presence or absence of maltreatment) was associated with more than a two-fold increase in risk for depression in adulthood (Li, D'Arcy, & Meng, 2016), and with the development of chronic, or recurrent, depression (Nanni, Uher, & Danese, 2012). Although sexual abuse has received the most empirical attention (see Liu, 2017), it is noteworthy that different types of maltreatment frequently co-occur (Petersen, Joseph, & Feit, 2014). Thus, rather than focus on a single type of maltreatment, it is important to characterize the relation between different types of child maltreatment and depression. This perspective is supported by the emerging theory that early experiences that are characterized by threat (e.g., abuse) have different effects on the emergence of psychopathology than do early experiences characterized by a lack of species-expected input (e.g., neglect; Humphreys & Zeanah, 2015). Further, although physical, sexual, and emotional abuse have all been linked to depression (Mullen, Martin, Anderson, Romans, & Herbison, 1996), their different prevalence rates (Edwards, Holden, Felitti, & Anda, 2003), and their differential links to depressogenic features (e.g., low self-esteem following emotional abuse; Mullen et al., 1996), underscores the importance of careful examination of different forms of maltreatment with depression.

Previous meta-analyses examining the association between maltreatment and depression are informative. However, while important, all are limited either by small number of available studies (e.g., 8 for Li et al., 2016; 12 for Infurna et al., 2016; 16 for Nanni et al., 2012) or by considerable variability in how child maltreatment was operationalized (e.g., Norman et al., 2012), which limits comparisons across studies. Given that different definitions, informants, and thresholds for characterizing maltreatment are likely to result in different patterns of findings, there is value in prioritizing the meta-analysis of studies that use a common measure to assess maltreatment. In one such example, Infurna and colleagues (2016) conducted a meta-analysis of studies using the Childhood Experience of Care and Abuse interview (CECA; Bifulco, Brown, & Harris, 1994). They also restricted their inclusion criteria to studies that required a clinical diagnosis of depression. This increased confidence

in their conclusions has a trade-off, which is that only 12 studies met inclusion criteria, which limited their ability to conduct moderator analyses. Moreover, experiences of maltreatment, as well as characterization of depression, may better be considered along a dimension (i.e., people vary in the severity of their maltreatment experiences [Humphreys & Zeanah, 2015; King, Humphreys, & Gotlib, 2019; McLaughlin, Sheridan, & Lambert, 2014] and depression to be represented both dimensionally and categorically [Ruscio & Ruscio, 2000]).

Thus, we sought to meta-analyze studies that assessed maltreatment experiences on a continuous scale using the Childhood Trauma Questionnaire (CTQ; Bernstein et al., 2003; Bernstein & Fink, 1998). The CTQ is the most widely used measure of this construct; it has been shown to have acceptable internal consistency, test-retest reliability, and strong convergence with interviews that assess child trauma (Bernstein et al., 1994). The CTQ assesses five types of maltreatment experiences (i.e., emotional abuse, physical abuse, sexual abuse, emotional neglect, and physical neglect) using a Likert-scale approach to assess the severity of each type of experience. By assessing maltreatment using a dimensional approach, and by using a single assessment measure (i.e., the CTQ), our meta-analysis maximizes consistency in the measurement of child maltreatment and increases confidence in the effect size estimates in relation to depression; moreover, this meta-analysis includes the largest set of studies and number of unique participants assessed using a single measure examined to date. Further, unlike prior meta-analyses that vary in the forms of maltreatment that were considered in their assessments, our approach allows us not only to probe associations between depression and overall maltreatment, but also to assess specific types of maltreatment measured at the same time using the same scale. Such an approach will yield insight into whether models indicating that the type of maltreatment or deviation from an expectable environment are differentially associated with depression (including neglect versus abuse; see Humphreys & Zeanah, 2015; McLaughlin & Sheridan, 2016; McLaughlin et al., 2014; or emotional maltreatment versus physical or sexual maltreatment). Finally, by including studies that examined depression using either a group-based approach (e.g., diagnoses) or a continuous approach (e.g., depression symptom scores), we can examine the strength and specificity using two widely used approaches to the assessment of depression.

Method

Study Selection

Each study satisfied the following inclusion criteria: (a) dimensional measurement of child maltreatment using the CTQ (either the long or short form); (b) dichotomous or dimensional assessment of depression; and (c) available data to calculate effect sizes (i.e., standardized mean difference in studies examining depression group and *Z* in studies examining depression scores).

Search Procedure—We used several strategies, outlined in the PRISMA flowchart (Figure 1), to identify the 190 journal articles with 192 independent samples that were ultimately included in this meta-analysis. First, we conducted computer-based searches using PubMed and Ovid for the following terms (or stems when appropriate) appearing

anywhere in the manuscript: (depress* OR MDD) AND (ctq OR “child trauma questionnaire” OR “childhood trauma questionnaire”). Second, we reviewed the bibliographies for additional studies using forward and backward searching. Third, we sent emails describing our meta-analysis and its inclusion criteria to professional membership LISTSERVs of research organizations including the Society for a Science of Clinical Psychology, the Association for Behavioral and Cognitive Therapies, and Division 53. The majority of reviewed studies were excluded due to the presence of confounding medical conditions (e.g., heart disease, diabetes, cancer), the lack of examination of CTQ as a predictor for MDD, and insufficient data for our quantitative analysis.

Data Extraction—Two trained raters independently coded each study. When raters provided contradictory judgments, disagreements were discussed and the lead authors made a final determination.

Moderator Variables—When heterogeneous effect sizes were detected, we tested whether potentially important demographic and methodological factors moderated the association between child maltreatment and depression. These moderators were selected on the basis of both recommendations from experts in meta-analysis (Lipsey & Wilson, 2001) and of prior work by the authors (Humphreys, Eng, & Lee, 2013; LeMoult et al., 2019; Muscatell, Humphreys, & Brosso, 2018). We coded the following demographic characteristics: (a) mean age of the sample at the depression assessment (in years) and whether the mean age was above or below age 18 years; (b) sex composition (percent male); and (c) racial diversity (percent Caucasian). We coded the following methodological characteristics of each study: (a) sample size; (b) year published; (c) sample source (i.e., clinic-referred; community; population-based; other); (d) assessment used to determine depression (i.e., Structured Clinical Interview for the Diagnostic and Statistical Manual [SCID] vs. other) or symptom scale (i.e., Beck Depression Inventory [BDI]; Center for Epidemiologic Studies Depression Scale [CES-D] vs. other); (e) whether the original 53 item version of the CTQ was used (vs. 25/28 item short-form); and (f) the language in which the measures were given (i.e., English vs. other).

Calculation of Effect Size—We calculated two different types of effect sizes depending on whether depression was operationalized as a dichotomous (diagnosis of depression) or a dimensional (depression scores) measure. When depression was operationalized as a dichotomous measure, we calculated the Hedge’s g standardized mean difference (SMD) in order to estimate the effect size of the association between child maltreatment total scores and the onset of a diagnosis of depression. An estimate of 0 for the SMD effect size indicated that child maltreatment scores were equivalent in individuals with and without depression, whereas an SMD greater than 0 indicated that the depressed group had higher scores on the CTQ than did individuals without depression, and an SMD less than 0 indicated that the depressed group had lower scores on the CTQ than did those without depression. When depression was operationalized dimensionally, we calculated the bivariate association between child maltreatment scores and depression scores by converting correlations and standardized β to Z values. A Z estimate of 0 indicated no association between child maltreatment and depression, whereas a Z value greater than 0 or less than 0

indicated that maltreatment had a positive or negative association, respectively, with depression scores. The 95 % confidence interval (CI) for the effect size represents the relative precision of the measurement (wider ranges are less precise). For each study, we calculated as many as 12 effect sizes: the two forms of depression measurement (diagnosis and scores) by CTQ total scores and the five types of child maltreatment. These procedures produced 609 total effect sizes estimated from 190 eligible studies. The number of studies were 39 for CTQ total score by depression *group* and 70 for CTQ total score by depression *scores* (see Tables 2 and 3).

Statistical analysis—We conducted random-effects models and estimated heterogeneity of effect sizes using the standard Cochran’s *Q* Test, which indicates the degree of consistency of findings across studies and approximates a chi-square distribution with $k-1$ degrees of freedom, where k is the number of effect sizes (Hedges & Olkin, 1983). A nonsignificant *Q* test statistic suggests that the pooled OR represents a unitary effect. When the *p*-value associated with the *Q* statistic was equal to or less than .05, we conducted random-effects meta-regression analyses to determine whether the study characteristics described above could explain variability across studies. We assessed publication bias via Egger’s test (Egger et al., 1997). When we observed heterogeneous effect sizes, we conducted leave-one-out sensitivity analyses to test whether a single study unduly influenced effect size estimates. In addition, we examined whether any of the moderator variables predicted significant variance in the effect sizes that had significant heterogeneity. We used STATA 14 to conduct the analyses.

Results

Table 1 presents descriptive information for each included study, including details of demographic and methodological moderators coded and outcomes obtained. Extracted and coded data is available and can be obtained by emailing the lead author.

Child Maltreatment and Continuous Depression Scores

The number of studies that examined the relation between severity of child maltreatment and depression scores was 70 for total CTQ scores, and ranged from 48 (physical neglect) to 81 (emotional abuse) for the subtype CTQ scores. Overall, there was a significant association between child maltreatment and depressive symptoms (Figure 2). The effect size estimates varied by type of child maltreatment: estimates were highest for emotional abuse and lowest for sexual abuse. All effect sizes differed significantly from 0, indicating a significant association between all types of child maltreatment and depression scores. Variation of the effect size within each meta-analysis is presented in Table 2. In addition, there was evidence of significant heterogeneity for all outcomes.

Child Maltreatment and Depression Diagnosis

The number of studies that examined the relation between severity of child maltreatment and diagnosis of MDD as 39 for total CTQ scores and 35 for each of the subtype CTQ scores. As with the correlational analyses, there was a significant association between total CTQ scores and a diagnosis of depression (Figure 3). The random-effects meta-analysis indicated that

individuals with depression reported higher child maltreatment scores than did individuals without depression, an effect that differed significantly from zero. The effect size estimates varied by type of child maltreatment: they were highest for emotional neglect and lowest for sexual abuse. All effect sizes obtained from meta-analyses differed significantly from zero, indicating a significant association between all types of child maltreatment and depression scores. Variation of the effect size within each meta-analysis is presented in Table 3. In addition, there was evidence of significant heterogeneity for all outcomes.

Moderators—We examined both methodological and demographic study-level variables that may explain variation in effect sizes within studies for each outcome (see Method for moderator variables of interest). We tested each coded moderator separately using simple regressions, weighted by the sample size for each study. Statistically significant moderators are presented by outcome in Tables 2 and 3. For total CTQ score and depressive symptoms, community samples were associated with larger effect size relative to other participant sources ($t(69) = 3.18, p = .002$). When the studies were divided based on whether the samples were drawn from the community vs. all others (e.g., clinic, population-based, etc.), we observed that the 48 samples not drawn from the community had a statistically significant ($Z = 16.08, p < .001$), but somewhat smaller estimate of the effect size ($Z = .32$ [95% CI, .28–.36]) than did the 22 studies of community participants ($Z = .43$ [95% CI, .37–.49]), whose overall effect statistically differed from zero ($Z = 14.06, p < .001$). In addition, studies that used the CES-D, relative to other measures (e.g., BDI, etc.), on average had larger effect sizes ($t(69) = 2.34, p = .022$). Again, when the studies were divided based on the depression assessment measure, we found that studies that used the CES-D ($n = 11$) had a larger effect size estimate ($Z = .43$ [95% CI, .36–.51]) than did studies that did not use the CES-D ($n = 59$) ($Z = .34$ [95% CI, .30–.37]), although both sets of studies had effects that differed significantly from zero).

For emotional abuse, whether the mean age of the sample fell into childhood or adulthood (i.e., split based on the mean age of 18 years) emerged as a significant moderator ($t(80) = 2.34, p = .022$). Analyses conducted within the 20 studies with child/adolescent samples yielded a larger association ($Z = .45$ [95% CI, .35–.54]) than did the 59 studies that included adults ($Z = .36$ [95% CI, .32–.39]), although in both cases the estimates significantly differed from zero ($Z = 9.28, p < .001$ and $Z = 20.86, p < .001$, respectively) and remained significantly heterogeneous. For this outcome, sample source was also significantly associated with effect size, such that population-based samples had smaller effect sizes than did other sample sources ($t(80) = -3.12, p = .003$). When the two studies that were population-based (i.e., Mikaeili, Barahmand, & Abdi, 2013; Schulz, Schmidt, et al., 2014) were excluded, the overall effect was similar to the full analyses ($Z = .38$ [95% CI, .35–.41]) and the effect statistically differed from zero ($Z = 24.72, p < .001$). In addition, year of publication was significantly associated with effect size (Coef. = 0.01, SE = 0.004; $t(80) = 2.35, p = .021$): on average, more recently published papers had larger effects. For both emotional neglect and physical neglect, population-based samples had smaller effect sizes than did other sample sources (emotional neglect: Coef. = -0.21, SE = 0.07; $t(57) = -2.87, p = .006$; physical neglect: Coef. = -0.21, SE = 0.10; $t(47) = -2.04, p = .047$). When population-based samples were excluded, the overall effect was just slightly larger relative to

the full analyses (emotional neglect: $Z = .31$ [95% CI, .27–.34], physical neglect: $Z = .24$ [95% CI, .20–.27]); the effects of non-population-based samples on depression differed statistically from zero (emotional neglect: $Z = 17.24$, $p < .001$, physical neglect: $Z = 14.34$, $p < .001$).

Finally, for the depression group analyses, a significantly larger effect size was found in studies that used the full 53-item version of the CTQ to assess the association between total CTQ score and depression group ($t(38) = -2.62$, $p = .013$). Analyses were repeated in the 11 studies that used the original version and the 28 studies that used the short form; in both sets, the effect size estimates differed significantly from zero (CTQ-53: $g = 1.64$ [95% CI, 1.14–2.14], $Z = 6.45$, $p < .001$ and CTQ-SF: $g = 0.93$ [95% CI, 0.82–1.05], $Z = 15.59$, $p < .001$). In addition, for CTQ total scores, the language in which the measure was administered moderated the observed effect size: studies conducted in English had smaller effect sizes than did non-English studies (Coef. = 0.50, SE = 0.22, $t(38) = 2.23$, $p = .032$); both English and non-English studies had effect size estimates that differed significantly from zero (English: $g = 1.40$ [95% CI, [1.10, 1.70], $Z = 9.09$, $p < .001$; non-English: $g = 0.89$ [95% CI, [0.80, 0.99], $Z = 18.45$, $p < .001$). The same pattern was found for both sexual abuse (English: $g = 0.65$ [95% CI, [0.48, 0.82], $Z = 7.40$, $p < .001$; non-English: $g = 0.37$ [95% CI, [0.31, 0.42], $Z = 12.46$, $p < .001$) and emotional neglect (English: $g = 1.17$ [95% CI, [0.93, 1.42], $Z = 9.29$, $p < .001$; non-English: $g = 0.85$ [95% CI, [0.73, 0.96], $Z = 14.16$, $p < .001$).

Publication Bias—For CTQ total score and depressive symptoms, the Egger’s test revealed statistically significant bias ($t(69) = -2.02$, $p = .047$). The negative intercept (Coef. = -0.91 , SE = 0.45) indicates that the effects from the smaller studies are less than the effects from the larger studies, indicating that small studies are not upwardly biasing the estimate. A trim and fill procedure identified 0 missing studies. For emotional abuse, there was evidence of publication bias. The Egger’s test was statistically significant ($t(80) = 2.41$, $p = .018$), with a positive intercept (Coef. = 1.42, SE = 0.59) indicating that smaller studies may be upwardly biasing the effect. A trim and fill procedure identified 27 missing studies, with a filled meta-analysis estimate of $Z = .29$ (95% CI, .25–.33).

For the group-based analyses, there was evidence of publication bias from Egger’s test for total CTQ scores (Coef. = 1.31, SE = 0.56, $t(34) = 2.32$, $p = .026$), emotional neglect (Coef. = 1.40, SE = 0.45, $t(34) = 3.12$, $p = .004$), physical neglect (Coef. = 1.52, SE = 0.51, $t(34) = 2.97$, $p = .005$). In all cases, smaller studies may have been upwardly biasing estimates. Trim and fill procedures indicated the following corrected effect size estimates for total CTQ scores: $g = .88$ (95% CI, 0.74–1.02; 8 missing), emotional neglect; $g = .77$ (95% CI, 0.65–0.90; 12 missing), and physical neglect: $g = .49$ (95% CI, 0.35–0.63; 10 missing). In all cases, these revised estimates had effects that differed significantly from zero. No other associations were characterized by statistically significant tests of publication bias.

Leave-one-out Sensitivity Analyses—Given the significant heterogeneity in effects, we conducted sensitivity analyses for all of the outcomes using the leave-one-out approach (i.e., conducting the random-effects model following the removal of each study individually, with replacement). Tables 2 and 3 provide data indicating that no single study unduly

influenced the effect size estimates; in all cases in which a study was removed, the effect size estimates remained significantly different from zero.

Discussion

In this paper we report the result of a meta-analysis of 192 unique samples from 190 studies, consisting of 68,830 individuals, conducted to test whether child maltreatment was associated with depression diagnosis and symptom scores in adulthood. This is the largest study examining the association between child maltreatment and depression, increasing our confidence in the strength of the observed effect sizes. Across both methods of assessing depressive symptomatology, we found a significantly increased risk for higher depression symptom scores and depressive disorders (typically meeting criteria for MDD) as a function of greater reported severity of child maltreatment. In addition, in order to examine whether there was specificity in the association between different types of child maltreatment and depression, we conducted analyses across five types of maltreatment, all assessed using the same measure of child maltreatment (i.e., the CTQ). Consistent with expectations, we found that all types of maltreatment were associated with significantly higher depression scores and greater risk for meeting criteria for MDD. Importantly, however, emotional abuse and emotional neglect had the strongest associations with depression; we found weaker associations for sexual and physical abuse and physical neglect. In addition, the magnitude of the effect between emotional abuse and depressive symptoms was larger in samples of children and adolescents than in samples of adults.

The estimated effect size between child maltreatment scores and later depression was large; specifically, individuals with depression had, on average, total child maltreatment scores that were approximately one standard deviation higher than scores of their nondepressed counterparts. Even after applying a trim-and-fill procedure following the identification of possible publication bias favoring smaller studies with larger effects, the estimated effect size was almost one standard deviation difference between groups. These effects are substantially larger than those previously reported, which is bolstered by the large number of unique individuals who contributed data to these analysis and the advances in methods by including a dimensional assessment of child maltreatment. For example, across 9 studies, a composite measure of childhood maltreatment was reported to be moderately associated with a diagnosis of depression, although the confidence interval included zero (SMD=0.43; Infurna et al., 2016). It is possible that this discrepancy is due to differences in the scales used in these two meta-analyses (CTQ vs. CECA); for example, the range of possible scores is substantially greater in the CTQ and, further, many of the studies in Infurna et al.'s study used dichotomized experiences of maltreatment rather than applying a dimensional approach to assessing maltreatment.

Although all forms of child maltreatment examined in the present study were significantly associated with depression, the strength of the association varied by type of maltreatment. Three prior meta-analyses are relevant in interpreting these findings. Mandelli, Petrelli, and Serretti (2015) meta-analyzed studies that examined the association between binary measures of child maltreatment and diagnosed depression. These investigators found that emotional abuse (k=8) and neglect (k=6) were most strongly associated with depression

(ORs=2.8), and reported a weaker association for physical abuse (k=10; OR=2.0). Infurna et al. (2016) found that psychological abuse and neglect were the types of maltreatment most strongly associated with depression, and reported weaker, although still statistically significant, associations for sexual abuse. Finally, Norman et al. (2012) examined three forms of child maltreatment in relation to depressive disorders, and found the strongest association with emotional abuse (OR=3.06), followed by neglect, broadly defined (OR=2.11), and the weakest association for physical abuse (OR=1.54). While all three effect estimates differed significantly from zero, the effect estimate for emotional abuse and depression was significantly stronger than that for physical abuse and depression. In the present study, although effect size estimates varied across types of maltreatment, for depression diagnosis we found that emotional abuse differed significantly from physical abuse and sexual abuse, and that emotional neglect differed significantly from physical abuse, sexual abuse, and physical neglect, as represented by non-overlapping CIs. Such findings suggest that, for depression, predictions are less informed by whether maltreatment experiences are characterized by threat versus deprivation (e.g., McLaughlin et al., 2014; Sheridan & McLaughlin, 2014); instead, emotional maltreatment in particular could be depressogenic.

Importantly, more “silent” forms of child maltreatment (i.e., emotional abuse and emotional neglect) are most strongly associated with depression. This finding is consistent with theoretical and empirical accounts of maltreatment and depression. Compared to sexual and physical abuse, emotional neglect has been found to be uniquely associated with anhedonic symptoms of depression (Van Veen et al., 2013). Furthermore, Rose and Abramson’s (1992) developmental extension of the hopelessness theory of depression provides a framework through which to view the potential differential effects of emotional maltreatment. Rose and Abramson hypothesized that emotional abuse leaves individuals particularly vulnerable to developing a negative cognitive style, which in turn increases risk for depression. According to this formulation, children seek to understand the cause of the adverse life events they experience. Initially, these explanations are external, unstable, and specific (e.g., concluding that the cause of the abuse is not due to their stable characteristics of themselves, but instead, to some outside, isolated reason—for example, a parent having a stressful day). However, in the case of recurrent abuse, children may develop a more depressogenic causal attribution for the abuse (i.e., an attribution that is internal, stable, and global). In this context, emotional abuse may be particularly detrimental to children’s cognitive style because the abuser may state the negative causal attribution to the child (e.g., being called names). This formulation is supported by empirical work: emotional maltreatment during childhood has been found to be associated with negative self-referential processing (Steinberg, Gibb, Alloy, & Abramson, 2003), one potential risk pathway for depression. Our findings suggest that emotional neglect plays a similarly harmful role; thus, a depressive cognitive style may stem not only from the communication of negative cognitions, as in the case of emotional abuse, but also from lack of emotional support, as is the case with emotional neglect.

Among the moderators examined in this study, sample source and language used (i.e., English vs. other languages) emerged as particularly salient in relation to the size of effects that were estimated. Specifically, population-based studies demonstrated smaller associations than did other study recruitment sources. Sample source has also been found to

be a relevant moderator in other studies; our findings are similar to those documenting a stronger association between child maltreatment and depression in clinical than in population-based samples (Infurna et al., 2016). Type of sample (i.e., community vs. clinical) has been found to be associated with type of maltreatment and risk for depression (Mandelli et al., 2015); across sample types, these investigators found a strong association between neglect and depression; in contrast, in community samples emotional abuse was a stronger predictor of depression. In addition, studies conducted in English had larger effect sizes, on average, than did those conducted in other languages. Language is confounded with geography and cultural factors, and it is difficult to disentangle which of these may be responsible for explaining the differences in effect size based on this moderator. In addition, we found significant evidence of publication bias in several of the meta-analyses here. Our analyses conducted to identify what is more likely to be unbiased effects all continue to demonstrate a significant association between maltreatment and depression, although the effect sizes are lower and are more likely to be an accurate estimate of the magnitude of the associations.

Despite the plausibility that other moderators (e.g., sex, age of participants) are meaningful in understanding the link between child maltreatment and depression, for nearly all outcomes we found no significant evidence that the size of the effect was explained by these factors. For emotional abuse, however, we did find evidence of a larger effect in the relation to child depressive symptoms than those found in adult samples. Such findings may indicate that the association between emotional abuse and depression symptoms weakens over time and as individuals enter adulthood.

We should note five limitations of the present meta-analysis. First, because the studies analyzed for this meta-analysis were cross-sectional, we cannot speak to a direct causal link between emotional maltreatment and depression. In this context, there may be gene-environment correlations for depression and maltreatment, given that parents with depression not only are passing on their genes, but also are more likely to engage in child maltreatment (Widom, DuMont, & Czaja, 2007). Second, the types of child maltreatment assessed in this meta-analysis do not occur independent of one another. Experiences of maltreatment, as well as other forms of stress in early life, are not randomly distributed: children who experience any one type of maltreatment are more likely to have experienced other types (Edwards et al., 2003). We are unable to determine the independent effect of each type using this approach, and we believe it would be useful going forward to use dimensional assessments of maltreatment type to document more thoroughly the overlap between each form of maltreatment. Third, we did not require that studies conduct clinical assessments to make diagnostic determinations of depression. While there are strengths to assessing depression dimensionally (see Ruscio & Ruscio, 2000), the use of clinical instruments may better capture functional impairment in relation to depression. Fourth, the assessment of child maltreatment in these studies was retrospective. While prospective studies also support the link between child maltreatment and depression (Li et al., 2016), there may be selective or biased reporting of adversity, which could affect the observed nature of the association between child maltreatment and depression (Colman et al., 2016; Patten et al., 2015). In fact, recent meta-analyses indicate that prospective and retrospective reports of maltreatment may identify different subgroups of individuals (Baldwin, Reuben,

Newbury, & Danese, 2019), which could mean that what we documented here as potential predictive pathways may instead be a better marker of concurrent mood and recollections of past experiences. Finally, the CTQ is not without flaws. We selected this measure given its widescale use, its ability to assess maltreatment using a dimensional approach, and its assessment of different subtypes of maltreatment. However, the CTQ does not provide details about the timing of events, which are likely to be important in understanding the association between stress and depression (Teicher, 2008). It also has psychometric limitations. In particular, researchers have noted low reliability of the physical neglect subscale (Gil et al., 2009; Paivio & Cramer, 2004), that has been attributed to greater variability in the types of items included on this subscale (Bernstein et al., 1994).

In closing, the present findings underscore the association between experiences of child maltreatment and depression in adulthood. The goal of the present study was to characterize the associations between depression in adulthood and child maltreatment generally, as well as specific forms of child maltreatment. Assuming that there is a causal link between child maltreatment and depression, next steps in this line of research include probing the potential mechanisms by which these early adverse experiences may lead to a diagnosis of depression and to increased levels of depressive symptomatology in adulthood. Identifying these mechanisms will be important in understanding why treatment response has been found to be moderated by childhood maltreatment status, with individuals who endorsed child maltreatment being less likely to respond to treatment (Nanni et al., 2012). Collectively, these results highlight the importance of reducing exposure to child maltreatment as a clear policy goal. Interventions and preventions that have been shown to reduce child maltreatment are important, and include the Nurse Family Partnership (Donelan-McCall, Eckenrode, & Olds, 2009) and the Triple P (Positive Parenting Program) (Prinz, Sanders, Shapiro, Whitaker, & Lutzker, 2009). While there is likely to be immediate benefit for the children and the parents who participate in these programs, it is notable that the effects may also have long-term positive mental health outcomes (Liu, 2017). Finally, researchers must consider emotional maltreatment (i.e., emotional abuse and emotional neglect) as influencing the etiology of depression; indeed, including these more silent forms of maltreatment in relevant studies should yield important insights concerning the causes of depression and treatment targets for individuals who are experiencing this debilitating disorder.

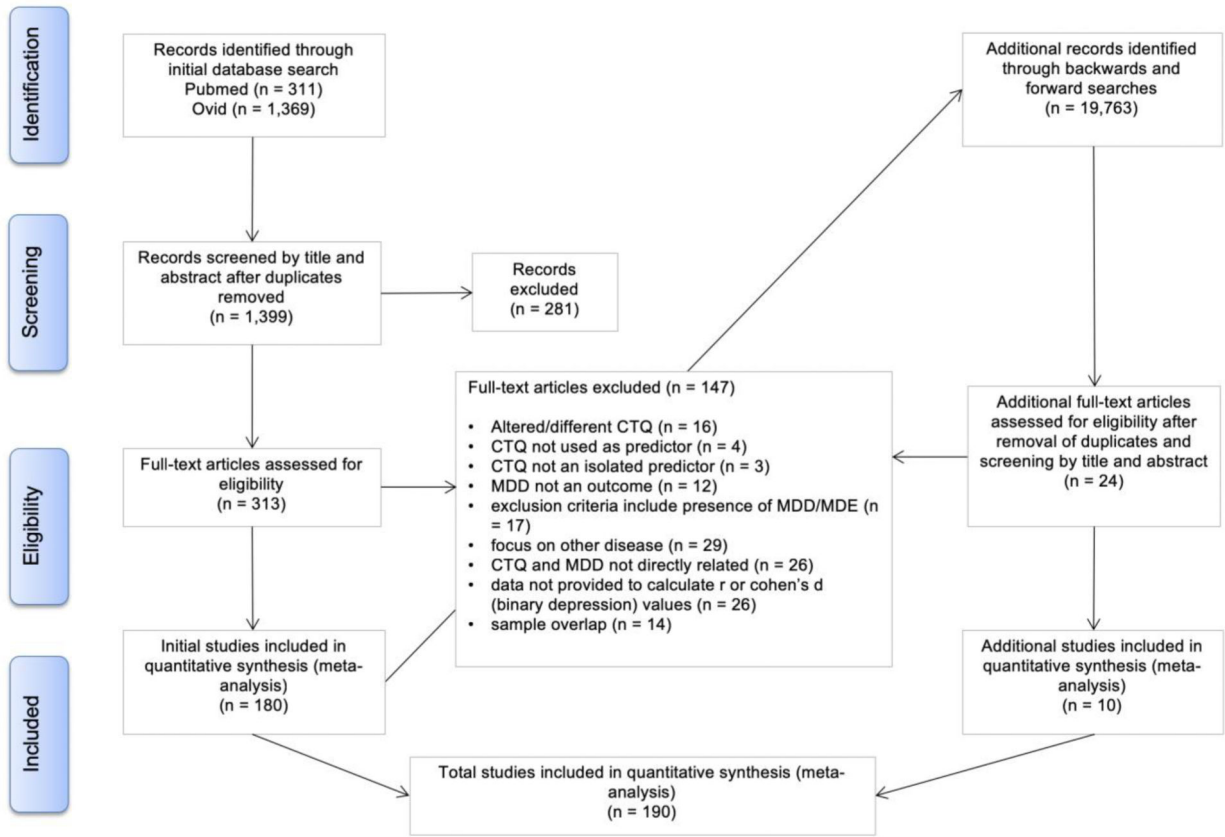

Figure 1. Identification of independent studies for inclusion in meta-analysis (PRISMA)

Figure 2. Estimated association (Z) between total childhood trauma questionnaire scores and depressive symptoms. Estimates of zero indicate no association. Positive values indicate a positive association between maltreatment scores and continuous depression scores.

Figure 3. Estimated standardized mean difference (Hedge's *g*) in childhood trauma questionnaire total scores between individuals with and without a diagnosis of depression. Estimates of zero indicate no differences, whereas an effect size of one indicates a full standard deviation difference in scores. Positive values indicate higher scores among those with a diagnosis of depression.

Note. NS = not specified. BDI = Beck Depression Inventory. BDI-FS = Beck Depression Inventory-Fast Screen. BDI-II = Beck Depression Inventory, 2nd edition. BSI = Brief Symptom Inventory. CDI = Children's Depression Inventory. CES-D = The Center for Epidemiologic Studies

Depression Scale. DASS = Depression Anxiety Stress Scales. DIS = Diagnostic Interview Schedule. EPDS = Edinburgh Postnatal Depression Scale. HAMD = Hamilton Depression Rating Scale (also known as HRSD = Hamilton Depression Rating Scale and HRSD = Hamilton Rating Scale for Depression). HSCL-25 = Hopkins Symptom Checklist-25. IDS-SR = The Inventory of Depression Symptomatology, Self-Report. MADRS = Montgomery-Asberg Depression Scale. MDI = Major Depression Index. MINI = The Mini International Neuropsychiatric Interview. PDSQ = Psychiatric Diagnostic Screening Questionnaire. PHQ = Patient Health Questionnaire. PDSS = Postpartum Depression Screening Scale (also known as PPDS = Postpartum Depression Screening Scale). PROMIS = Patient-Reported Outcomes Measurement Information System. QIDS = Quick Inventory of Depression Symptomatology. RADS-2 = Reynolds Adolescent Depression Scale, Second Edition. RCADS = Revised Children's Anxiety and Depression Scale. SCAN = Schedules for Clinical Assessment in Neuropsychiatry. SCID = Structured Clinical Interview. SCID-I = Structured Clinical Interview for Axis I Disorders. SCID-I/P = Structured Clinical Interview for Axis I Disorders, Patient Edition. SCL-90-R = Symptom Checklist-90-Revised. SDS = Zung Self-Rating Depression Scale. SMFQ = Short Mood and Feelings Questionnaire. TDS = trait depression subscale of the State-Trait Depression Questionnaire. TSCC = Trauma Symptom Checklist for Children. TSI = Trauma Symptom Inventory.

^a Provided 162 participants for the depression scores analyses, presented here, and a subset (104) for the diagnostic group analysis (42% male, mean age = 42.40).

^b Compared 10 individuals with MDD to 1000 individuals from a population representative sample.

^{**} Provided 117 participants for the diagnostic group analysis, presented here, and a subset (91) for the depression scores analyses (45% male, mean age = 36.60).

Table 2.

Summary of Meta-Analysis Statistics by Correlations Between Continuous Depression Scores and Childhood Trauma Questionnaire Scores

Outcome	k	Coeff. (95% CI)	Effect estimate differed from 0	Test for heterogeneity	I^2	Pooled Z range using leave-one-out analyses	Moderators with significant associations
Total CTQ scores	70	$Z = .35 (.32-.38)$	$Z = 21.21, p < .001$	$Q = 418.26, p < .001$	84%	.35-.36	+ in community samples; + using CES-D
Emotional Abuse	81	$Z = .38 (.34-.41)$	$Z = 22.15, p < .001$	$Q = 607.42, p < .001$	87%	.37-.38	+ year published; – in population-based samples
Physical Abuse	66	$Z = .22 (.18-.25)$	$Z = 12.70, p < .001$	$Q = 393.85, p < .001$	84%	.21-.22	--
Sexual Abuse	72	$Z = .20 (.17-.23)$	$Z = 14.22, p < .001$	$Q = 287.82, p < .001$	74%	.19-.20	--
Emotional Neglect	58	$Z = .30 (.26-.34)$	$Z = 15.83, p < .001$	$Q = 444.84, p < .001$	87%	.30-.30	– in population-based samples
Physical Neglect	48	$Z = .23 (.20-.27)$	$Z = 13.15, p < .001$	$Q = 237.41, p < .001$	80%	.23-.24	– in population-based samples

Note. CTQ = childhood trauma questionnaire.

Table 3.

Summary of Meta-Analysis Statistics by Depression Diagnosis and Childhood Trauma Questionnaire Scores

Outcome	k	Coeff. (95% CI)	Effect estimate differed from 0	Test for heterogeneity	I^2	Pooled g range using leave-one-out analyses	Moderators with significant associations
Total CTQ scores	39	$g = 1.07$ (0.95–1.19)	$Z = 16.98, p < .001$	$Q = 248.65, p < .001$	85%	1.02–1.09	+ CTQ-53; + English language
Emotional Abuse	35	$g = 0.85$ (0.77–0.94)	$Z = 18.16, p < .001$	$Q = 64.94, p < .001$	48%	0.84–0.87	--
Physical Abuse	35	$g = 0.47$ (0.37–0.57)	$Z = 9.42, p < .001$	$Q = 77.88, p < .001$	56%	0.45–0.49	--
Sexual Abuse	35	$g = 0.44$ (0.36–0.53)	$Z = 10.17, p < .001$	$Q = 58.89, p = .005$	42%	0.42–0.46	+ English language
Emotional Neglect	35	$g = 0.96$ (0.85–1.08)	$Z = 16.52, p < .001$	$Q = 102.43, p < .001$	67%	0.93–0.98	+ English language
Physical Neglect	35	$g = 0.65$ (0.53–0.78)	$Z = 10.39, p < .001$	$Q = 129.67, p < .001$	74%	0.58–0.68	--

Note. CTQ = childhood trauma questionnaire. CTQ-53 = original 53 item version of the CTQ (vs. the short form with 25 scorable items).
