Abstract

Goal: To investigate associations of pre- and post-diagnosis use of statins and metformin on overall survival of patients with diabetes who later develop HCC

Background: Statins and metformin have received considerable interest as potential chemopreventive agents against hepatocellular carcinoma (HCC) in individuals with type 2 diabetes mellitus (T2DM); however, their impact on overall survival of patients with T2DM who later develop HCC (diabetic HCC patients) is unclear.

Study: Data on 2,499 elderly diabetic HCC patients obtained from the SEER-Medicare program (2009–2013) were analyzed. Patients were categorized based on use of statins only, metformin only, both, or neither (reference for all comparisons). The patients were further categorized based on: (1) metformin dose: 1,500 **or** >1,500 mg/day; (2) statins functional form: hydrophilic (pravastatin and rosuvastatin) **or** lipophilic (atorvastatin, fluvastatin, lovastatin, and simvastatin); (3) statins potency: high (atorvastatin, rosuvastatin, and simvastatin) **or** low (fluvastatin, lovastatin, and pravastatin); and (4) individual statins type. Multivariable-adjusted hazard ratios (HR) and 95% confidence intervals (CIs) were calculated using Cox proportional hazard models.

Results: Pre-diagnosis use of metformin dose 1,500 mg/day was associated with lower risk of death after HCC diagnosis in patients with T2DM (HR=0.72, 95% CI: 0.58–0.91), adjusting for post-diagnosis metformin dose, diabetes severity, Charlson comorbidity index, tumor characteristics, and other relevant factors. No association was found for pre-diagnosis metformin dose >1500 mg/day or post-diagnosis metformin use. Further, no association was found for either pre- or post-diagnosis statins use.

Conclusions: Pre-diagnosis use of metformin dose 1,500 mg/day could improve overall survival of elderly diabetic HCC patients.

Keywords

Liver cancer; hepatocellular cancer; HCC; statins; metformin

Introduction

Hepatocellular carcinoma (HCC) is the most common form of primary liver cancer and accounts for about 80% of all liver cancer diagnoses worldwide.¹ In the United States (US), liver cancers, including HCC and the less common cholangiocarcinoma, are projected to become the third leading cause of cancer death by 2030.² Major risk factors for HCC include chronic hepatitis C virus (HCV) and hepatitis B virus (HBV) infections, alcoholic liver disease and metabolic disorders, such as type 2 diabetes mellitus (T2DM) and metabolic syndrome.³ HCC currently has a 5-year survival rate of 18%, which is due mostly to delayed diagnosis.⁴ When diagnosed at an early stage, HCC is often treated with surgical resection, liver transplantation, or radiofrequency ablation, all of which are associated with improved prognosis. Systemic medications, such as sorafenib, regorafenib and nivolumab, have also shown some modest benefits for management of advanced HCC.⁵⁻⁷ However, there remains a pressing need to identify modifiable factors that can help further prolong survival of HCC patients.

T2DM is a global epidemic.⁸ Incidence of T2DM has been increasing in the US in parallel with the increasing incidence of obesity.^{8,9} Many patients with T2DM develop HCC after the diagnosis of T2DM (diabetic HCC patients)^{10,11}, and pre-existing T2DM is now recognized as not just a risk factor for HCC but also an independent predictor of shorter survival after diagnosis of HCC.¹² T2DM is often managed with metformin, a first-line oral antihyperglycemic agent. Studies have shown that metformin is commonly taken simultaneously with statins (cholesterol lowering medications) because most patients with T2DM have also hyperlipidemia.^{13,14} Experimental studies suggest that both statins and metformin may have therapeutic potential for prolonging survival of HCC patients.^{15,16} The proposed mechanisms for the role of statins in cancer survival include cell-cycle arrest, apoptosis induction, and posttranslational modification of RAS proteins.¹⁷⁻¹⁹ Postulated anticancer effects of metformin also include attenuation of metabolic abnormalities²⁰ and suppression of the mammalian target of rapamycin (mTOR) signaling pathway that is known to enhance cancer cell proliferation.²¹⁻²³ Nonetheless, findings from epidemiologic association studies are mixed.²⁴⁻²⁷

At least two epidemiological studies have examined the association between use of statins and overall survival of HCC patients and have reported conflicting results.^{24,25} The same is the case for metformin, with at least two studies reporting a beneficial association^{26,27} and one study reporting a null association.²⁸ Although many patients taking metformin for T2DM take also statins for hyperlipidemia²⁹, none of the existing studies examined associations for combined use of statins and metformin on overall survival of diabetic HCC patients. Additionally, no study has examined associations for pre- and post-diagnosis use of

statins or metformin while adjusting for the effect of the other. Pre- and post-diagnosis statins or metformin use may have differential association with survival in HCC patients as seen in other malignancies.³⁰ These gaps in knowledge necessitate further investigations to delineate the roles of statins and metformin in survival of diabetic HCC patients. Thus, we investigated associations of pre- and post-diagnosis use of statins and metformin, both independently and jointly, on overall survival after HCC diagnosis in a nationally representative sample of elderly patients with T2DM using data from the Surveillance, Epidemiology, and End Results (SEER) registry linked to Medicare claims information (SEER-Medicare).

Material and Methods

Data Source and Study Population

Following approval by the Mayo Clinic Institutional Review Board (IRB), we obtained data from the SEER-Medicare program. A detail description of the SEER-Medicare program has been provided.³¹ In brief, the SEER program is supported by the National Cancer Institute and includes data collected from population-based cancer registries that cover 18 geographic regions: Atlanta, Georgia; Connecticut; Detroit, Michigan; Hawaii; Iowa; New Mexico; San Francisco-Oakland, California; Seattle-Puget Sound, Seattle Washington; Utah; Los Angeles, California; San Jose-Monterey, California; Rural Georgia; Alaska; Greater California; Greater Georgia; Kentucky; Louisiana; and New Jersey. The Medicare program provides payments for hospital, physician, and outpatient medical services for about 97% of US citizens of age 65 years or older.³¹ Data on cancer patients reported to SEER who are 65 years or older are linked to Medicare claims data of the respective patients for SEER-Medicare studies. The areas covered by the SEER-Medicare program represents about 25% of the general US population.³¹ The Medicare claims files include information on medical diagnosis, medical procedures, and prescription drug claims. The Medicare Part A file contains claims for hospital, skilled nursing facility, and hospice services. The Medicare Part B file covers claims for physician and outpatient services, and the Medicare Part D file covers prescription drug claims. As of June 2018, data on SEER-Medicare Parts A and B were available through December 2014. Complete data on Medicare Part D prescription drug coverage were available from 2008 to 2013. To allow for a 1-year window for assessment of baseline comorbidities and utilization of Medicare Part D prescription drug coverage, analyses were restricted to patients diagnosed with HCC from January 1, 2009 to December 31, 2013. The *International Classification of Disease, 9th Revision (ICD-9)* code 250.xx was used to identify patients with T2DM in the SEER-Medicare data, following which the *International Classification of Diseases, 10th Revision, Clinical Modification (ICD-10-CM)* topography code C22.0 was used to identify the T2DM cases with diagnosis of liver cancer. We then used the *International Classification of Diseases for Oncology, 3rd revision (ICD-O-3)* histologic codes 8170 to 8174 to subset to the liver cancers to HCC only. The HCC diagnosis date had to have occurred after T2DM diagnosis date for inclusion in the study. Details of the sample selection process are provided in Figure 1. In Brief, we identified 9,204 patients with T2DM with first primary histologically-confirmed HCC cases diagnosed between January 1, 2009 and December 31, 2013. We then excluded patients co-enrolled in Medicare and Private Health Maintenance Organizations (n=778) and those who

were not continuously enrolled in Medicare Parts A and B in the 12 months preceding HCC diagnosis until death or last follow-up (n=3846). We further excluded patients not enrolled in Medicare Part D prescription drug coverage in the 12 months before diagnosis until death or last follow-up (n=2,081), leaving a final sample of 2,499 patients with T2DM with incident HCC for analyses (Figure 1).

Sociodemographic Information, Clinic Characteristics, and Outcome Variable

Sociodemographic information, including age, sex, race/ethnicity, marital status, body mass index (BMI), neighborhood level income, and percentage of persons with a 4-year college education in neighborhood were abstracted from the Patient Entitlement and Diagnosis Summary File (PEDSF). Information on tumor characteristics, including stage, grade and size were obtained from the SEER file. Data on comorbid conditions (e.g., cardiovascular disease, diabetes, HBV, and HCV) were identified using ICD-9 codes from the PEDSF, the Medicare Provider Analysis and Review (MEDPAR), Carrier data, and Outpatient Standard Analytical File. Comorbidities had to have existed at least 1-year before HCC diagnosis and we calculated the Charlson comorbidity index, as described.³² Because all participants had diagnosis of T2DM, we further calculated diabetes severity index as described in detail by Young *et al.*³³ Data on cancer treatment received by the patients were derived from the Medicare Provider Analysis and Review, the Carrier, Outpatient, and the Standard Analytical Files using ICD-9 codes. The outcome of interest was overall survival. Survival time was calculated as the number of completed months from the date of diagnosis to the date of death, date last known to be alive, or date of last follow-up (December 31, 2013), whichever occurs first. Individuals who were alive at the end of follow-up were censored at that time.

Statins and Metformin Use

Data on statins and metformin use were abstracted from the Medicare Part D prescription drug file. Statins and metformin use before and after diagnosis of HCC were determined by comparing the prescription date to the date of HCC diagnosis. Pre-diagnosis medication use was defined as medication use initiated at least a year before HCC diagnosis and post-diagnosis medication use defined as medication use initiated at least one day after diagnosis. Medication use was initially categorized as statins only, metformin only, both statins and metformin, or neither. Average daily metformin dose was calculated as the total milligrams of metformin dispensed divided by the total number of days of prescription and the metformin users were categorized into 1,500 mg/day or >1,500 mg/day.³⁴ Statins users were categorized further based on (1) the functional form of the statins: hydrophilic (pravastatin and rosuvastatin) or lipophilic (atorvastatin, fluvastatin, lovastatin, and simvastatin)³⁵, (2) statins potency: high potency (atorvastatin, rosuvastatin, and simvastatin) or low potency (fluvastatin, lovastatin, and pravastatin)³⁶, and (3) the individual statins types.

Statistical Analysis

Distributions of sociodemographic and clinical characteristics of the participants were compared by pre-diagnosis use of statins only, metformin only, both, or neither, using chi-square tests for categorical variables and Student's t-test for continuous variables. Cox

proportional hazard models were used to calculate hazard ratios (HRs) and 95% confidence intervals (CIs). Prior to fitting the Cox proportional models, the proportional hazard assumption was assessed by creating interaction variables between the predictors and a log transformation of survival time³⁷ and was determined to have been satisfied. Association analyses were performed in minimally-adjusted and fully-adjusted models. The minimally-adjusted model included age, sex, and pre- and post-diagnosis medication use. In the fully-adjusted model, additional adjustment for year of diagnosis, race/ethnicity, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, presence of chronic obstructive pulmonary disease (COPD), dyslipidemia, and hepatitis status (HBV, HCV, both, none) was performed as categorized in Table 1. Associations for pre- and post-diagnosis medication use were initially assessed among users of statins only, metformin only, both, and neither (i.e., non-users; reference group). Associations for use of pre- and post-diagnosis hydrophilic and lipophilic statins and for use of high or low potency statins were assessed compared with non-users. We assessed also associations for individual statins type (pravastatin, rosuvastatin, atorvastatin, fluvastatin, lovastatin, and simvastatin) compared with non-users. Finally, we examined associations for average daily metformin dose (1,500 mg/day, >1,500 mg/day vs. non-users) used pre- and post-diagnosis of HCC. All statistical tests were two-sided and a p-value lower than 0.05 was considered statistically significant. Analyses were performed in SAS® version 9.4 (SAS Institute, Cary, North Carolina).

Results

Descriptive characteristics of the study participants, including age, marital status, and HCC tumor stage, grade and size, were examined among pre-diagnosis users of statins only, metformin only, both statins and metformin, and non-users (Table 1). The statins only users were slightly older (mean age: 77 years) and included a higher proportion of non-Hispanic Whites (58%) than users of metformin only (mean age: 73 years; 55% non-Hispanic Whites), both statins and metformin (mean age: 76 years; 56 non-Hispanic Whites), or non-users (mean age: 75 years; 57% males). Users of both statins and metformin were more likely to present with stage III or IV HCC tumors (41%) compared with users of statins only (35%), metformin only (32%), and non-users (30%). Statins only users were more likely to have larger tumors (i.e., ≥ 5 cm; 53%) than users of metformin only (39%), both statins and metformin (50%), and non-users (37%). Additionally, users of both statins and metformin had higher Charlson comorbidity index, while users of statins only had higher diabetes severity index compared to the other groups, but no differences were observed by sex, marital status, neighborhood income or education level, tumor grade, or treatment with chemotherapy or radiation. Other findings are reported in Table 1.

Median survival in the entire population was 9.2 months; it was highest among non-users (10.7 months), followed by pre-diagnosis users of metformin only (9.5 months), both metformin and statins (8.0 months), and lowest among statins only users (7.1 months). Results for associations of statins and/or metformin use and overall survival after HCC diagnosis did not show any significant association for either pre- or post-diagnosis use of statins only, metformin only, or both when compared with non-users (Figure 2). Kaplan-

Meier survival curves for pre-diagnosis use of statins only, metformin only, both statins and metformin, and non-use did not show any differences in overall survival across follow-up (Log-rank p-value = 0.06) (Figure 3).

We evaluated additional details about statins and metformin use regarding functional form of the statins, statins potency, and average daily dose of metformin (Figure 4). In the fully-adjusted model that included adjustment for post-diagnosis metformin dose, pre-diagnosis average daily metformin dose 1,500 mg was associated with a 28% lower risk of death after HCC diagnosis (HR = 0.72, 95% CI: 0.58–0.91; 1,500 mg/day vs. non-users). By contrast, average pre-diagnosis metformin dose in excess of 1500 mg/day was not associated with survival after HCC diagnosis (HR = 0.98, 95% CI: 0.86–1.11; >1,500 mg/day vs. non-users), after adjusting for post-diagnosis metformin dose and other covariates. Similarly, no association was found for either pre- or post-diagnosis statins form, statins potency, or post-diagnosis metformin dose (Figures 4 and 5). We further examined associations for individual statins type used either pre- or post-diagnosis of HCC and no association was found for any of the individual statins type (Figure 6).

Discussion

In this population-based study of elderly patients with diabetes, we examined associations of independent and joint use of statins and metformin both pre- and post-diagnosis of HCC on overall survival. The results show that pre-diagnosis use of average daily metformin dose 1,500 mg is associated with a 28% lower risk of death after HCC diagnosis in T2DM patients. No associations was found for pre-diagnosis metformin dose >1500 mg/day or post-diagnosis metformin use, irrespective of dose. Pre- and post-diagnosis use of statins also was not associated with risk of death in patients with T2DM after HCC diagnosis. In summary, the study suggests that pre-diagnosis metformin dose 1,500 mg/day may improve survival of elderly diabetic HCC patients.

Metformin and statins are two of the most commonly prescribed medications among the elderly in the US^{13,14} and both have shown some promise for potential use as chemopreventive agents or adjuvant therapy for HCC.^{38,39} Metformin is the most widely used oral hypoglycemic agent for treatment of T2DM.¹³ In patients with T2DM, metformin improves insulin sensitivity, suppresses hepatic gluconeogenesis, and reduces glycogenolysis.⁴⁰ Pre-existing T2DM is a known risk factor for HCC and associated with 2- to 4-fold increased risk for HCC.^{10,41–43} In a case-control study of diabetics, Donadon *et al.* reported an inverse association between metformin use and HCC risk.⁴³ Nkontchou *et al.* also found inverse association between metformin use and risk for HCC in a prospective study of diabetics with HCV-induced cirrhosis.⁴⁴ However, the association between metformin use and survival after diagnosis of HCC in individuals with T2DM is not clear. Some^{26,27}, but not all²⁸, studies have reported an inverse association between metformin use and mortality after HCC diagnosis. None of the existing studies examined independent associations of pre- or post-diagnosis metformin use while accounting for the effect of the other. In the present study, we found that average daily metformin dose 1,500 mg/day taken before HCC diagnosis is associated with a 28% lower risk of death after diagnosis of HCC, adjusting for post-diagnosis metformin use, comorbidities, diabetes severity, tumor

characteristics, and other relevant factors. However, pre-diagnosis metformin use in excess of 1500 mg/day and post-diagnosis metformin use were not associated with mortality after HCC diagnosis. From the perspective of cancer survival, metformin is known to inhibit cancer proliferation through induction of cell-cycle arrest and apoptosis⁴⁵, promote of AMP-activated protein kinase signaling that result in inhibition of mammalian target of rapamycin (mTOR) pathway^{21,22}, and attenuate metabolic abnormalities²⁰, all of which could be mechanisms by which metformin may improve survival in HCC patients.

Many elderly patients with diabetes in the US take both metformin and statins for management of T2DM and hyperlipidemia.^{13,14} Statins, the HMG-CoA reductase inhibitors used primarily for hyperlipidemia, are thought to play a potential role in survival after HCC diagnosis.²⁴ Experimental studies suggest that statins inhibit HCC progression by promoting G1/S cell cycle arrest and enhancing apoptosis.¹⁷ Other suggested mechanisms include inhibition of the P13K-AKT-mTOR pathway, which is important for cancer cell survival.¹⁸ It is worth noting that not all statins have hepatic-selectivity or enhanced suppression of HMG-CoA reductase. Lipophilic statins (i.e., atorvastatin, fluvastatin, lovastatin, and simvastatin) permeate both hepatic and extrahepatic cells with passive diffusion, while hydrophilic statins (i.e., pravastatin and rosuvastatin) selectively accumulate in the liver through a reaction mediated by transporters expressed in hepatocytes.^{24,35} The discriminatory accumulation of hydrophilic statins in the liver suggests that they may have some role in liver cancer risk and progression.²⁴ In this context, pravastatin has been found to impede the progression and metastasis of established HCC.¹⁵ Few epidemiologic studies have examined the association between statins use and mortality after HCC diagnosis.^{24,25} Jeon *et al.* did not find an association between use of pravastatin and overall survival after diagnosis of stage I or II HCC in an observational study²⁴, while in a clinical trial, Kawata *et al.* found that pravastatin use prolonged survival of patients with advance HCC.²⁵ In the present study, overall statins use (hydrophilic and lipophilic combined) either pre- or post-diagnosis was not associated with survival after HCC diagnosis, neither was combined use of statins and metformin. No association was also found when statins were grouped into their functional forms (lipophilic vs. hydrophilic) or when individual statins were examined. Given the generally limited data on statins use and survival of HCC patients coupled with the inconclusive findings among existing studies, further studies, including from randomized controlled trials, are needed before firm conclusions can be drawn about the role of statins in overall survival of diabetic HCC patients.

Our study has several strengths and limitations. It is limited by the use of SEER-Medicare data that restricted the study population to elderly patients of age 65 years or older. Hence, the findings may not be applicable to younger patients. Information on medication use prior to age 65 years are not available in the SEER-Medicare data; this could have led to misclassification of medication use and may have biased the results to some extent. Moreover, the retrospective nature of the data precludes causal inferences about metformin exposure and mortality after HCC diagnosis. Because the Medicare claims data are designed for billing purposes, detail information on some of the study variables, such as radiation dose, chemotherapy type and dose, were not available. Thus, there is the possibility of residual confounding by these factors. Confounding by unmeasured factors, such as tobacco smoking history, extent of liver injury, and blood cholesterol levels cannot be ruled out.

Severity of liver injury is often measured by circulating levels of aspartate aminotransferase (AST) and aminotransferase (ALT). Statins use is contraindicated in patients with extremely high ALT⁴⁶; hence, patients with high ALT levels, for example, may not have been prescribed statins. The absence of information on circulating ALT and AST levels could have confounded the findings either toward or away from null. Additionally, low blood cholesterol level would lead to less frequent use of statins, which we were unable to assess or account for in the analysis. Despite these limitations, the data source provided comprehensive, population-based resource for investigating the impact of medication use on cancer outcomes and included detail patient information, such as comorbidities and indices of diabetes severity, which were accounted for in the analyses. Additional strengths include the ability to control for post-diagnosis medication use when examining association for pre-diagnosis use and *vice versa*. The large sample size and stringent HCC case definition, which excluded potential metastatic cases, add to the study strengths.

The findings of this study suggest that pre-diagnosis use of metformin dose 1,500 mg/day may improve overall survival of elderly diabetic HCC patients. Given the sparse data on associations between pre-diagnosis metformin dose and overall survival after HCC diagnosis, verifications are warranted in larger prospective studies with adequate representation of younger patients.

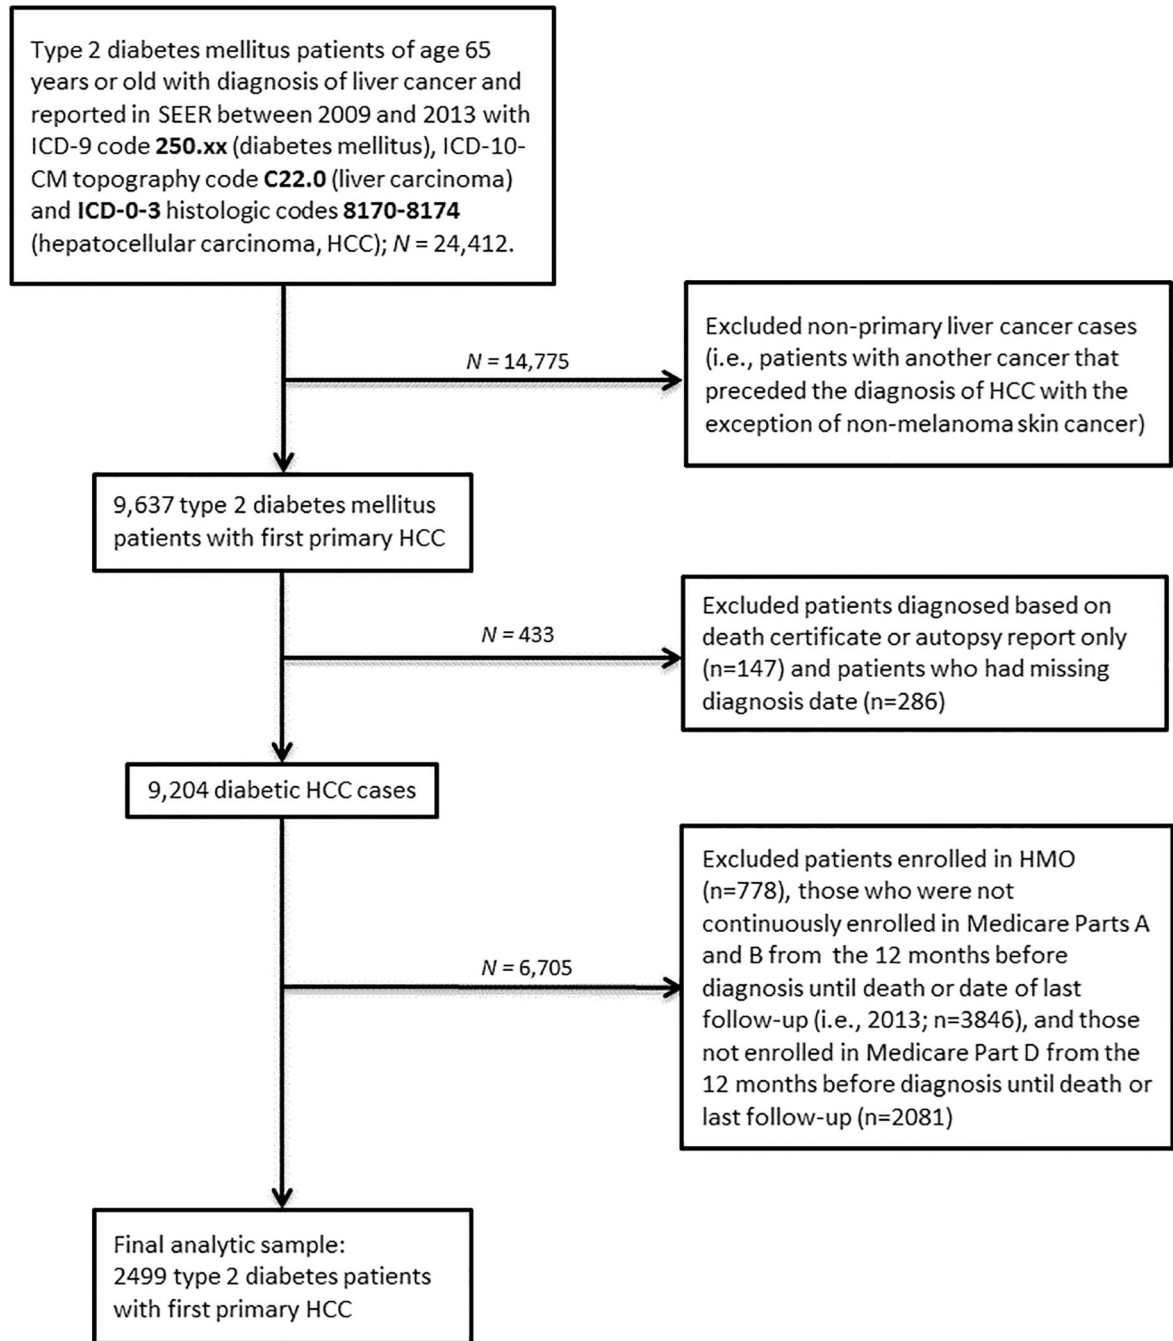

Figure 1:
Flow chart of study sample selection process.

Figure 2: Association between use of statins and/or metformin by patients with diabetes pre- and post-diagnosis of HCC and risk of death after HCC diagnosis. ^a Adjusted for age (continuous), sex, and post-diagnosis medication use (statins only, metformin only, both, neither). ^b Adjusted for everything in “a” plus year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, presence of COPD, dyslipidemia, and hepatitis as categorized in Table 1. ^c Adjusted for age, sex, and pre-diagnosis medication use (statins only, metformin only, both, neither). ^d Adjusted for everything in “c” with additional adjustment for year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, COPD, dyslipidemia, and hepatitis as categorized in Table 1. Abbreviation: HCC, hepatocellular carcinoma.

Figure 3:
Kaplan-Meier survival curve for overall survival by pre-diagnosis medication use.

Figure 4: Association between statins form, statins potency, and metformin dose taken by patients with diabetes pre-diagnosis of HCC and risk of death after HCC diagnosis, $N= 2499$. ^a Adjusted for age (continuous), sex, and post-diagnosis statins form (lipophilic, hydrophilic, neither). Metformin only users were excluded from this analysis. ^b Adjusted for everything in “^a” plus year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, COPD, dyslipidemia, and hepatitis status as categorized in Table 1. Metformin only users were excluded from the analysis. ^c Adjusted for age, sex, and post-diagnosis statins potency (high potency, low potency, non-users). Metformin only users were not included in the analysis. ^d Adjusted for everything in “^c” plus year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, COPD, dyslipidemia, and hepatitis as categorized in Table 1. Metformin only users were excluded from the analysis. ^e Adjusted for age (continuous), sex, and post-diagnosis metformin use dose ($\leq 1,500$ mg/d, $>1,500$ mg/d, non-users). Statins only users were excluded from this analysis. ^f Adjusted for everything in “^e” plus year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, COPD, dyslipidemia, and hepatitis as categorized in Table 1. Statins only users were excluded from the analysis. Abbreviation: HCC, hepatocellular carcinoma; COPD, chronic obstructive pulmonary disease. Lipophilic statins: atorvastatin, fluvastatin, lovastatin, and simvastatin. Hydrophilic statins: pravastatin and rosuvastatin. High potency statins: atorvastatin, rosuvastatin, and simvastatin. Low potency statins: fluvastatin, lovastatin, and pravastatin.

Figure 5: Association between statins form, statins potency, and metformin dose taken by patients with diabetes post-diagnosis of HCC and risk of death after HCC diagnosis, $N = 2499$. ^a Adjusted for age (continuous), sex, and pre-diagnosis statins form (lipophilic, hydrophilic, neither). ^a Adjusted for age (continuous), sex, and pre-diagnosis statins form (lipophilic, hydrophilic, neither). Metformin only users were excluded from this analysis. ^b Adjusted for everything in “^a” plus year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, COPD, dyslipidemia, and hepatitis status as categorized in Table 1. Metformin only users were excluded from the analysis. ^c Adjusted for age, sex, and pre-diagnosis statins potency (high potency, low potency, non-users). Metformin only users were not included in the analysis. ^d Adjusted for everything in “^c” plus year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, COPD, dyslipidemia, and hepatitis as categorized in Table 1. Metformin only users were excluded from the analysis. ^e Adjusted for age (continuous), sex, and pre-diagnosis metformin use dose (< 1,500 mg/d, >1,500 mg/d, non-users). Statins only users were excluded from this analysis. ^f Adjusted for everything in “^e” plus year of diagnosis, race, marital status, neighborhood income level, percent with 4-year college in neighborhood, tumor grade, tumor stage, chemotherapy, radiation, Charlson comorbidity index, diabetes severity index, obesity, COPD, dyslipidemia, and hepatitis as categorized in Table 1. Statins only users were excluded from the analysis. Abbreviation: HCC, hepatocellular carcinoma; COPD, chronic obstructive pulmonary disease. Lipophilic statins: atorvastatin, fluvastatin, lovastatin, and simvastatin. Hydrophilic statins: pravastatin and rosuvastatin. High potency

statins: atorvastatin, rosuvastatin, and simvastatin. Low potency statins: fluvastatin, lovastatin, and pravastatin.
