#### (See the Major Article by Gupta et al on pages 425-35.)

**Background.** Household contacts (HHCs) of individuals with multidrug-resistant tuberculosis (MDR-TB) are at high risk of infection and subsequent disease. There is limited evidence on the willingness of MDR-TB HHCs to take MDR-TB preventive therapy (MDR TPT) to decrease their risk of TB disease.

*Methods.* In this cross-sectional study of HHCs of MDR-TB and rifampicin-resistant tuberculosis (RR-TB) index cases from 16 clinical research sites in 8 countries, enrollees were interviewed to assess willingness to take a hypothetical, newly developed MDR TPT if offered. To identify factors associated with willingness to take MDR TPT, a marginal logistic model was fitted using generalized estimating equations to account for household-level clustering.

**Results.** From 278 MDR-TB/RR-TB index case households, 743 HHCs were enrolled; the median age of HHCs was 33 (interquartile range, 22–49) years, and 62% were women. HHC willingness to take hypothetical MDR TPT was high (79%) and remained high even with the potential for mild side effects (70%). Increased willingness was significantly associated with current employment or schooling (adjusted odds ratio [aOR], 1.83 [95% confidence interval {CI}, 1.07–3.13]), appropriate TB-related knowledge (aOR, 2.22 [95% CI, 1.23–3.99]), confidence in taking MDR TPT (aOR, 7.16 [95% CI, 3.33–15.42]), and being comfortable telling others about taking MDR TPT (aOR, 2.29 [95% CI, 1.29–4.06]).

**Conclusions.** The high percentage of HHCs of MDR-TB/RR-TB index cases willing to take hypothetical MDR TPT provides important evidence for the potential uptake of effective MDR TPT when implemented. Identified HHC-level variables associated with willingness may inform education and counseling efforts to increase HHC confidence in and uptake of MDR TPT.

Keywords. tuberculosis; contacts; drug resistance; prophylaxis; preventive therapy.

Tuberculosis (TB) is the leading infectious cause of mortality worldwide with an estimated 10.0 million new cases and 1.3 million deaths in 2017 alone [1]. Multidrug-resistant TB (MDR-TB; ie, resistant to at least isoniazid and rifampicin)

#### Clinical Infectious Diseases® 2020;70(3):436–45

and rifampicin-resistant TB (RR-TB) are estimated to have caused 558 000 of these new cases and a disproportionately high number of deaths [1]. Household contacts (HHCs) of individuals with active TB are at high risk of infection due to prolonged exposure in shared environments [2, 3]. The development of MDR-TB disease among HHCs [2–4] has severe implications for already TB-affected households due to poor treatment outcomes despite lengthy, costly, and toxic regimens [5, 6]. Prevention of MDR-TB disease, therefore, remains a critical public health priority.

Received 16 October 2018; accepted 26 March 2019; published online March 28, 2019. <sup>a</sup>N. S. and M. M. contributed equally to this work.

Preventing new TB cases through the treatment of TB infection among persons exposed to an infectious TB case is a pillar of the End TB Strategy. Isoniazid- and rifamycin-containing regimens have been demonstrated to reduce the risk of TB disease among HHCs exposed to drug-susceptible TB [7–9]. However, observational studies on MDR-TB preventive therapy (MDR TPT), primarily describing the use of fluoroquinolone-based regimens, have been inconclusive, resulting in a conditional recommendation for treatment of only high-risk HHCs [4, 9, 10]. Ongoing clinical trials are evaluating new potential regimens to treat MDR-TB infection [11], but little evidence exists on the willingness of HHCs to take MDR TPT were it available.

Studies of knowledge, attitudes, and practices have the potential to provide insights into the willingness of populations to utilize a proposed prevention or treatment strategy, as well as elucidate barriers and enablers of uptake. These findings can provide context to an intervention's acceptability [12], inform health education efforts [13, 14], and characterize provider opinions and preparedness [15]. We conducted a multicountry, cross-sectional study of HHCs of MDR-TB/RR-TB index cases in diverse high-TB-burden settings to understand how HHCs' TB-related knowledge, attitudes, and practices (KAP) are associated with their willingness to take a hypothetical MDR TPT.

#### **METHODS**

#### **Study Setting**

The study was conducted from October 2015 to April 2016 at 16 clinical research sites in 8 countries—Botswana (1 site), Brazil

(1), Haiti (1), India (2), Kenya (1), Peru (2), South Africa (7), and Thailand (1), in preparation for the Protecting Households on Exposure to Newly Diagnosed Index Multidrug-resistant Tuberculosis Patients (PHOENIx) trial being conducted by the AIDS Clinical Trials Group (ACTG; https://actgnetwork. org/) and International Maternal Pediatric Adolescent AIDS Clinical Trials Network (IMPAACT; http://impaactnetwork. org/). Information on local TB program activities, including contact tracing and TB preventive therapy (TPT), was collected through key informant interviews (Table 1).

#### **Study Participant Eligibility Criteria and Recruitment**

Pulmonary MDR-TB/RR-TB index cases were eligible for enrollment if they met the following inclusion criteria: (1) documented rifampicin resistance by Xpert MTB/RIF assay, line probe assay, or phenotypic drug sensitivity testing; (2) MDR-TB treatment initiation within 6 months of study enrollment; (3)  $\geq$ 1 HHC; (4) permission for the study team to enumerate and screen HHCs; and (5) residing at a distance deemed by the site-level study team close enough for study conduct. HHCs were defined as (1) any person currently living or having lived in the same dwelling unit or plot of land; (2) currently sharing or having shared the same housekeeping arrangements as the index case; and (3) reporting exposure within 6 months prior to the index case starting MDR-TB treatment. Index cases were recruited and all eligible adult and adolescent HHCs (≥13 years of age) without active TB were asked to complete a KAP questionnaire.

#### **Data Collection and Variables**

A semi-structured KAP questionnaire was adapted for MDR-TB from a recent World Health Organization guide for tuberculosis KAP survey development [16]. The survey was pilot tested among TB community health workers at one study site (India site 2). Additional HHC information obtained included demographic, social, medical, and household characteristics. All questionnaires were completed in-person by trained field staff or clinicians prior to participant education or counseling by anyone affiliated with the study.

The primary outcome in this analysis was willingness to take hypothetical, newly developed MDR TPT. Additionally, HHC willingness to take this therapy even if it were to cause mild temporary side effects was analyzed as a secondary outcome. MDR TPT was not offered to any HHC participating in the study, and no additional questions were asked about how side effects would change interest in taking MDR TPT. Both outcome variables, as well as HHC willingness to have a blood test (ie, interferon- $\gamma$  release assay), to provide a sputum sample, and to obtain a chest radiograph to determine if the HHC was a good candidate for TPT were collected as categorical (yes, not sure, no) and dichotomized as yes vs not sure or no for analysis.

TB knowledge was analyzed as a binary variable, where appropriate knowledge was defined as correctly identifying all of the following: cough  $\geq$ 3 weeks is a TB symptom; TB is a curable disease; TB is transmitted via air when an infected person coughs or sneezes, and MDR-TB cure is possible through directly observed therapy [17]. "Incomplete" knowledge was defined as not correctly identifying all 4 items above. Confidence in taking MDR TPT was defined as HHCs feeling confident or very confident in being able to perform all 5 of the following (5-point Likert scale): meeting with study staff monthly to collect medications, coping with difficulties TPT may cause, taking all doses, continuing to take medications even if feeling healthy, and completing medications. A review of systems was completed differently for HHCs <15 and  $\geq$ 15 years of age to identify the presence of TB-related symptoms at the time of interview. For adolescents or children (<15 years), TB-related symptoms included any of the following at the time of interview: neck swelling, fever, night sweats, cough ≥10 days, poor weight gain, less playful, convulsion, or decreased consciousness. For adults (≥15 years), symptoms included any of the following in the past month: cough  $\geq 10$  days, fever, night sweats, unintentional weight loss, or enlarged lymph nodes.

#### **Statistical Analysis**

The primary objective of this analysis was to evaluate the association between HHC-level KAP factors and willingness to take hypothetical, newly developed MDR TPT. Among enrolled HHCs with complete KAP data, aggregate and site-level exploratory data analysis was conducted using summary statistics and scatterplots. Simple (adjusting only for research site) and multivariable marginal logistic models for willingness to take MDR TPT were fitted using generalized estimating equations with robust variance estimates to account for household-level clustering assuming an exchangeable within-household correlation structure [18]. Household contact age was rescaled by dividing the variable by a constant (10 years) to improve interpretability. Fixed-effect dummy variables for research sites were included to adjust for variation between sites. Informed by a literature review and the Health Belief Model (Supplementary Figure 1) [19], covariates of interest were selected prior to analysis from a larger set of variables available through the PHOENIx Feasibility Study.

If any site reported 100% willingness to take MDR TPT, the outcome status of one randomly selected HHC at the respective site was set to "not willing" in order to allow for model fit. The sensitivity of model parameter estimates to this random outcome reassignment was examined. The potential confounding of HHC-level associations by corresponding household-level aggregate variables was also evaluated. Model diagnostics included examining the influence of individual HHCs and research sites on parameter estimates as well as residual plots [20]. All analyses were conducted in Stata version 13.1 software (StataCorp, College Station, Texas) except for the creation of stacked bar charts [21].

#### **Human Research Ethics Approvals**

Ethical approval was obtained from each research site's local institutional review board. Written informed consent was obtained for all participating MDR-TB/RR-TB index cases and household contacts prior to study interviews and procedures.

#### RESULTS

#### **Study Recruitment**

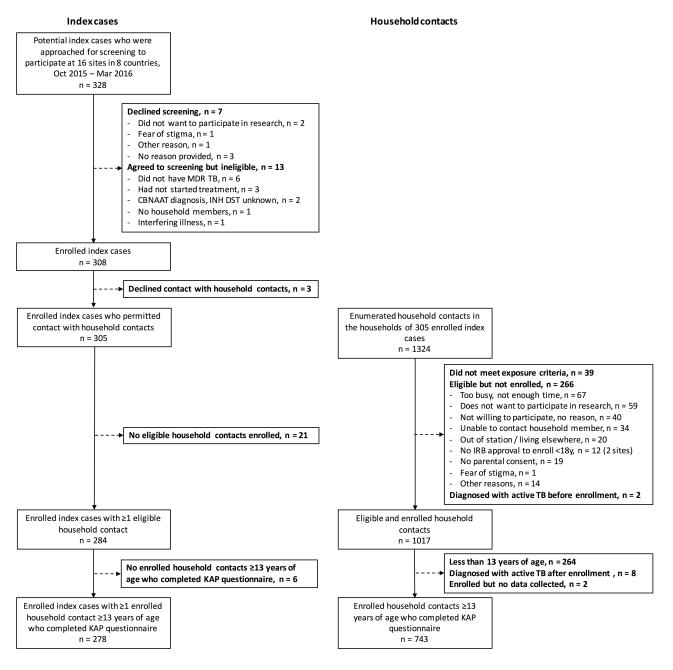

Across all sites, 328 adult pulmonary MDR-TB/RR-TB index cases were screened during the recruitment period; 20 declined screening or were ineligible. Three declined contact with HHCs, and 27 had no eligible, enrolled HHCs who also completed the KAP questionnaire. The final study sample included 278 index cases and their HHCs.

#### Characteristics of MDR-TB/RR-TB Index Cases and Their Households

Among included index cases (n = 278), the median time between MDR-TB treatment initiation and study enrollment was 68 days (interquartile range [IQR], 29–125 days) with a majority also reporting a history of prior TB (53%). The median number of eligible, enumerated HHCs of all ages in these index case households was 4 (IQR, 2–5) with 32% of households having  $\geq$ 1 adolescent HHC (13 to <18 years of age), 31% with  $\geq$ 1 HHC who was <5 years of age, and 6% with  $\geq$ 1 pregnant HHC.

#### Characteristics of Enrolled HHCs of MDR-TB/RR-TB Index Cases

For the analysis of factors associated with willingness to take MDR TPT, complete KAP data were available for 743 adult and adolescent HHCs (99.7% of 745 enrolled, and 79% of 946 without active TB and eligible for the KAP study) from 278

**Figure 1.** Eligibility, enrollment, and participation of 743 adult and adolescent household contacts from 278 multidrug-resistant tuberculosis (TB)/rifampicin-resistant TB index case households participating in the Protecting Households on Exposure to Newly Diagnosed Index Multidrug-resistant Tuberculosis Patients (PHOENIx) feasibility TB knowledge, attitudes, and practices study. Abbreviations: CBNAAT, cartridge-based nucleic acid amplification test; DST, drug susceptibility testing; INH, isoniazid; IRB, institutional review board; KAP, knowledge, attitudes, and practices; MDR-TB, multidrug-resistant tuberculosis.

MDR-TB/RR-TB index case households (median, 2 enrolled HHCs with complete KAP data per HH [IQR, 1–3]) (Figure 1). The median number of MDR-TB/RR-TB index cases and HHCs enrolled per site and included in this analysis was 14 (IQR, 10–25) and 39 (IQR, 22–70), respectively.

Among HHCs participating in the KAP study, the median age was 33 years (IQR, 22–49 years), 62% were women, 58% had secondary school education or higher, and 46% were currently

employed or in school. Overall, 10% of HHCs reported prior TB treatment and 21% current tobacco use. For alcohol use, 58 HHCs (9%) reported daily or almost daily use in the last year, and 8 (1%) refused to answer the question. Similarly, 57 (8%) reported illegal drug use in the last year and 3 (0.4%) refused to answer (Table 2). Participation in the KAP study was not associated with age, but females were more likely to participate than males (83% vs 72%, P < .001).

### Willingness to Take MDR-TB Preventive Therapy • CID 2020:70 (1 February) • 441

Table 2. Continued

#### MDR-TB/RR-TB HHCs and Their TB-related Knowledge and Attitudes

Appropriate MDR-TB knowledge was demonstrated by 66% of enrolled HHCs, with substantial site-level variation (Supplementary Figure 2), notably low knowledge at India site 1 (5%). A majority of HHCs (64%) were concerned about being infected with MDR-TB from their diagnosed household member, and 84% believed that someone could die from MDR-TB without proper treatment. Regarding perceived stigma, 28% of HHCs reported that a person with TB is usually rejected by their community, and 34% stated that they would be uncomfortable telling family members or friends they were taking MDR TPT (Table 2).

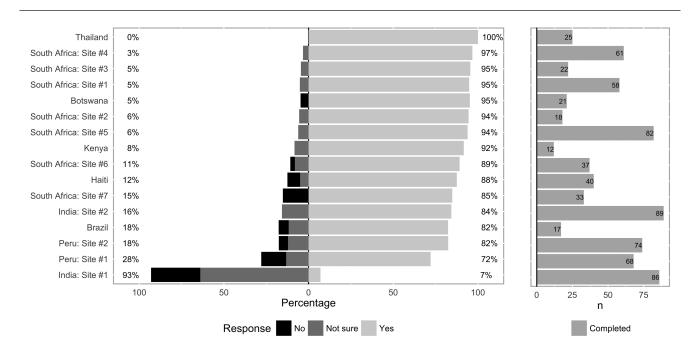

## Willingness to Take Hypothetical, Newly Developed MDR TPT Among HHCs of MDR-TB/RR-TB Index Cases

HHC willingness to take hypothetical, newly developed MDR TPT was high overall (79%) with observed site-level variation (site-level median, 90% [IQR, 84%–95%]; Figure 2). At India site 1, only 7% of HHCs reported willingness (29% not willing, 64% not sure). Willingness to take MDR TPT with potential mild temporary side effects was somewhat lower across sites (70% overall; site-level median, 80% [IQR, 66%–91%]). Reported HHC willingness to complete prerequisite steps to determine MDR TPT eligibility was high at all sites except one: blood test (96% [IQR, 88%–98%]), provide sputum sample (97% [IQR, 95%–100%]), and obtain chest radiograph (100% [IQR, 97%–100%]).

In the multivariable model for the primary outcome (Table 2), increased willingness to take MDR TPT was significantly associated with the following HHC characteristics: currently employed or in school (adjusted odds ratio [aOR], 1.83 [95%]

confidence interval {CI}, 1.07–3.13]), appropriate TB-related knowledge (aOR, 2.22 [95% CI, 1.23–3.99]), confidence in taking MDR TPT (aOR, 7.16 [95% CI, 3.33–15.42]), being comfortable telling family or friends about taking MDR TPT (aOR, 2.29 [95% CI, 1.29–4.06]). Increased willingness was also marginally associated with knowledge that one can die of MDR-TB without treatment (aOR, 2.48 [95% CI, 1.00–6.13]). In a multivariable model including the same set of covariates, the secondary outcome of willingness to take MDR TPT with side effects was significantly associated with increased HHC-level concern about being infected from the index case (aOR, 2.01 [95% CI, 1.30–3.09]) and confidence in taking MDR TPT (aOR, 7.86 [95% CI, 4.41–14.01]).

Site-level variation was observed in the unadjusted associations between willingness to take MDR TPT and covariates of interest (Supplementary Table 2); however, the direction of these associations was highly consistent for the most significant covariates identified through the multivariable model: appropriate TB-related knowledge, comfort telling family or friends about taking MDR TPT, and confidence in taking MDR TPT. After adjustment for all covariates included in the multivariable model, predicted willingness of HHCs at India site 1 remained significantly lower than all other sites on pairwise comparisons with Bonferroni correction. Potential confounding of observed HHC-level associations by betweenhousehold effects was examined by creating household-level summary means for all HHC-level covariates [22]. Including all aggregate household-level variables in the final multivariable model did not qualitatively change any HHC-level association

except HHC education, which was not significant in either model. In sensitivity analyses, the direction and magnitude of HHC-level variable associations with willingness to take MDR TPT was robust to exclusion of India site 1 and primary outcome reassignment of each of the 25 individual HHCs at the Thailand research site, at which all HHCs reported willingness (Supplementary Figures 3 and 4).

#### DISCUSSION

In this large multicountry study of HHCs of MDR-TB/RR-TB index cases residing in diverse high-TB-burden regions, willingness to take a hypothetical, newly developed MDR TPT was high (79%), along with willingness to complete prerequisite steps to determine eligibility for treatment. In the context of multiple ongoing clinical trials to identify effective MDR TPT regimens [11], our study provides evidence from diverse geographic settings for the potential high uptake of these therapies when implemented in the high-risk population of household contacts. The identification of factors associated with increased willingness to take TPT can inform counseling efforts, generate hypotheses for more contextualized local studies of KAP factors, and identify populations where implementation of MDR TPT may be particularly effective or challenging.

These findings are similar to prior observational studies and case series from limited settings that documented high levels of MDR TPT initiation among contacts. In studies identified through recent systematic reviews on MDR TPT [4, 9, 23], treatment initiation data have been reported for 8 generally small cohorts (median, 30 contacts [IQR, 22-36]) (Supplementary Table 1). For these studies, treatment initiation, defined as taking any MDR TPT for ≥2 weeks, was reported to be high overall (median, 85.6% [IQR, 71.2%-93.4%]); however, data were not available on factors associated with uptake [24-30]. Considerably more evidence exists for drug-susceptible TPT. In a recent meta-analysis of 25 cohorts, 88% of individuals were estimated to have started TPT if it was recommended; factors associated with initiation included younger age, high perceived risk of TB, and no prior treatment for TB infection [31].

We found that appropriate TB-related knowledge, being comfortable speaking with family and friends about taking MDR TPT, and, most notably, confidence in properly taking TPT were all associated with increased willingness to start treatment. The marginal association between current HHC tobacco smoking, and increased willingness to take MDR TPT suggests a possible opportunity for increased TPT uptake and tobacco cessation services among a population at higher risk of both TB infection and active disease [32]. Many of these factors have been previously identified to be associated with drugsusceptible TPT initiation or completion [31, 33, 34]. Factors included in the present study's KAP questionnaire were primarily patient-level, social, and lifestyle [34]; however, health system factors (eg, clinic wait times, provider opinions on TPT) and therapy characteristics (eg, duration, side effects) have also been demonstrated to be important predictors of treatment initiation and completion [31, 33–36]. Observed associations may furthermore be confounded by unmeasured HHC- or household-level variables.

The decreased willingness of HHCs to take MDR TPT with mild side effects is also consistent with prior research, which has identified side effects as a primary reason for treatment discontinuation [26, 30]. Although some studies have documented high TPT completion rates among initiators [25, 27, 28], completion has been demonstrated to be one of the main gaps in the TPT cascade of care [31]. Furthermore, self-reported willingness to initiate treatment may not be a strong proxy for HHC treatment completion or even future initiation due to social desirability bias and prohibitive treatment costs as well as changes in beliefs, attitudes, or circumstances over time [37, 38]. Selection bias may also have been introduced if HHCs of eligible index cases who had initiated TB treatment differed from HHCs of ineligible index cases who had not initiated treatment. An additional limitation of this research was variable site-level sample sizes due to a constrained period of enrollment after the overall target of 300 index cases was met. As a result, the study sample was weighted toward sites starting enrollment earlier and with faster rates of recruitment (Figure 2) as well as households with greater numbers of HHCs. Across research sites, unadjusted associations for key risk factors were highly consistent; however, there was insufficient power to detect within-site differences in associations between measured HHC factors and willingness to take MDR TPT. Last, the generalizability of these findings may be limited by a lack of data from some high-burden countries as well as potential future implementation challenges, including patient-level costs.

In conclusion, the high percentage of HHCs of MDR-TB/ RR-TB index cases willing to take hypothetical, newly developed MDR TPT provides important evidence for the potential uptake of effective TPT when implemented. Identified HHClevel variables associated with decreased willingness to take MDR TPT may inform education and counseling efforts to increase HHC confidence in and uptake of MDR TPT. Possible interventions to improve uptake include collaborations with patient advocacy groups, community sensitization workshops, and the provision of educational tools and training to TB healthcare workers. Data on caregiver willingness to provide preventive therapy to children were also collected through this study and are currently being analyzed. While this study focused on willingness to take MDR TPT at the HHC level, further research examining the site-specific context of TB-related KAP through qualitative or mixed-methods studies offers promise in guiding the rollout of MDR TPT to reduce the burden of TB in these high-risk populations.
