

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Coronavirus 2019 (COVID-19)—Associated Encephalopathies and Cerebrovascular Disease: The New Orleans Experience

Tyler Scullen^{1,2}, Joseph Keen¹, Mansour Mathkour^{1,2}, Aaron S. Dumont^{1,2}, Lora Kahn¹

■ **BACKGROUND:** The coronavirus 2019 (COVID-19) pandemic has had a dramatic impact on health care systems and a variable disease course. Emerging evidence demonstrates that severe acute respiratory syndrome coronavirus 2 is associated with central nervous system disease. We describe central nervous system manifestations in critical patients with COVID-19 at our tertiary center.

■ **METHODS:** We conducted a single-center retrospective analysis of all actively critical patients with COVID-19 admitted to our tertiary care academic center in New Orleans, Louisiana, on April 22, 2020, with new onset of neurologic disease. Patients were grouped into 1 of 3 categories according to imaging and clinical features; encephalopathy, acute necrotizing encephalopathy, and vasculopathy.

■ **RESULTS:** A total of 27 of 76 (35.5%) critical patients with COVID-19 met inclusion criteria. Twenty patients (74%) were designated with COVID-19—associated encephalopathy, 2 (7%) with COVID-19—associated acute necrotizing encephalopathy, and 5 (19%) with COVID-19—associated

vasculopathy. Sixty-three percent of neurologic findings were demonstrated on computed tomography, 30% on magnetic resonance imaging, and 44% on electroencephalography. Findings most often included ischemic strokes, diffuse hypoattenuation, subcortical parenchymal hemorrhages, and focal hypodensities within deep structures. Magnetic resonance imaging findings included diffuse involvement of deep white matter, the corpus callosum, and the basal ganglia. For patients with large-territory ischemic stroke, all but one displayed irregular proximal focal stenosis of the supraclinoid internal carotid artery.

■ **CONCLUSIONS:** Analysis of active critical COVID-19 admissions at our revealed a high percentage of patients with new neurologic disease. Although variable, presentations followed 1 of 3 broad categories. A better understanding of the neurologic sequelae and radiographic findings will help clinicians mitigate the impact of this disease.

INTRODUCTION

The coronavirus disease 2019 (COVID-19) pandemic that is due to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has had a dramatic impact on health care systems.¹ Although the majority of patients experience mild disease, a subset develops complex multiorgan failure.¹ Confirmed disease has afflicted 2.92 million patients globally as of April 26, 2020, with 829,000 recovered and an associated mortality of 204,000 (5.2%).²

SARS-CoV-2 is a member of the coronaviridae family, composed of enveloped positive-sense single-stranded RNA viruses typically responsible for a spectrum of respiratory and gastrointestinal diseases but with occasional neurotropism.¹ Notable members include the 2003 severe acute respiratory syndrome coronavirus 1 (SARS-CoV-1) and 2012 Middle East Respiratory Syndrome (MERS) coronavirus, which have demonstrated the ability to produce neuromuscular and neurologic symptoms.^{3–8} Experimental studies suggest early brainstem involvement and secondary damage via exaggerated host immune responses.^{9,10} In addition, known homologues such as the human coronaviruses OC34 and 229E (HCoV-OC34 and HCoV-229E) have been detected in brain tissue of patients with multiple sclerosis, and human T-cell lines have been found to cross-react with myelin basic protein and viral antigens, suggesting molecular mimicry and a potential pathogenesis for central nervous system (CNS) injury.^{11,12}

Emerging evidence demonstrates that SARS-CoV-2 is associated with neurologic disease,^{13–15} including meningoencephalitis, virus-associated necrotizing encephalopathy similar to the influenza-associated encephalopathy (IAE), and secondary cytokine-induced acute necrotizing encephalopathy syndromes observed in members of the *Orthomyxoviridae* family such as the hemagglutinin 1 neuraminidase 1 influenza virus.^{13–15} These findings highlight the additional challenge facing the neurosciences during this pandemic.¹⁶ In this work, we describe and categorize the CNS manifestations observed in critical patients with COVID-19 who were admitted on 1 day to our tertiary academic center.

METHODS

This is a single-center retrospective cross-sectional analysis of all patients admitted to our tertiary care academic center in New Orleans, Louisiana, on April 22, 2020, who presented in critical condition and had confirmed SARS-CoV-2. Patients were included if they required intensive care unit (ICU) level of care and had active COVID-19 confirmed by positive qualitative reverse-transcription polymerase chain reaction (RT-PCR) or qualitative RNA nucleic acid amplification technique (NAAT). Demographic data, clinical course, and radiographic findings were reviewed. Patients were excluded if they either did not have clear clinical or radiographic evidence of neurologic disease, if neurologic manifestations were explained completely by a pre-existing condition, or if neurologic involvement preceded active viral disease, as evident by chronology of confirmatory tests.

Based on imaging, patients were grouped into 1 of 3 informal categories. Patients were categorized as having “COVID-19—associated encephalopathy” if they had either scalp

electroencephalography (EEG) showing either generalized encephalopathy or epileptic encephalopathy as well as changes on computed tomography (CT) and/or magnetic resonance imaging (MRI) of the head. Patients were designated “COVID-19—associated acute necrotizing encephalopathy” if they demonstrated significant changes in midline and periventricular structures on MRI and/or CT and had evidence of hemorrhagic conversion on either gradient echo or susceptibility-weighted imaging (SWI) MRI sequences. An informal diagnosis of “COVID-19—associated vasculopathy” was given to patients with evidence of acute ischemic stroke affecting large-vessel territories with or without evidence of large-vessel occlusion (LVO) on computed tomography angiography or magnetic resonance angiography (CTA and MRA, respectively).

Diagnostic criteria for the aforementioned categorizations were derived from existing defined viral-associated disease presentations, such as IAE,^{13–15} influenza-associated acute necrotizing encephalopathy,^{13–15} human immunodeficiency virus (HIV)-associated vasculitis,¹⁷ and human herpes virus (VZV) 3-associated vasculopathy.¹⁷

RESULTS

A total of 76 patients were admitted on April 22, 2020, to one of several repurposed respiratory intensive care units (RICUs). The patients were in critical condition and confirmed to have COVID-19. Of these, 27 patients (35.5%) had evidence of new-onset neurologic disease, which ranged from mild headache and dysgeusia to severe focal deficits (Table 1). All but 1 patient with neurologic involvement developed altered mental status (AMS) during their hospital course (96.3%). Eight (30%) patients tested positive for SARS-CoV-2 on multiple interval tests. As patients without active disease as well as those who had confirmed negative RT-PCR and/or NAAT testing along with no clinical evidence of COVID-19 at the time of neurologic involvement were excluded, and no recurrent infections were observed, zero patients tested negative. Positive tests were documented on 37 occasions, 8 (22%) of which were confirmed via NAAT and the remainder via RT-PCR. As of April 23, 2020, 3 patients (11%) have died.

Patients had a mean age of 59.8 years (range 35–91 years) and 48% were female. The vast majority of patients had an underlying medical condition, with hypertension (63%), diabetes mellitus type 2 (DM2) (52%), obesity (26%), and chronic kidney disease (22%) being the most common (Table 1). During their clinical course, 51.8% of patients suffered secondary infection, ranging from bacteremia (22%), urinary tract infection (15%), bacterial pneumonia (11%), to fungemia (4%). Patients with neurologic manifestations had a greater proportion of DM2 (52% vs. 40%) but this did not reach statistical significance ($P = 0.32$).

Seventy-one percent of included patients were imaged with 2 or more modalities. All included patients underwent noncontrast CT of head, 10 patients of whom were scanned for new-onset focal deficit and 13 for persistent AMS in the absence of sedatives. An additional 8 patients underwent MRI for further investigation of suspected large territory infarct, hemorrhagic, or encephalitic process. Three patients underwent CTA without MRI to acutely evaluate suspected LVO, and another 4 underwent MRA in addition to nonvascular magnetic resonance for concern for ongoing

vasculopathy. Thirteen patients received continuous EEG for pronounced encephalopathy not explained by previous CT alone ($n = 9$) or combined CT and MRI ($n = 4$) findings.

A total of 23 patients (85%) demonstrated radiographic or electrographic evidence of neurologic disease: 63% had positive findings on CT, 30% on MRI, and 15% on noninvasive vascular imaging. Forty-four percent of included patients (100% who received EEG) demonstrated abnormal findings on EEG. CT findings most often included subacute ischemic strokes, diffuse hypoattenuation, subcortical parenchymal hemorrhages, and focal hypodensities in deep structures (Table 2). MRI findings often resembled viral encephalitis with diffuse involvement of the deep white matter, corpus callosum, and basal ganglia.

Vascular imaging was obtained most often to rule out acute ischemic stroke. Four large-territory infarcts were discovered on MRI—3 involving an extensive middle cerebral artery (MCA) territory and one involving the posterior cerebral artery territory. Of the posterior circulation strokes, one study demonstrated LVO of the posterior cerebral artery P2B segment that corresponded with evolving infarct. The other 3 studies showed irregular proximal focal stenosis of the supraclinoidal internal carotid artery (ICA), particularly at the area of the terminus, with patent anterior circulation vasculature (Table 2).

EEG on affected patients yielded a high proportion of generalized encephalopathy, with 1 patient showing activity suggestive of nonconvulsive status epilepticus (Table 2). Encephalopathy typically consisted of irregular slowing with delta and theta frequency oscillations.

Twenty patients (74%) were diagnosed with COVID-19—associated encephalopathy, 2 (7%) with COVID-19—associated acute necrotizing encephalopathy, and 5 (19%) with COVID-19—associated vasculopathy. Of the last group, 1 patient had evidence of LVO, whereas the other 4 had focal stenosis at the ICA terminus and distal supraclinoid segments with patent distal vasculature.

Representative Cases

COVID-19—Associated Encephalopathy. A 63-year-old female patient with hypertension and obesity presented with 4 days of fever, cough, shortness of breath, and chest pain. Due to respiratory failure and hypoxemia, the patient was intubated and transferred to the RICU. RT-PCR confirmed SARS-CoV-2 infection. She developed multisystem disease, including renal failure requiring continuous renal-replacement therapy (CRRT) and fungal pneumonia. She was treated with glucocorticoids and a 5-day course of hydroxychloroquine. Quantitative D-dimer assay was elevated at 12.02 mg/L and systemic anticoagulation was initiated with heparin titrated to anti-factor Xa (range 0.3–0.7 IU/mL) on day 5 of admission. On ventilator day 10, the patient was weaned from sedation and found to have significant AMS without focal deficit. Lumbar puncture showed normal glucose and protein levels with a cell differential suggestive of a traumatic tap. Noncontrast CT of the head demonstrated hypodensities within bilateral globus pallidi as well as a focal parenchymal hemorrhage in the left occipital pole (Figure 1). MRI showed fluid-attenuated inversion recovery (FLAIR) changes at the same locations and diffusion restriction in bilateral globus pallidi and bilateral centrum semiovale (Figure 1). Gradient echo showed subtle changes in bilateral

developed multisystem organ failure, including renal failure requiring CRRT and bacteremia requiring broad-spectrum antibiotics. The patient was treated with glucocorticoids and started on therapeutic heparin anticoagulation titrated to anti-factor Xa for an elevated D-dimer of 3.44 mg/L. On ventilator day 15, the patient was weaned from sedation and found to be significantly altered; she demonstrated extensor posturing of the right extremities and left hemiplegia. MRI of the brain showed FLAIR changes in bilateral mesial temporal structures, lenticular nuclei, crus cerebri, and centrum semiovale (Figure 2). Diffusion-weighted imaging showed restriction of those areas together with the splenium, body, and genu of the corpus callosum (Figure 2). SWI sequences showed hemorrhagic conversion in the left cerebral peduncle and bilateral basal ganglia (Figure 2). The patient was presumptively diagnosed with acute disseminated encephalomyelitis (ADEM) and started on a 5-day course of

plasma exchange (PLEX). The patient remains in critical condition with poor neurologic function.

COVID-19—Associated Vasculopathy. A 53-year-old male patient with hypertension presented with dyspnea and ultimately required mechanical ventilation and RICU care. CRRT was started for acute renal failure and broad-spectrum antibiotics were administered for bacterial pneumonia. The patient was started on therapeutic heparin anticoagulation for an elevated D-dimer of 9.52 mg/L. SARS-CoV-2 infection was confirmed with RT-PCR. On ventilator day 8, the patient was extubated but shortly thereafter developed left hemiparesis and right gaze deviation. Noncontrast CT of the head showed a subcortical parenchymal hemorrhage at the right temporal pole with associated vasogenic edema (Figure 3). The patient was reintubated and followed with interval imaging, which showed suspicion for cytotoxic edema secondary to acute ischemic stroke. Diffusion-weighted imaging sequences confirmed restriction of the entire right MCA territory suspicious of LVO, as well as within the lateral lenticulostriate territory (Figure 3). MRA was negative for LVO, demonstrating focal stenosis of the ICA supraclinoidal segments and patency in the anterior and posterior MCA M2 trunks (Figure 3). The patient remains in critical condition. The findings of ICA terminus stenosis with patent distal vessels were demonstrated on MRA in several other cases of vasculopathy, as well as on CTA in a 65-year-old male patient who developed a large territory infarct of the MCA territory (Figure 4).

DISCUSSION

Evolving evidence concerning critically hospitalized patients with confirmed COVID-19 links comorbidities of DM2, hypertension, chronic obstructive pulmonary disease, chronic kidney disease, obesity, and cardiovascular disease with an increased risk of more severe disease course and multisystem effects.^{13-16,18-23} Given that the aforementioned comorbidities are seen in patients undergoing treatment for neurologic conditions, particularly in the context of ischemic occlusive and hemorrhagic cerebrovascular disease, neurologic and neurosurgical patients are at heightened risk.^{13-16,18-23} In contrast to the typical bimodal patterns of age distribution of moderate and severe viral disease, data have demonstrated that increased age is significantly associated with greater odds of mortality for every additional year of life.²¹⁻²³ Patients in our cohort carried a high proportion of comorbidities and were relatively young. It is possible that the age phenomenon is confounded by the presence of complex multisystemic disease states such as DM2 and CKD, as every year of life increases the probability of developing a comorbid disease. We hypothesize that our patient population's high rate of comorbid disease is responsible for the more serious course of illness being experienced.

It is intuitive that severe strain on pulmonary function via acute respiratory distress syndrome (ARDS) would exacerbate pre-existing systemic disease via various pathophysiologic pulmonary mechanisms and accelerate such conditions.^{13-16,18-23} Furthermore, a pre-existing history of ischemic or hemorrhagic stroke has been demonstrated to be a significant risk factor for the development of ARDS in the neurointensive setting.^{13-16,18-23} Severe COVID-19 carries an association of vascular thrombosis.²⁴ It thus

becomes critical to accurately characterize disease pathophysiology to rule out direct injury secondary to viral infection from consequent systemic pathophysiology.

Much of SARS-CoV-2 pathophysiology has been derived from literature concerning SARS-CoV-1.²⁵⁻³¹ Both viruses have been shown to enter lower respiratory epithelium via attachment to the angiotensin-converting enzyme 2 receptor.²⁵⁻³¹ Although angiotensin-converting enzyme 2 receptor is found primarily in lung alveolar epithelium, it is present on the surface of CNS neurons, suggesting potential neurotropism.²⁵⁻³¹ An axodendritic trans-synaptic route has been reported as a potential mechanism for CNS dissemination.⁹ Rodent models infected with intranasal SARS-CoV-1 have demonstrated particular tropism for the cerebrum, thalamus, and rhombencephalon derivatives typical of viral encephalitis.⁹

Although coronaviridae CNS entry is well documented, its role in neurologic disease remains under investigation. Reports implicate potential central involvement of respiratory failure compounding primary pulmonary injury via direct infection of the pontine and medullary respiratory groups in COVID-19.⁹ With a median onset of 8 days for the development of ARDS, SARS-CoV-2 CNS involvement is possible by the time of ICU admission, reinforcing the hypothesis of a mixed central and peripheral etiology of pulmonary compromise.²⁵⁻³¹

In addition, SARS-CoV-2 may incite noninflammatory encephalopathy, which has been previously implicated in SARS-CoV-1 infection.²⁵⁻³¹ In MERS, viral-associated encephalopathy has been reported with resulting confusion, coma, ataxia, and focal motor deficits.⁸ A significant proportion of our patients showed evidence of direct neurologic injury. Diffuse hypoattenuation of

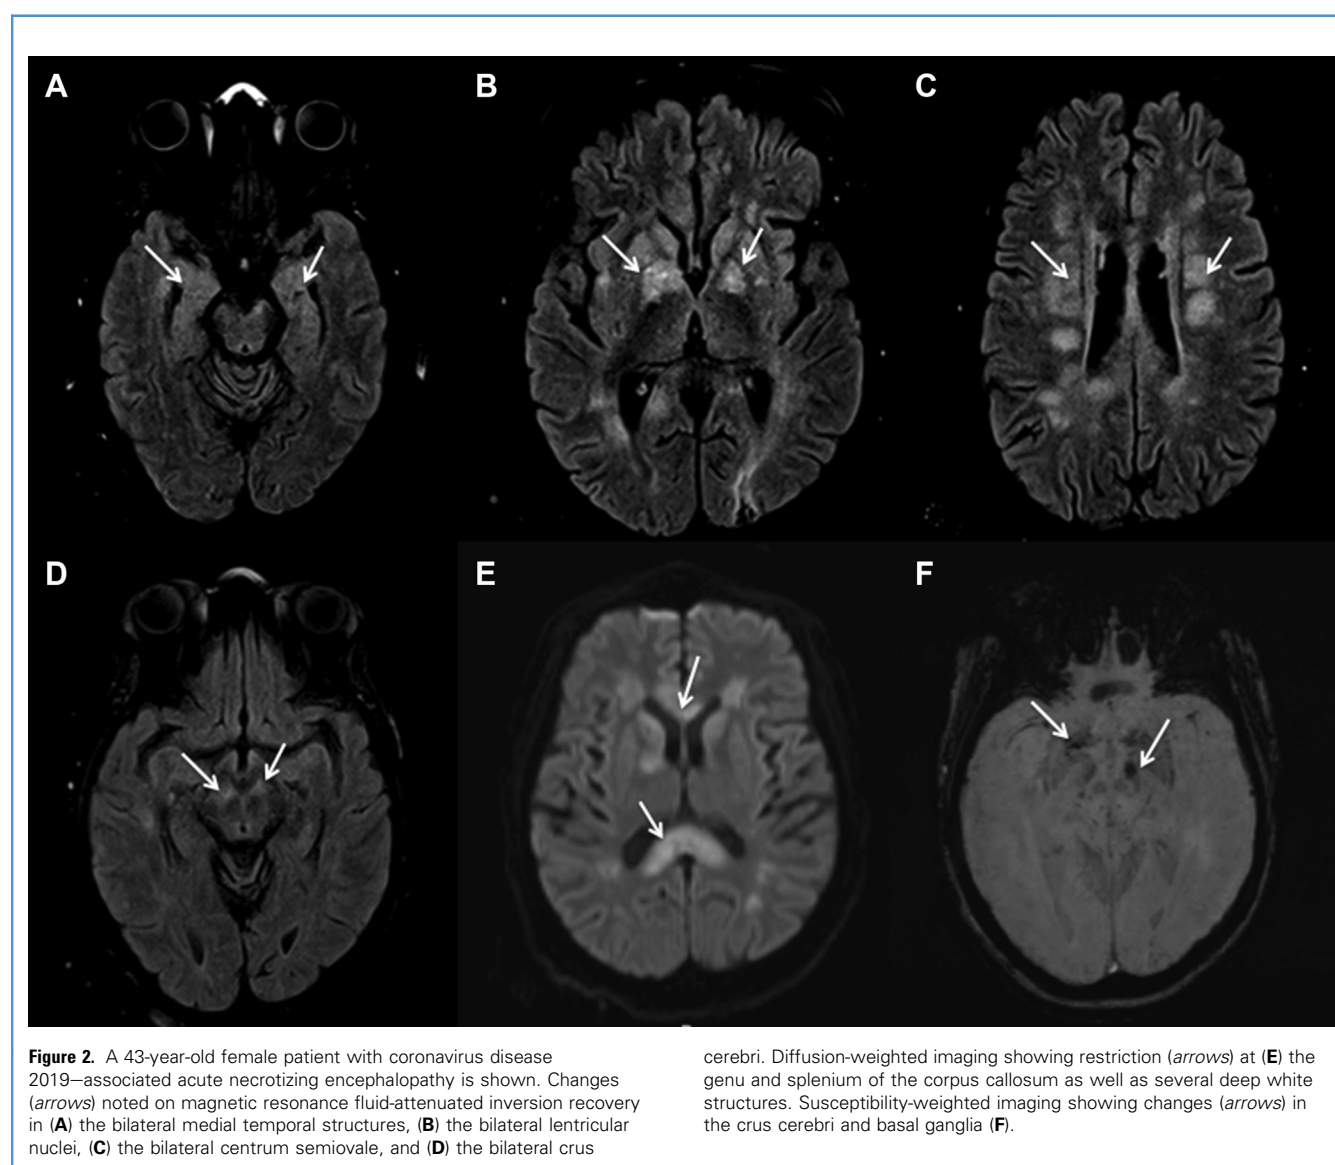

Figure 1. A 63-year-old female patient with coronavirus disease 2019-associated encephalopathy is shown. Noncontrast computed tomography scan of the head showed (A) hypodensities in bilateral globus pallidus pars interna (arrows) and (B) focal intraparenchymal hematoma at occipital pole (arrow). Magnetic resonance fluid-attenuated inversion

recovery (C) and gradient echo (D) showed changes at bilateral globus pallidus (arrows) and occipital pole. Diffusion-weighted imaging showing restriction at bilateral globus pallidus (arrows) (E) and at focal points in the centrum semiovale (arrows) (F).

deep white matter tracts and focal hypodensities of both white and gray deep structures on noncontrast CT observed in our patients are similar to the focal encephalitis and vasculitides associated with members of the *Herpesviridae* family.¹⁷ MRI was seldom ordered due to containment precautions and instability of the patients; however, when completed, findings were most often consistent with viral encephalitis: restriction and FLAIR changes in bilateral deep structures as well as the corpus callosum. Basal ganglia involvement with focal restriction, diffuse FLAIR changes on MRI, or discrete hypodensities on CT were common, and several patients had petechial changes noted on SWI similar to necrotizing encephalopathy.¹³⁻¹⁵ One patient had FLAIR changes in the cortical region of the bilateral pre-central frontal gyri and deep structure changes characteristic of anoxic injury.

Reported cases of severe neurologic disease in COVID-19 are rare but have heterogeneous presentation and progress rapidly.¹³⁻¹⁵ Our patients progressed variably along 1 of 3 presentation spectrums. The majority of patients developed severe electrographic nonspecific encephalopathy during their disease course, with clinical AMS ranging from mild to obtunded. These patients often had nonspecific imaging findings such as hypodensity or hypoattenuation of deep structures. It would be reasonable to classify these patients as having COVID-19-associated encephalopathy. One of our patients developed nonconvulsive status epilepticus, which is similar to literature descriptions of COVID-19-associated epileptic encephalopathy.¹²

In severe cases, CT and MRI findings were consistent with other viral encephalitis, particularly IAE and acute necrotizing encephalopathy. It appears that acute necrotizing encephalopathy is

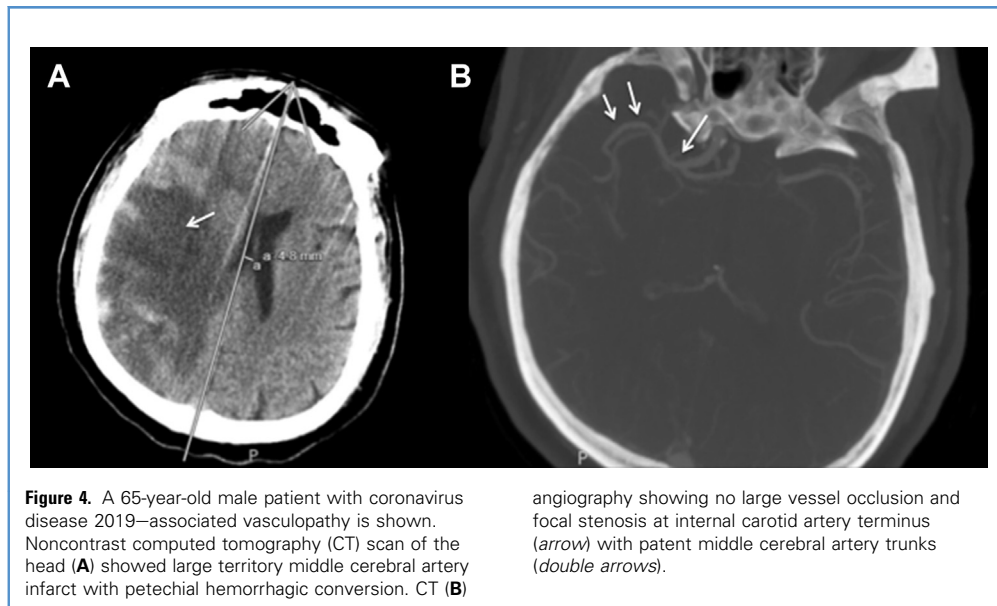

not a diagnosis restricted to hemagglutinin 1 neuraminidase 1 influenza virus *Orthomyxoviridae* infection and may be a sequela of SARS-CoV-2 pathogenesis. As previously mentioned, coronaviridae can alter neuroinflammatory cascades, and given the suspected pathogenesis of COVID-19–associated ARDS, it is plausible that necrotizing encephalopathy progresses similarly. These diagnoses remain subjective and clinical. None of our patients had their CSF tested for viral positive-sense single-stranded RNA, although there may be utility in doing so, given reports of CSF infection despite a negative nasopharyngeal swab.¹³

This is particularly relevant when performing intrathecal procedures, such as lumbar puncture, as CSF to mucous membrane transmission has been demonstrated to be a viable mechanism in HIV 1 and 2.³² Furthermore, there is evidence that a negative oropharyngeal swab does not rule out active COVID-19 disease.^{1,32}

Available literature on the treatment of CNS involvement in COVID-19 is variable and sparse, with reports including intravenous immunoglobulin and corticosteroids in the treatment of encephalitis.¹² Intravenous immunoglobulin, which has been used

in treating other necrotizing forms of IAE, is theorized to treat severe cytokine storming and may ameliorate secondary vasogenic edema from blood–brain barrier compromise.¹⁴ Similarly, PLEX may help relieve secondary disease patterns radiographically similar to ADEM.¹⁴ One patient in our cohort, who was presumed to have ADEM, and likely had early sequelae of COVID-19—associated acute necrotizing encephalopathy, underwent a 5-day course of PLEX. Seizure activity should be managed per protocol with antiepileptics,¹³ and anecdotal reports of treatment success with anti-inflammatories/antiparasitics such as hydroxychloroquine and viral protease inhibitors such as lopinavir and ritonavir may be considered,¹³ although either option has yet to yield promising results. Patients with elevated levels of D-dimer have been reported to have a worse prognosis and greater risk of thromboembolic complications in COVID-19, presumably secondary to consumptive coagulopathy.^{33–36} In accordance with recent literature,³⁷ all critical patients with COVID-19 at our center are therapeutically anticoagulated with heparin titrated against anti-factor Xa unless otherwise contraindicated.

The increased prevalence of acute cerebrovascular disease in patients with severe infection is thought to be related to elevated D-dimer levels, which have been previously shown to correlate with unfavorable outcomes in stroke patients.³³ Furthermore, cerebrovascular disease is a known predisposing factor for the development of ARDS in a neurocritical care setting.³³ Although there are no specific guidelines concerning pre-existing stroke or elevated D-dimer in the setting of COVID-19, it is easy to speculate that these patients likely have an increased likelihood of progressing to ARDS and warrant increased vigilance in monitoring disease course.

Five patients in our cohort experienced largescale cerebrovascular accident, 4 of which occurred after presentation. Two of these were purely parenchymal hematomas located in the subcortical occipital lobe. One of these patients presented with a

focal intracerebral hematoma (ICH) in the left inferior occipital gyrus toward the occipital pole and the other with a similar location, though below the lateral occipital sulcus in the second occipital gyrus. Both of these patients had negative vascular imaging on MRA and CTA but had deep structure involvement including corpus callosal and focal hypodensities in the basal ganglia. These findings suggest a COVID-19—associated small vessel vasculopathy, such as that observed in VZV infection.¹⁷ One patient with a history of an occipital pole infarct was found to have restriction of bilateral frontotemporoparietal and insular cortices. Although MRA did not show any LVO, it revealed focal stenosis of the ICA terminus with preserved distal flow. A fourth patient with a subtotal infarct of the right MCA M2 superior division experienced an interval expansion of his stroke several days into his stay to include the entire MCA territory with hemorrhagic conversion, hemorrhagic infarction type 2. On MRA, the patient was also found to have bilateral focal non-occlusive stenosis of the ICA terminus with patent distal anterior vasculature. Another patient with a subcortical superior temporal gyrus ICH near the temporal pole progressed to total infarct of the MCA territory, including the region supplied by the lateral lenticulostriates in the basal ganglia. This patient was found to have focal supraclinoidal ICA stenosis with patent distal vasculature on MRA. Only 1 patient in our cohort developed an ischemic stroke secondary to LVO, and this occurred at the distal end of the P2B segment of the posterior cerebral artery, an atypical location too distal for neuroendovascular intervention.

In our cohort of patients with COVID-19, stroke involved either focal subcortical lobar ICH, large-territory anterior circulation infarcts in the presence of focal ICA terminus stenosis without LVO, or both. Although COVID-19 is known to induce thrombosis-associated complications, including stroke, reports did not confirm LVO to be the actual etiology.²⁴ Our patient population suggests large territory infarct may occur via transient or

hemodynamic ischemic condition in the absence of LVO. Observation in other viral infections with similar presentation are often deemed to derive from associated vasculopathies.¹⁷

All of our patients with vasculopathy had elevated D-dimer, 4 of whom were on therapeutic anticoagulation at the time of insult. The sole patient who was not receiving anticoagulation suffered LVO. There may be separate mechanisms accounting for acute ischemic stroke in COVID-19. The first may be LVO as a direct consequence of hypercoagulability, similar to reports of CTA-confirmed pulmonary embolism.³⁷ This was likely the sequela suffered by the patient with a posterior territory infarct. The remaining 4 with evidence of focal ICA terminus stenosis were therapeutically anticoagulated at the time of infarct, suggesting a separate mechanism. Large-vessel vasculopathy has been documented in both HIV-1 and 2 as well as VZV infection.^{38,39} VZV vasculopathy, in particular, presents with focal segmental stenosis of both large and small vessels with secondary ischemic infarcts,³⁹ whereas HIV vasculopathy has typical dilatation of the proximal large vessels of the anterior circulation and small vessel thickening.³⁸ Both HIV and VZV vasculopathy may present with both lacunar and large hemispheric strokes in the absence of LVO on noninvasive imaging.^{38,39} Likewise, both MERS and SARS have been associated with varying degrees of direct cardiovascular and cerebrovascular involvement.^{40,41}

Limitations

We acknowledge our report is limited by the retrospective nature of analysis and our limiting inclusion criteria to patients actively admitted to our center in critical condition with confirmed COVID-19. Future investigations will seek to expand our data in a prospective manner for all patients with confirmed SARS-CoV-2—positive assay. Likewise, at the time of data collection, we were not actively evaluating patients' CSF for the presence of viral genetic material. Prospective CSF analysis also will be included in ongoing

studies, as delineation of associated clinical factors and chronology of positive viral tests in CSF as compared with other mediums is critical in understanding disease pathobiology and transmissibility. Furthermore, as neurologic disease in COVID-19 is actively being characterized, we did not have a specific imaging protocol for such patients, and all patients were imaged secondary to clinical findings. As such, not all patients received combined CT, EEG, vascular studies, and MRI, potentially masking relevant radiographic findings.

CONCLUSIONS

As the SARS-CoV-2 pandemic continues, we increasingly appreciate the neurologic manifestations of COVID-19. We present the neurologic and ischemic sequelae observed in 27 of 76 critically ill patients with COVID-19 who were admitted on 1 day to our tertiary academic center in New Orleans, Louisiana. Presentations were heterogeneous but fit into one of several categories. These included COVID-19—associated encephalopathy, COVID-19—associated acute necrotizing encephalopathy, and COVID-19—associated vasculopathy. No disease pattern is likely mutually exclusive. Further investigations exploring pathogenesis, management, and outcomes are warranted.
