Abstract

Recent genome-wide association studies (GWAS) have found cerebellum as a top hit for sleep regulation. Restless legs syndrome (RLS) is a sleep-related sensorimotor disorder characterized by uncomfortable sensations in the extremities, generally at night, which is often relieved by movements. Clinical studies have found that RLS patients have structural and functional abnormalities in the cerebellum. However, whether and how cerebellar pathology contributes to sleep regulation and RLS is not known. GWAS identified polymorphisms in BTBD9 conferring a higher risk of sleep disruption and RLS. Knockout of the BTBD9 homolog in mice (Btbd9) and fly results in motor restlessness and sleep disruption. We performed manganese-enhanced magnetic resonance imaging on the Btbd9 knockout mice and found decreased neural activities in the cerebellum, especially in lobules VIII, X, and the deep cerebellar nuclei. Electrophysiological recording of Purkinje cells (PCs) from Btbd9 knockout mice revealed an increased number of nontonic PCs. Tonic PCs showed increased spontaneous activity and intrinsic excitability. To further investigate the cerebellar contribution to RLS and sleep-like behaviors, we generated PC-specific Btbd9 knockout mice (Btbd9 pKO) and performed behavioral studies. Btbd9 pKO mice showed significant motor restlessness during the rest phase but not in the active phase. Btbd9 pKO mice also had an increased probability of waking at rest. Unlike the Btbd9 knockout mice, there was no increased thermal sensation in the Btbd9 pKO. Our results indicate that the Btbd9 knockout influences the PC activity; dysfunction in the cerebellum may contribute to the motor restlessness found in the Btbd9 knockout mice.

Conflict of interest: None.

Introduction

Restless legs syndrome (RLS), also known as Willis-Ekbom disease, is a sleep-related sensorimotor disorder that affects up to 10% of the general population (Chen et al., 2019; Trenkwalder and Paulus, 2010). The sensory components of RLS include uncomfortable sensations and an urge to move. The motor components are characterized by movements to relieve the leg discomfort and by involuntary periodic leg movements (PLM) (Allen et al., 2014). The symptoms often occur at night and while lying at rest. The perturbation of the sleep cycle occurs commonly, affecting the patient's overall quality of life (Abetz et al., 2004; Giannaki et al., 2017).

To date, no neurodegeneration has been observed in RLS patients. However, imaging studies have found structural and functional alterations in multiple brain regions, including the cerebellum. A regional decrease of cerebellar gray matter volume has been shown with voxel-based morphometry (Chang et al., 2015). In another study, the activity of the anterior tibial muscle of RLS patients was recorded. There is a negative association between the sensory leg discomfort (SLC) and the tonic muscle activity, as well as the tonic muscle activity and the activation in the cerebellum (Spiegelhalder et al., 2008). The results indicate increased RLS-related subjective SLC and cerebellum activity during muscle relaxation at rest. In addition, the cerebellum is bilaterally activated both during SLC, and SLC combined with PLM conditions (Bucher et al., 1997; Margariti et al., 2012). Furthermore, cerebellar GABA levels are negatively correlated with both PLM indices and RLS severity in RLS subjects (Winkelman et al., 2014). In summary, these clinical studies suggest that RLS patients have increased activity within cerebellar circuits, which may be caused by the lower level of GABA and is correlated with sensory (SLC) and motor symptoms (PLM) (Winkelman et al., 2014).

As a region of emerging importance in sleep-wake regulation, the cerebellum has been found participating in the neuronal circuitry underlying the sleep-wake regulation and shows sleep stagedependent activity (Canto et al., 2017). In addition, recent GWAS identified the cerebellum as the top brain region for genes associated with circadian rhythms and sleep duration (Dashti et al., 2019; Jones et al., 2019a).

GWAS have also implicated up to nineteen risk loci, including *BTBD9*, as genetic risk factors of RLS (Schormair et al., 2017; Stefansson et al., 2007; Winkelmann et al., 2007). Other GWAS identified *BTBD9* as an associated gene of sleep duration, sleep timing, and daytime sleepiness (Jones et al., 2019b; Wang et al., 2019). However, how the altered function of *BTBD9* could lead to or contribute to RLS and sleep regulation are unclear. *BTBD9* is ubiquitously expressed and codes for a protein belonging to the BTB (broadcomplex, tramtack and bric à brac) protein family. Proteins of BTB family are involved in transcriptional regulation, cytoskeleton organization, regulation of ion channels, and protein ubiquitination (Stogios et al., 2005; Stogios and Prive, 2004). BTBD9 also contains a BACK

(BTB and C-terminal Kelch) domain, which may play a role in substrate orientation in Cullin3-based E3 ligase complexes (Stogios et al., 2005). Cullin3 and some BTB proteins have been suggested to be important for dopaminergic and glutamatergic functions in the brain (Laezza et al., 2007; Rondou et al., 2008; Salinas et al., 2006; Schaefer and Rongo, 2006). Dysregulated iron homeostasis and dysfunctional dopaminergic system can lead to RLS (Ferre et al., 2019). One of the two original GWAS shows an association of the *BTBD9* variant with serum ferritin concentration (Stefansson et al., 2007), which was replicated partially by others (Ji et al., 2018; Sorensen et al., 2012). Interestingly, both iron deficiency and excess of iron can cause impairments in the dopaminergic system (Jellen et al., 2012).

A quantitative trait loci (QTL) analysis in mice identified several QTLs related to the iron in the ventral midbrain, including one on mouse chromosome 17 that contains Btbd9 (Jones et al., 2003). Changes in hippocampal synaptic plasticity and neurotransmission have been found in Btbd9 (mouse homolog of human BTBD9 gene) knockout mice (DeAndrade et al., 2012b). Gene silencing of the BTBD9 homolog, dBTBD9, in fly has been used to understand the function of BTBD9 protein in RLS, and the flies were found to have increased motor activity, decreased dopamine levels, and fragmented sleep patterns (Freeman et al., 2012). Knockdown of dBTBD9 in subsets of dopaminergic neurons is able to reproduce these phenotypes, which are rescued by a dopamine receptor agonist pramipexole (Freeman et al., 2012). Additionally, over-expression of BTBD9 in HEK cells decreases iron-responsive element-binding protein, IRP2, and increases ferritin expression (Freeman et al., 2012). Similarly, Btbd9 knockout (KO) mice show motor restlessness, thermal hypersensitivity, increased serum iron level, and a disruption in sleep structure (DeAndrade et al., 2012a). The sensory deficit of *Btbd9* KO mice can be rescued by a dopamine receptor agonist ropinirole (DeAndrade et al., 2012a). These studies indicate systematic Btbd9 KO mice as a viable genotypic RLS animal model to elucidate the pathophysiology of RLS and other sleep disorders (Allen et al., 2017; DeAndrade et al., 2012a; DeAndrade and Li, 2015).

We hypothesize that *Btbd9* mutation leads to altered cerebellar activity that contributes to the disruption of sleep-like behaviors and pathogenesis of RLS. To test the hypothesis, we performed *in vivo* manganese-enhanced MRI (MEMRI) with the systematic *Btbd9* KO mice to characterize abnormal cerebellar regions. This was followed by electrophysiological recordings to measure both intrinsic excitability and spontaneous firing activity of Purkinje cells (PCs). Finally, we generated a PC-specific *Btbd9* KO mouse model to test if the loss of BTBD9 in PCs alone is sufficient to induce behavioral abnormalities, as we observed in the systematic *Btbd9* KO mice.

Experimental Procedures

Mice

The experiments described here comply with the ARRIVE guidelines and are in accordance with the National Institute of Health Guide for the Care and Use of Laboratory Animals (NIH Publications No. 80-23) revised 1996. All mice used in the experiments were male adults unless specified in the text.

The generation of the systematic Btbd9 KO mice

The systematic *Btbd9* KO mice used for imaging were described previously (DeAndrade et al., 2012a). The systematic *Btbd9* KO mice for electrophysiological recordings and Western blot were generated from a line of mice imported from the European Mouse Mutant Archive (EMMA) (EMMA ID: 05554) as previously described (Lyu et al., 2019b). The mice were housed at 23-25 C under normal twelve hours light and twelve hours dark condition (12-LD). To confirm the loss of *Btbd9* mRNA in the cerebellum, we dissected out the cerebellum from *Btbd9* KO and their wildtype (WT) littermates, and flash froze the tissue in liquid nitrogen. RNA was isolated using an RNAeasy Mini kit (Qiagen) following the manufacturer's instructions. cDNA was made subsequently with SuperScript III reverse transcriptase (Invitrogen). *Btbd9* mRNA expression was detected by PCR primers specific to *Btbd9* exons 4 and 5 (forward: GAC TCT TGT CTC CGG ATG CT; reverse: TCA CAA CCT GAG CCC CAT AC; Fig. 4A).

The generation of PC-specific Btbd9 knockout mice

The PC-specific Btbd9 knockout mice (Btbd9 pKO) were generated from Btbd9 loxP mice crossed with *Pcp2-cre* mice (Zhang et al., 2004) as described (Lyu et al., 2019b; Yokoi et al., 2012a; Yokoi et al., 2012b; Zhang et al., 2011). Mice doubly heterozygous for both Btbd9 loxP and Pcp2-cre were then crossed with Btbd9 loxP hetero- or homozygous mice to derive Btbd9 pKO mice and their control littermates, including WT littermates, Pcp2-cre+/-(animals only expressing Pcp2-cre) and Btbd9 loxP+/- (animals only having loxP sites in one allele) or Btbd9 loxP-/- (animals having loxP sites in both alleles). PCRs were used for genotyping the Pcp2-cre (forward: ATC TCC GGT ATT GAA ACT CCA GCG C; reverse: CAC TCA TGG AAA ATA GCG ATC) and *loxP* sites (forward: ACA TCA CCC ATT ACT TAG AAC CTC; reverse: CAC AGC TAT TTC CTG TCA TTC TGG ACA). To assess the specific deletion of Btbd9 in the cerebellum, we dissected out brain regions following the protocol (Spijker, 2011) and conducted PCR with primers specific for recombined locus (forward: AAG GCG CAT AAC GAT ACC ACG AT; reverse: TGG TGA TTC AAA TCT CCT TCC AAC ACA) (Fig. 4C). However, due to the lack of a high-quality BTBD9 antibody, we did not provide a direct indication of the specific missing of the BTBD9 protein in the Purkinje cells in the pKO mice. The *Pcp2-cre* mice we used (Zhang et al., 2004) are well-established and have been used extensively in at least 23 published original research studies based on citation analysis. Five out of 23 studies used fluorescent indicators to mark *Pcp2-cre* positive neurons. Six out of 23 articles did not assess protein or mRNA expression of the floxed gene. The Pcp2-cre mice appear to work with at least 26 different floxed loci.

Manganese-enhanced MRI

Data were collected at the same time and the same set of mice as previously described (Lyu et al., 2019b).

Electrophysiological recording

Slice preparation—Experiments were conducted using six WT male mice and six systematic *Btbd9* KO male littermates around 8 months of age. The electrophysiological

recordings were assessed by investigators who were blind to genotypes. Parasagittal brain slices (300 µm in thickness) were cut inside a chamber filled with ice-cold, oxygenated saline using a Vibratome (Leica VT 1000s). The concentrations of solutes in the holding chamber were (in mM): 180 sucrose, 2.5 KCl (potassium chloride), 1.25 NaH₂PO₄ (monosodium phosphate), 25 NaHCO₃ (sodium bicarbonate), 10 D-glucose, 1 CaCl₂ (calcium chloride), and 10 MgCl₂ (magnesium chloride). The slices were recovered for 60 minutes at 35°C in a holding chamber with oxygenated artificial cerebrospinal fluid (ACSF; in mM: 126 NaCl, 2.5 KCl, 1.25 NaH₂PO₄, 25 NaHCO₃, 2 MgCl₂, 2 CaCl₂, and 10 D-glucose). The slices were then incubated at room temperature until electrophysiological recording.

Cell-attached recordings—The slices were transferred to a recording chamber with ACSF continuously perfused and bubbled by 5% CO₂ and 95% O₂ at a rate of 1.5 ml/minute while being visualized with an upright microscope (Zeiss, Germany) using a $40\times$ waterimmersion objective with infrared optics. The temperature was kept at $34.5-35.5^{\circ}$ C. PCs from the apex and bank of lobules IV to VI of the cerebellums were randomly selected and recorded.

Cell-attached recordings were performed with a K-gluconate-based internal solution with the following concentrations (in mM) of: 112.5 K-gluconate, 4 NaCl, 17.5 KCl, 0.5 CaCl₂, 5 MgATP (adenosine 5'-triphosphate magnesium salt), 1 NaGTP (adenosine 5'-triphosphate sodium salt), 5 EGTA (ethylene glycol-bis(β -aminoethyl ether)-N,N,N',N'-tetraacetic acid), 10 HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid); with pH of 7.2 (270–280 mOsm) and resistance of 5–10 M Ω . Positive pressure was applied to the patch electrode as it approached the PC. Suction was applied to the electrode to create a seal (> 5 G Ω) between the recording pipette and the cell membrane. Action potential (AP) current was recorded in a voltage-clamp mode that was maintained at an average of 0 pA holding current. Picrotoxin (10 μ M) and CGP55845 (1 μ M) were used to block inhibitory synaptic transmission, while kynurenic acid (5mM) was used to block excitatory synaptic transmission (Fremont et al., 2017).

Whole-cell recordings—After breaking through the cell membrane, access resistance was maintained throughout at <15 M Ω . Resting membrane potential was recorded in current-clamp mode. AP for current step recording was triggered using depolarizing current steps of 300 ms.

All experiments were conducted at 35±0.5°C by a dual automatic temperature controller (TC-344B). Cell-attached and whole-cell recordings were obtained from PCs using Axopatch 1D Amplifier (Molecular Devices). Electrophysiological recording data were acquired using pCLAMP 10 software (Molecular Devices). Signals were filtered at 5 kHz, digitized at 10 kHz with a DigiData 1440 (Molecular Devices). Cell firing activity was derived using the Mini Analysis Program. All data had been adjusted with the liquid junction potential.

Behavioral studies

Continuous open field—Six male *Btbd9* pKO mice and seven male control littermates with an average age of 3 months were maintained on 12-LD for 7 days. As described previously (Lyu et al., 2019a; Meneely et al., 2018), each mouse was placed in a VersaMax Legacy open field apparatus with sufficient corncob bedding, food, and water. The apparatus has infrared sensors along the walls that detect any breaks in the beams, which are then decoded by VERSDATA software (version 2.70-127E, AccuScan Instruments Inc.) into behavioral outputs. The data were recorded every 15 minutes throughout 7 days. Data from the first three days were excluded because the animals were acclimating to the device. Data processing was done as previously described (Lyu et al., 2019b; Lyu et al., 2020). Briefly, to compare the total distance traveled between Btbd9 pKO and WT mice, we separated the data into light and dark phases because mice are nocturnal. Each phase contains 4 periods, from day 4 to day 7, or night 4 to night 7. The distance traveled during each period was added up from the 15 min bins. To compare the probability of waking between the two groups, we recoded the data according to the total distance traveled during each 15 min bin. Although an immobile mouse may or may not be asleep, if the total distance traveled during the 15 min was "0", the mouse was assumed as sleeping and coded as "0"; otherwise, the mouse was considered as awake, and coded as "1". The method was established and validated by others (Davies et al., 2017; Singh et al., 2019). A similar method of activity-based sleep estimation was applied to humans. Pubmed search using the keywords "accelerometer" and "sleep" produced 144 articles for human studies from January 1st, 2019 to April 26, 2020. It appears activity-based method is widely used to estimate sleep with the caveat that actual sleep and immobility may commingle (Acosta et al., 2019; Dashti et al., 2019; Devine et al., 2019; Ettore et al., 2019; Jones et al., 2019b; Kessler et al., 2019; Kuula et al., 2019; Lane et al., 2019; Papandreou et al., 2019; Wendt et al., 2020).

Wheel running—Nine male *Btbd9* pKO mice and eleven male control littermates with an average age of 6 months were maintained on 12-LD for seven days. Wheel running activity was recorded as the number of wheel revolutions in 5 minutes bins using Lafayette Instrument Activity Wheel Monitors. The activity from the last 4 days was included in the data analysis, grouped by light and dark phases.

Tail flick—Ten male *Btbd9* pKO mice and eleven male control littermates with an average age of 8 months were tested for the sensitivity to warm stimuli using the Tail Flick Analgesia Meter (San Diego Instruments) as previously described (DeAndrade et al., 2012a). Briefly, each mouse was placed in an acrylic restrainer with the distal end of its tail protruding under a heat lamp. The lamp, together with a timer, was turned on, both of which stopped automatically when the mouse flicked its tail away from the light. The latency to respond was limited to 30 seconds to prevent injury to the mouse.

Statistical analysis

Brain images were acquired and analyzed as previously reported (Lyu et al., 2019b; Perez et al., 2013). Mean number of voxels for each region of interest (ROI) was compared by an unpaired two-tailed t-test (homoscedastic variances, α 0.05). Other data were tested for normality first using the SPSS statistical package. Tiring frequency obtained by injection of

step currents, spontaneous firing data, tonic/non-tonic cell distribution, continuous open field, and wheel running data were not normally distributed and analyzed by generalized mixed model ANOVA (GENMOD, SAS statistical package). For tonic/non-tonic cell distribution analysis, GENMOD with binomial distribution was used. The tail-flick data were normally distributed and therefore analyzed by mixed model ANOVA and repeated measurement ANOVA (SAS). Age was used as a continuous variable in both GENMOD and ANOVA. The hourly activities in Figures 5 and 6 were processed as described previously (Lyu et al., 2019b; Lyu et al., 2020). Briefly, for Figure 5, we summed the interval counts during each hour for each animal. Wheel-running activity during the last 96 hours was analyzed. Therefore, each animal had 4 data points for each hour. The mean interval counts within each hour were calculated for each genotype. The p values, derived from the unpaired Student's t-test, were marked above hours in the figure. For figure 6A, we summed the total distance traveled during each hour for each animal and did the rest the same as the wheelrunning test (Fig. 5) described above. To generate the hourly probability of waking in Figure 6B, we determined the sleep status by the total distance traveled during 15 min in the continuous open field test, as mentioned above. Therefore, there were 4 data points for each animal during each hour, which were coded from 1 to 4 as "sample". The open field activity of the last 4 days was analyzed. Hence each animal had 4 days of data, which were coded from 4 to 7 as "period". The probability of waking was compared between pKO mice and controls during each hour using SAS GENMOD with a binomial distribution and with repeated measurement of period and sample. The significant p values were marked above hours in the figure.

Results

Decreased cerebellar neural activity in the systematic Btbd9 KO mice

MEMRI has been extensively used to detect Ca^{2+} -dependent synaptic activity (Chiu et al., 2015; Dudek et al., 2015; Hsu et al., 2008; Lu et al., 2007; Perrine et al., 2015). Mn^{2+} penetrates active synapses through voltage-gated calcium channels as a calcium analog (Fukuda and Kawa, 1977; Narita et al., 1990) and is sequestered and transported transportedly either antero- or retrogradely across active neural circuits (Murayama et al., 2006; Pautler et al., 1998; Saleem et al., 2002; Sloot and Gramsbergen, 1994; Takeda et al., 1998a; Takeda et al., 1998b). The presence of the paramagnetic Mn^{2+} ion in the brain increases longitudinal relaxation rates and enhances signal intensity in T1 weighted scans, and is utilized for functional mapping of synaptic activity (Duong et al., 2000). Here, after intraperitoneal injection of Mn^{2+} into the mice, the images of ROI were acquired (Fig. 1A). These ROIs were further parceled into smaller sub-sections for subsequent qualitative inspection of neural activity. In Btbd9 KO mice the activated number of voxels were generally decreased in the cerebellar region, especially in the lobules VIII, lobules X and the deep cerebellar nuclei (DCN) (Fig. 1B, p < 0.05, unpaired two-tailed t-test). The result suggests Btbd9 KO mice have a lower level of neural activity in certain cerebellar regions.

Increased percentage of non-tonic PCs and spontaneous activity in tonic PCs of the systematic *Btbd9* KO mice

PCs constitute the sole output of the cerebellum. They send inhibitory output to the DCN, which connects to the thalamus, then to the striatum and cortical areas that modulate movement and sensation (D'Mello and Stoodley, 2015). PCs either fire at a relatively constant rate, tonic firing, or intermittently with pauses separating the firing periods, nontonic firing (Engbers et al., 2013; Loewenstein et al., 2005; Womack and Khodakhah, 2002; Yartsev et al., 2009). Here, we grouped those cells without pause of the spontaneous firing lasting for more than 300 msec during the cell-attached patch-clamp as tonic cells (Tian et al., 2013) and otherwise as non-tonic cells. To understand how the loss of BTBD9 affects the function of PCs, we firstly employed cell-attached recording to monitor the spontaneous activity of PCs in both Btdb9 KO and WT mice (Fig. 2A). There was a significant increase in the percentage of non-tonic PCs in the Btbd9 KO mice (Fig. 2A, table at the bottom, p =0.002, GENMOD with a binomial distribution). Analysis of passive membrane properties revealed that Btbd9 KO PCs had no changes in the membrane potential (Supplementary Fig. 1A, p = 0.27, ANOVA) and resistance (Supplementary Fig. 1C, p = 0.13, ANOVA), but showed decreased capacitance (Supplementary Fig. 1B, p = 0.049, ANOVA) compared with WT PCs. Membrane capacitance is proportional to the membrane surface area (Golowasch et al., 2009). Membrane resistance is a function of the number of open ion channels (Holmes et al., 1992). Our results indicate that KO PCs were smaller in size. When comparing the firing activity of both tonic and non-tonic cells together, we did not find significant differences in the frequency (Fig. 2B, left panel, p = 0.28, GENMOD with a gamma distribution) nor the coefficients of variation (CV; Fig. 2B, right panel, p = 0.34, GENMOD with a gamma distribution) of the spontaneous firing between the *Btbd9* KO and WT groups. However, the spontaneous firing frequency of the tonic cells was significantly increased (Fig. 2C, left panel, p = 0.04, GENMOD with a gamma distribution) but CV was unchanged in *Btbd9* KO mice (Fig. 2C, right panel, p = 0.71, GENMOD with a gamma distribution). Both firing frequency (Fig. 2D, left panel, p = 0.79, GENMOD with a gamma distribution) and CV (Fig. 2D, right panel, p = 0.91, GENMOD with a gamma distribution) of non-tonic cells remained unchanged between the two groups.

Increased intrinsic excitability in tonic PCs of the systematic Btbd9 KO mice

Next, we performed the whole-cell current-clamp recordings of identified tonic and nontonic cells in both Btbd9 KO and WT mice (Fig. 3A). By stimulating with depolarizing current steps and measuring firing frequency as a function of current step amplitude, we found that PCs of Btbd9 KO mice, overall, fired at a similar frequency in response to the applied step currents (Fig. 3B, p = 0.33, GENMOD with a negative binomial distribution) compared with WT PCs. When separately analyzed, tonic PCs of Btbd9 KO mice exhibited a significantly higher intrinsic excitability (Fig. 3C, p = 0.04, GENMOD with a negative binomial distribution) compared with WT tonic PCs. In contrast, non-tonic PCs of Btbd9 KO mice did not differ from those of WT PCs (Fig. 3D, p = 0.70, GENMOD with a negative binomial distribution). The results indicate that the loss of BTBD9 increased the intrinsic excitability of the tonic PCs.

Finally, *Btbd9* mRNA expression was assessed in both *Btbd9* KO and WT mice. *Btbd9* cDNA was not detectable in the cerebellum of the KO mice (Fig. 4A).

Generation and behavioral analysis of Btbd9 pKO mice

A principal feature of RLS is the desire to move. Previous phenotypic mouse or fruit fly models of RLS have shown altered activity levels and sleep disruption (DeAndrade et al., 2012a; Freeman et al., 2012). Therefore, to test if PC-specific *Btbd9* KO contributes to these phenotypes, we generated *Btbd9* pKO mice using the *Cre-loxP* system (Fig. 4B). To confirm the tissue specificity of the knockout, we dissected out different brain regions from the *Btbd9* pKO mice and their controls. DNAs were extracted from different brain regions, and PCR reactions were conducted. Only the DNA extracted from the cerebellum of *Btbd9* pKO mice showed the recombined band (Fig. 4C), indicating the knockout was restricted to the cerebellum.

Next, we assessed the voluntary activity level of the strain by the wheel running test. The activity level of Btbd9 pKO mice showed a significant increase during the light phase (Fig. 5A, light phase, p = 0.04, GENMOD with a negative binomial distribution), when the animals are normally sleeping or resting, but no change during the dark phase, when the animals are usually active (Fig. 5B, dark phase, p = 0.92, GENMOD with a negative binomial distribution). Hourly analysis indicated that the wheel running activity of Btbd9 pKO mice was especially high at 9:00 AM (Fig. 5A) and especially low during the 1st half of the active phase (Fig. 5B). With a continuous open field, we examined the total activity of the mice. Similarly, the activity level of Btbd9 pKO mice showed a significant increase during the rest phase (Fig. 6A, light phase, p < 0.0001, GENMOD with a gamma distribution), and during the active phase (Fig. 6A, dark phase, p < 0.0001, GENMOD with a gamma distribution). Different from the wheel running study, continuous open field tests showed that Btbd9 pKO mice were more active throughout the time during both day and night (Fig. 6A). In addition, analysis of sleep-like behaviors indicates an increased probability of waking of the *Btbd9* pKO mice in the rest phase (Fig. 6B, left panel, p < 0.0001, GENMOD with a binomial distribution), especially at 7:00 AM, 8:00 AM, and the 2nd half of the rest phase, but not in the active phase (Fig. 6B, right panel, p = 0.10, GENMOD with a binomial distribution). The results suggest that there is a significant increase in day-time activity in the Btbd9 pKO mice. Loss of the BTBD9 protein only in PCs can lead to a circadian components-dependent motor restlessness.

RLS patients usually have uncomfortable sensations in the legs that are associated with the urge to move. Therefore, we tested the Btbd9 pKO mice for abnormalities in the sensory system using the tail-flick test. There was no significant difference between the Btbd9 pKO mice and their control littermates in the latency to withdraw from the heat stimuli (Fig. 6C, p = 0.35, GENMOD with a gamma distribution). Hence Btbd9 pKO mice did not have increased thermal sensation as reported in the systematic Btbd9 KO mice.

Discussion

The function of *Btbd9* and how the mutations lead to the symptoms of the RLS patients are not fully understood. The cerebellum is widely known to participate in movement control

and receives increasing attention for its role in sleep regulation (Canto et al., 2017). In addition, brain imaging studies indicate that RLS patients have structural and functional abnormalities in their cerebella (Bucher et al., 1997; Chang et al., 2015; Margariti et al., 2012; Spiegelhalder et al., 2008; Winkelman et al., 2014). Here, we utilized a previously generated systematic Btbd9 KO mice, which exhibit several symptoms observed in RLS patients (DeAndrade et al., 2012a), and a newly-created PC-specific Btbd9 KO mouse model to test the role of the cerebellum in sleep disorders, especially RLS. Our results demonstrated that systematic Btbd9 KO had decreased neural activity in the cerebellum, more non-tonic PCs, and increased excitability of tonic PCs. Sole BTBD9 deficiency in PCs can cause increased activity during the rest phase. However, specifically knocking out Btbd9 in PCs is not sufficient for the development of sensory deficit. The results presented here highlight the importance of the cerebellum, especially the PCs, in the motor restlessness and sleep disruption observed in the Btbd9 KO mice. Although earlier studies from other groups have validated the use of continuous monitoring as a noninvasive alternative for sleep estimation for rodents (Davies et al., 2017; Singh et al., 2019), the limitation of the current study is the lack of sleep analysis by polysomnography.

PCs send inhibitory output to the DCN (Han et al., 2014). Therefore, the increased excitability of PCs revealed by electrophysiological recording (Fig. 2 and 3) is consistent with decreased neural activity in the DCN that we observed in our brain imaging experiment (Fig. 1). Additionally, it has been found that Cav1.2, a subunit of the voltage-gated Ca²⁺ channel, is highly involved in neuronal Mn²⁺ influx after systemic injections (Bedenk et al., 2018). Reduced MEMRI signal in the DCN indicates a lower activity level of Cav1.2, which may result from increased PC firing. The DCN inhibits the activity of thalamus, which excites the cerebral cortex. It can be postulated that decreased neural activity in the DCN will lead to altered activity in the thalamus and cerebral cortex, both of which have been shown to have structural or functional alterations in RLS patients (Rizzo et al., 2017). Moreover, the dentate nucleus of the cerebellum has a disynaptic projection to the striatum (Chen et al., 2014; Hoshi et al., 2005; Ichinohe et al., 2000). The striatal dopaminergic system has also been shown to have functional alterations in RLS patients (Cervenka et al., 2006; Connor et al., 2009; Earley et al., 2014; Earley et al., 2011; Earley et al., 2013; Kim et al., 2012; Michaud et al., 2002; Montplaisir et al., 1991; Okun et al., 2005; Ruottinen et al., 2000; Turjanski et al., 1999). Taken together, our results suggest that hyperactive PCs may alter the sensorimotor integration through multi-synaptic loops existing among the cerebellum, striatum, and cerebral cortex.

Btbd9 KO mice showed circadian rhythm-dependent hyperactivity similar to the systematic Btbd9 KO mice and RLS patients. Previously, extensive studies have linked RLS to the spinal cord (Clemens et al., 2006), A11 dopaminergic neurons (Qu et al., 2007), the thalamus (Allen et al., 2013; Rizzo et al., 2012), cortical excitability (Lanza et al., 2017), corticostriatal pathways (Yepes et al., 2017), the ventral tegmentum (Connor et al., 2009) and the striatum (DeAndrade et al., 2012a; Lai et al., 2017; Lyu et al., 2019b). Here, we emphasized the role of the cerebellum in the generation of motor and sleep symptoms of RLS. The cerebellum is known to be essential for maintaining kinetic movement mechanisms (Heiney et al., 2014). It has been suggested that dysregulated PC firing may cause an irregularity in DCN activity (De Schutter and Steuber, 2009), which contributes to

the generation of movement disorders (Goodkin and Thach, 2003; Sarnaik and Raman, 2018; White and Sillitoe, 2017). It is interesting that continuous open field mimics RLS-like behaviors better than the wheel-running experiment, possibly because wheel running assesses the voluntary activities of mice, which are influenced by motivation and reward systems (Novak et al., 2012). Interestingly, *Btbd9* pKO mice did not show a sensory deficit. It is possible that the motor restlessness of RLS is independent of sensory abnormalities, which is consistent with the fact that not all RLS patients have sensory deficits (Garcia Borreguero et al., 2017). The cerebellum is wellconnected to the thalamus, which is critically involved in both arousal regulation and sensory function. Thalamus of RLS patients has been found to have a higher level of glutamatergic activity (Allen et al., 2013) and a lower level of endogenous opioids (Walters et al., 2009). Lack of sensory deficit observed in pKO mice may be caused by compensatory effects from other parts of the multisynaptic loops existing among the cerebellum, striatum, and cerebral cortex. Hence, abnormal neural activity or circuit architecture in the cerebellum may serve as a key for the pathogenesis of RLS.

Our work is consistent with the role of BTBD9 and cerebellum in sleep regulation. GWAS studies have identified the cerebellum as a top hit for sleep-wake regulation (Dashti et al., 2019; Jones et al., 2019a). In addition, *BTBD9* has also been implied to be associated with sleep duration, sleep timing and daytime sleepiness (Jones et al., 2019b; Wang et al., 2019). Previously, systematic *Btbd9* KO mice showed increased awake time and increased number of wake bouts per hour during the rest phase in the polysomnographic study (DeAndrade et al., 2012a). Here, by the noninvasive continuous open field monitoring, we observed that specific knockout of *Btbd9* in the cerebellum led to an increased probability of waking during the rest phase, especially the first 2 hours. The result indicates that pKO mice seem to have a shorter sleep duration, immobility, or both. *Btbd9* mutation targeted to the cerebellum may be sufficient to cause abnormal sleep-like behaviors.

Highlights:

1. The systematic *Btbd9* KO mice had decreased neural activity in the cerebellum.

- 2. Btbd9 KO mice had more non-tonic Purkinje cells.
- **3.** Tonic Purkinje cells in *Btbd9* KO mice had increased spontaneous firing and intrinsic excitability.
- **4.** Purkinje cell-specific *Btbd9* KO mice were restless at rest but had no sensory deficit.
- **5.** Purkinje cell-specific *Btbd9* KO mice had an increased probability of waking at rest.

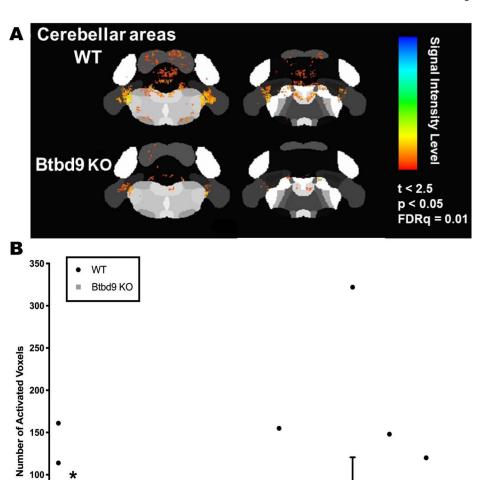

Figure 1.MEMRI recordings of neural activity in cerebellar regions of the systematic *Btbd9* KO mice (n=6) and their WT littermates (n=8). *Btbd9* KO mice had significantly decreased neural activity in cerebellar lobules VIII, cerebellar lobules X and deep cerebellar nuclei. Cb: cerebellum lobules; 7N: facial nucleus; Cer: cerebellar nuclear area; Sim: Simple lobule. Bars represent means plus standard error of means (SEMs). *, *p* 0.05.

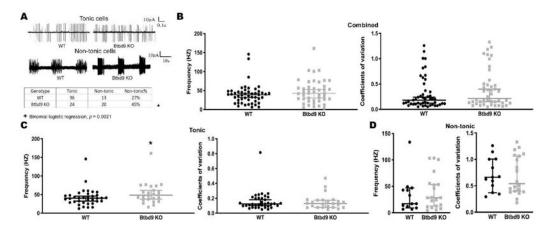

Figure 2.
Cell-attached recording of PCs of the systematic *Btbd9* KO mice (n=6) and their WT littermates (n=6). (A) Representative spontaneous activity traces of WT and *Btbd9* KO in acute brain slides. The percentage of non-tonic cells showed a significant increase with *Btbd9* knockout. (B) Both spontaneous firing frequency and coefficients of variation were not changed between *Btbd9* KO (n=49) and WT (n=44) PCs. (C) The spontaneous firing frequency was significantly higher in *Btbd9* KO tonic cells (n=24) compared with the WTs (n=36), while the coefficient of variation was not changed in *Btbd9* KO tonic cells. (D) There was no change in either spontaneous firing frequency or regularity between *Btbd9* KO non-tonic PCs (n=30) and the WT non-tonic PCs (n=13). The data in B-D are presented as the median with the 95% confidence intervals (CIs). *, p 0.05.

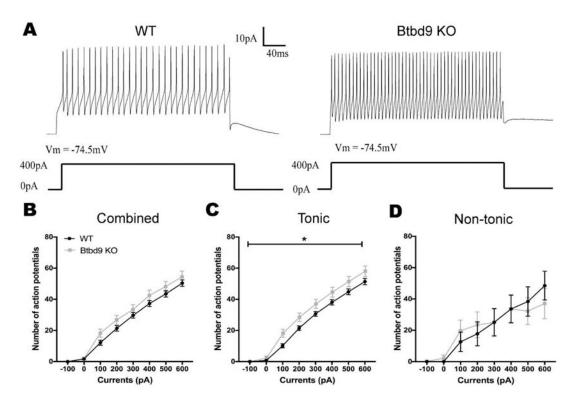

Figure 3. Whole-cell recording of PCs of the systematic *Btbd9* KO mice (n=6) and their WT littermates (n=6). (A) Representative traces with stimulation at 400pA. (B) PCs of *Btbd9* KO mice (n=31) fired at a similar level of frequency as that of the WTs (n=37) in response to the stimulation. (C) Tonic PCs of *Btbd9* KO mice (n=22) had a significantly higher simulative firing frequency than that of the WTs (n=29). (D) Non-tonic PCs of *Btbd9* KO mice (n=9) did not show a difference in response to the introduced step currents compared with that of the WTs (n=8). Data at each current step represent means plus SEMs. *, p 0.05.

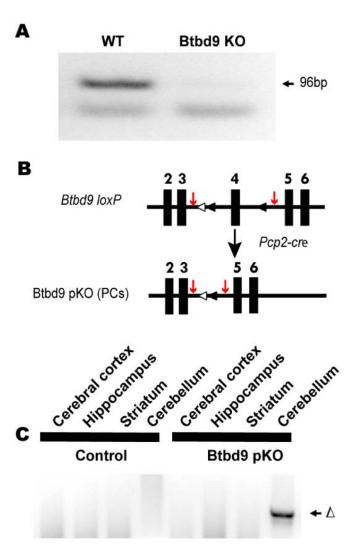

Figure 4. Generation and molecular characterization of *Btbd9* pKO mice. (A) No *Btbd9* mRNA in the cerebellum of the *Btbd9* KO mice. (B) Schematic diagram of the generation of the *Btbd9* pKO mice. Filled boxes represent exons. Filled triangles indicate *loxP* sites. Open triangles indicate the *FRT* sites that were incorporated to remove the neo cassette. In *Btbd9* pKO mice, exon 4 is deleted in PCs because *cre* is expressed specifically and the recombination occurs in the PCs. The red arrows indicate the sites of the PCR primers used to detect the recombination event. (C) Tissue-specific deletion of *Btbd9* exon 4 in *Btbd9* pKO mice was confirmed by PCR using DNA isolated from each brain region. The deletion () was detected only in the cerebellum (includes PCs) of *Btbd9* pKO mice as predicted.

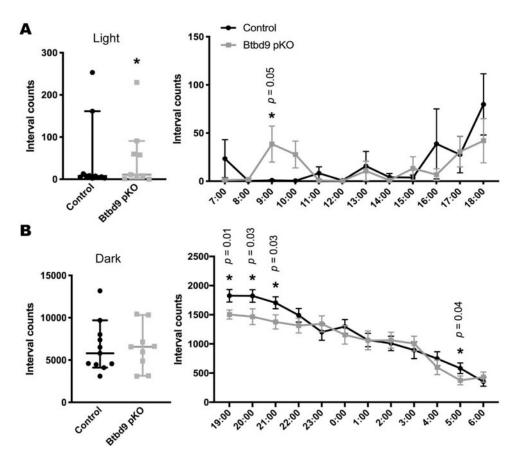

Figure 5. Wheel running test of *Btbd9* pKO mice. *Btbd9* pKO mice (n=9, 4 periods), compared with the controls (n=11, 4 periods), showed an increased level of activity in the wheel running test specifically during the light phase (A), but not during the dark phase (B). Detailed hourly activities were presented next to the related scatter plots. Scatter plots were presented as median with 95% CIs. Each dot in the scatter plots is an averaged value from 4 periods for each animal. Significant *p* values are marked above the corresponding time points. *, *p* 0.05.

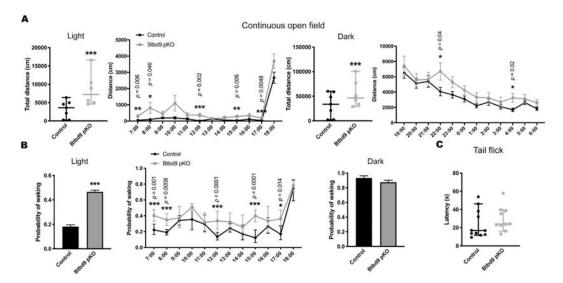

Figure 6.

Continuous open field and tail-flick tests of *Btbd9* pKO mice. (A) *Btbd9* pKO mice (n=6, 4 periods) showed an increased level of activity in the continuous open field test both during the light phase and during the dark phase, compared with the control group (n=7, 4 periods). Detailed hourly activities were presented next to the corresponding scatter plots. (B) *Btbd9* pKO mice showed an increased probability of waking during the light phase, but not during the dark phase, in the continuous open field test. A detailed hourly probability of waking was presented next to the corresponding histogram. (C) *Btbd9* pKO mice (n=10, 3 trials) did not have sensory deficit compared with the controls (n=11, 3 repeats) in the tail-flick test. Scatter plots and histograms were presented as median with 95% CIs. Each dot in the scatter plots is an averaged value from 4 periods or 3 trials for each animal. Significant *p* values are marked above the corresponding time points. ***, p 0.001 **, p 0.01, *, p 0.05.
