## RESEARCH LETTER

10.1029/2020GL089269

### Special Section:

The COVID-19 pandemic:  
Linking health, society and  
environment

### Key Points:

- Meteorological patterns were especially favorable for low NO<sub>2</sub> in much of the United States in spring 2020, complicating comparisons with spring 2019
- Weather variations between years can cause column NO<sub>2</sub> differences of ~15% over monthly timescales
- NO<sub>2</sub> drops attributed to COVID-19 lockdowns ranged between 9.2% and 43.4% among 20 cities in North America, with a median of 21.6%

**Abstract** TROPOMI satellite data show substantial drops in nitrogen dioxide (NO<sub>2</sub>) during COVID-19 physical distancing. To attribute NO<sub>2</sub> changes to NO<sub>x</sub> emissions changes over short timescales, one must account for meteorology. We find that meteorological patterns were especially favorable for low NO<sub>2</sub> in much of the United States in spring 2020, complicating comparisons with spring 2019. Meteorological variations between years can cause column NO<sub>2</sub> differences of ~15% over monthly timescales. After accounting for solar angle and meteorological considerations, we calculate that NO<sub>2</sub> drops ranged between 9.2% and 43.4% among 20 cities in North America, with a median of 21.6%. Of the studied cities, largest NO<sub>2</sub> drops (>30%) were in San Jose, Los Angeles, and Toronto, and smallest drops (<12%) were in Miami, Minneapolis, and Dallas. These normalized NO<sub>2</sub> changes can be used to highlight locations with greater activity changes and better understand the sources contributing to adverse air quality in each city.

**Plain Language Summary** Nitrogen dioxide (NO<sub>2</sub>) is an air pollutant whose prevalence in urban areas is linked to fossil fuel combustion. The NO<sub>2</sub> in our atmosphere is primarily a function of the magnitude of nitrogen oxide (NO<sub>x</sub>) emissions and weather factors such as sun angle, wind speed, and temperature. In this work, we developed two novel methods to account for weather impacts on daily pollution levels during COVID-19 precautions. Once we accounted for favorable weather conditions that in some cases kept air pollution low independent of tailpipe emissions, calculated air pollutant emission reductions varied dramatically (9–43%) among 20 North American cities. Results can be used to understand factors contributing to inconsistent NO<sub>2</sub> changes during physical distancing, which can inform the effectiveness of COVID-19 protocols and aid future policy development. These methodologies will allow us to respond more quickly in future unintended experiments when emissions change suddenly.

## 1. Introduction

Nitrogen dioxide (NO<sub>2</sub>) is unique due to its relatively short photochemical lifetime, which varies from 2–6 hr during the summer daytime (Beirle et al., 2011; de Foy et al., 2014; Laughner & Cohen, 2019; Valin et al., 2013) to 12–24 h during winter (Beirle et al., 2003; Shah et al., 2020); the main loss pathway of NO<sub>2</sub> is reaction with OH (Stavrakou et al., 2013). Due to the relatively short lifetime of NO<sub>2</sub>, tropospheric NO<sub>2</sub> concentrations are strongly correlated with local NO<sub>x</sub> emissions, which are often anthropogenic in origin. However, due to the effects of meteorology and solar zenith angle on the NO<sub>2</sub> abundance, NO<sub>2</sub> can vary by a factor of two simply due to seasonal changes (Pope et al., 2015; Wang et al., 2019). Therefore, satellite data are typically averaged over long timeframes (approximately seasonal/annual) to assess changes in NO<sub>x</sub> emissions (Duncan et al., 2016; Geddes et al., 2016; Georgoulias et al., 2019; Hilboll et al., 2013, 2017; Kim et al., 2009; Krotkov et al., 2016; Lamsal et al., 2015; McLinden et al., 2016; van Der et al., 2008).

With the COVID-19 crisis, there is now broad interest in rapid assessments of NO<sub>x</sub> emission changes on short timescales in locations that have implemented stay-at-home orders or other physical distancing measures. Using satellite data in this instance can be advantageous due to its global coverage at immediate timescales. However, current methods of averaging satellite NO<sub>2</sub> data over many months to minimize random daily effects of weather will not provide the temporal granularity needed to quantify short-lived NO<sub>x</sub> emission changes.

**Writing – review & editing:** Susan C. Anenberg, Debora Griffin, Chris A. McLinden, Zifeng Lu, David G. Streets

Preliminary satellite-based studies indicate that NO<sub>2</sub> dropped substantially in China following stringent COVID-19 physical distancing actions (Liu et al., 2020; Zhang et al., 2020). Similar declines have also been seen over northern Italy (ESA, 2020b) and India (ESA, 2020a). Although lockdown measures—and adherence to them—have been looser in the United States than in China, India, and Italy, preliminary analyses show that NO<sub>2</sub> amounts are declining across United States cities as well (NASA, 2020). These declines have, in some cases in the media (Holcombe & O'Key, 2020; Plumer & Popovich, 2020), been attributed to the emission changes during lockdowns, without accounting for the potentially substantial influences of meteorology and seasonality. Accounting for natural NO<sub>2</sub> fluctuations are especially important during spring, a time when the NO<sub>2</sub> concentrations and lifetimes are quickly changing due to transitioning meteorology, solar zenith angle, and snow cover.

Understanding how NO<sub>x</sub> emissions have changed in response to physical distancing measures requires new methods to account for solar zenith angle and meteorological conditions over very short time scales (days/weeks), as opposed to the traditional method of averaging over seasons and years. Here, we use three different methods to assess the NO<sub>2</sub> decreases associated with COVID-19 lockdowns. We combine TROPOMI NO<sub>2</sub> data with ERA5 reanalysis and a regional chemical transport model to determine the effects of the solar zenith angle and meteorological factors—such as wind speed and wind direction—on NO<sub>2</sub> column amounts. The NO<sub>2</sub> changes after this “normalization” are more likely to represent the NO<sub>x</sub> emissions changes due to COVID-19.

## 2. Methods

### 2.1. TROPOMI NO<sub>2</sub>

TROPOMI was launched by the European Space Agency (ESA) for the European Union's Copernicus Sentinel 5 Precursor (S5p) satellite mission on 13 October 2017. The satellite follows a Sun-synchronous, low-Earth (825 km) orbit with a daily equator overpass time of approximately 13:30 local solar time (van Geffen et al., 2019). TROPOMI measures total column amounts of several trace gases in the Ultraviolet-Visible-Near Infrared-Shortwave Infrared spectral regions (Veefkind et al., 2012). At nadir, pixel sizes are 3.5 × 7 km<sup>2</sup> (reduced to 3.5 × 5.6 km<sup>2</sup> on 6 August 2019) with little variation in pixel sizes across the 2,600 km swath.

Using a differential optical absorption spectroscopy (DOAS) technique on the radiance measurements in the 405–465 nm spectral window, the top-of-atmosphere spectral radiances can be converted into slant column amounts of NO<sub>2</sub> between the sensor and the Earth's surface (Boersma et al., 2018). In two additional steps, the slant column quantity can be converted into a tropospheric vertical column content, which is the quantity used most often to further our understanding of NO<sub>2</sub> in the atmosphere (Beirle et al., 2019; Dix et al., 2020; Goldberg, Lu, Streets, et al., 2019; Griffin et al., 2019; Ialongo et al., 2020; Reuter et al., 2019; Zhao et al., 2020). For this analysis, we use the operational “off-line” TROPOMI NO<sub>2</sub> data set, Version 1.2 preceding 26 March 2019 and Version 1.3 post-27 March 2019.

### 2.2. Meteorological Data Set

We use ERA5 meteorology (Copernicus Climate Change Service (C3S), 2017) for the wind speed and direction in our analysis. When filtering the data based on wind, we use the average 100-m winds during 16–21 UTC, which approximately corresponds to the TROPOMI overpass time over North America. To downscale the ERA5 reanalysis, which is provided at 0.25° × 0.25°, we spatially interpolate daily averaged winds to 0.01° × 0.01° using bilinear interpolation. Due to our dependence on 0.25° × 0.25° meteorology, any micro-scale features (e.g., sea breezes) will not be accounted for, but these effects should be minor for our particular analysis.

### 2.3. Calculation of NO<sub>2</sub> Changes

We calculate the NO<sub>2</sub> changes using three different methods and a control. In the control (Method 0), a simple difference before (1 January to 29 February 2020) and after (15 March to 30 April 2020) COVID-19 precautions is calculated; this represents the true change in NO<sub>2</sub> column densities over time. The 15 March to 30 April 2020 period is the timeframe of the most stringent lockdown in North America—some U.S. states began to transition out of the lockdown on 1 May 2020. In Method 1, we compare an average of 15 March

to 30 April 2020 to the same timeframe of 2019 and would therefore account for impact of changes due to solar zenith angle; this year-over-year comparison is used most often in satellite studies quantifying long-term changes in NO<sub>x</sub> emissions. In Method 2, we develop a strategy to account for varying weather patterns without the use of a chemical transport model. In this method, we normalize each day's NO<sub>2</sub> observation to a day with "standard" meteorology—similar to standard temperature and pressure (STP) conditions in a laboratory setting. We do this by accounting for four different day-varying effects; these are solar zenith angle, wind speed, wind direction, and day-of-week. In all cases, we normalize city-specific conditions to those that are climatological on 15 April. Finally, in Method 3, we infer a TROPOMI NO<sub>2</sub> column amount assuming no COVID-19 precautions using the GEM-MACH regional chemical transport model, which is operationally run in forecast mode (Pendlebury et al., 2018), and then compare the actual TROPOMI columns to the theoretical columns. Methods 2 and 3 both account for year-varying meteorology, while Method 1 does not. A detailed description of Methods 2 and 3 can be found in the supporting information.

### 3. Results

#### 3.1. Solar Zenith Angle and Meteorological Relationships

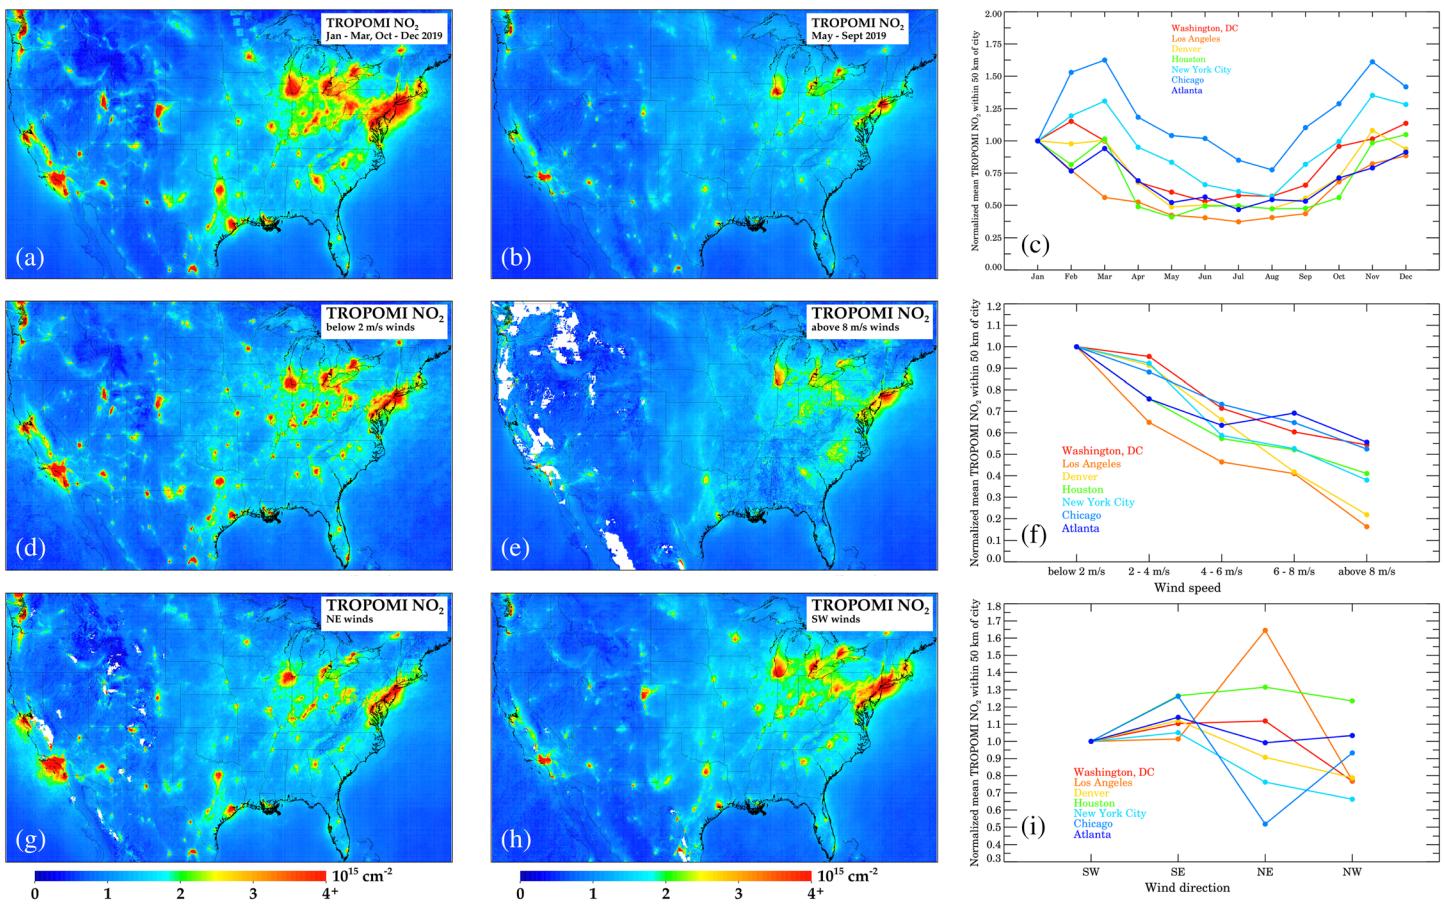

In the top row of Figure 1, we show 2019 NO<sub>2</sub> column densities during the high solar zenith angle "cold" season (January–March and October–December) and low solar zenith angle "warm" season (May–September) in the continental United States and southern Canada.

Column NO<sub>2</sub> is larger during the cold season than during the warm season over the majority of our domain, despite NO<sub>x</sub> emissions generally peaking during summer months due to a heavy air conditioning load (Abel et al., 2017; He et al., 2013) and more vehicle miles traveled (<https://www.transtats.bts.gov/osea/seasonaladjustment/?PageVar=VMT>). The larger NO<sub>2</sub> concentrations during the winter are instead due to the longer NO<sub>2</sub> lifetime during the cold season, primarily due to slower photolysis rates. When NO<sub>x</sub> is emitted during the warm season, it is transformed into other chemical species, such as O<sub>3</sub> and HNO<sub>3</sub>, more quickly than during the winter. Also, the fraction of NO<sub>x</sub> that is in the form of NO<sub>2</sub> (rather than NO) is variable, largely due to relative levels of O<sub>3</sub> and sunlight. We find that in most near-urban locations column NO<sub>2</sub> amounts are 1.5–3 times larger during the winter than during the summer and can vary substantially between city.

In a next step, we account for wind speed and wind direction in the spatiotemporal variation of NO<sub>2</sub> columns. In the middle and bottom panels of Figure 1, we demonstrate the effects of wind speed and wind direction on the NO<sub>2</sub> in our domain. Increases in wind speed yield NO<sub>2</sub> decreases due to quicker dispersion away from the city centers. For example, in New York City, Washington DC, Atlanta, and Chicago, all cities with relatively flat topography and located in the eastern United States, increasing wind speeds from nearly stagnant to >8 m/s decreases NO<sub>2</sub> by 30–60%. Conversely, in Denver and Los Angeles, cities with more heterogeneous topography and with general isolation from an agglomeration of cities show a stronger dependence on wind speed; increasing wind speeds from nearly stagnant to >8 m/s decreases NO<sub>2</sub> by 70–85%. In both instances, these examples show the strong dependence of wind speed on local NO<sub>2</sub> amounts.

Similarly, wind direction has a large role in the local NO<sub>2</sub> amounts, although the effects of wind direction are nonlinear. Generally, northwest winds yield the cleanest conditions in most U.S. cities, but the effects of other wind directions are more nuanced. For example, southwesterly winds yield the worst air quality in New York City, while northeasterly winds yield the largest NO<sub>2</sub> in Washington, D.C. This is due to the fact that the other city lies upwind in each opposing scenario. Changes in wind direction, given the same wind speed, can yield differences in NO<sub>2</sub> in major cities by up to 70%, and must be accounted for if properly attributing NO<sub>2</sub> changes to NO<sub>x</sub> emissions. Climatological patterns for all cities are shown in the supporting information (Figures S2–S4).

While 2-m air temperature and boundary layer depth may be affecting the NO<sub>2</sub> concentrations, these are not independent of the aforementioned factors: solar zenith angle, wind speed, and wind direction. In fact, solar zenith angle, wind speed, and wind direction are by themselves highly skilled predictors of near-surface temperatures and boundary layer depth in most instances. Since we are focused on mostly clear-sky days, clouds have limited effects here. Previous day's precipitation may also be a contributing factor to daily NO<sub>2</sub> amounts, but in many areas, the wind direction will partially account for this, since northwest winds usually follow large rain events in most areas.

**Figure 1.** Effects of meteorology and solar zenith angle on column NO<sub>2</sub>. Top panels show (a) TROPOMI NO<sub>2</sub> during the warm season (May–Sept 2019), (b) during the cold season (January–March and October–December 2019), and (c) the monthly variation in seven U.S. cities normalized to January 2019. Middle panels show (d) TROPOMI NO<sub>2</sub> when winds are <2 m/s, (e) when winds are >8 m/s, and (f) variations in NO<sub>2</sub> as a function of wind speed for seven cities normalized to stagnant conditions. Bottom panels show (g) TROPOMI NO<sub>2</sub> when winds are northeasterly, (h) when winds are southwesterly, and (i) variations as a function of wind direction for seven cities normalized to southwesterly winds. Wind variations are using the complete TROPOMI record preceding 1 January 2020 (1 May 2018 to 31 December 2019).

### 3.2. Effects of COVID-19 Physical Distancing on NO<sub>2</sub>

In order to quantify rapid changes in NO<sub>x</sub> due to COVID-19 physical distancing, we calculate NO<sub>2</sub> changes in North American cities using three different methods and a reference method. The results for all cities are shown in Table 1.

The reference method, Method 0, compares the prelockdown and postlockdown periods and represents the “true” NO<sub>2</sub> change; however, this method does not account for seasonal changes and, thus, is not considered in the medians/means.

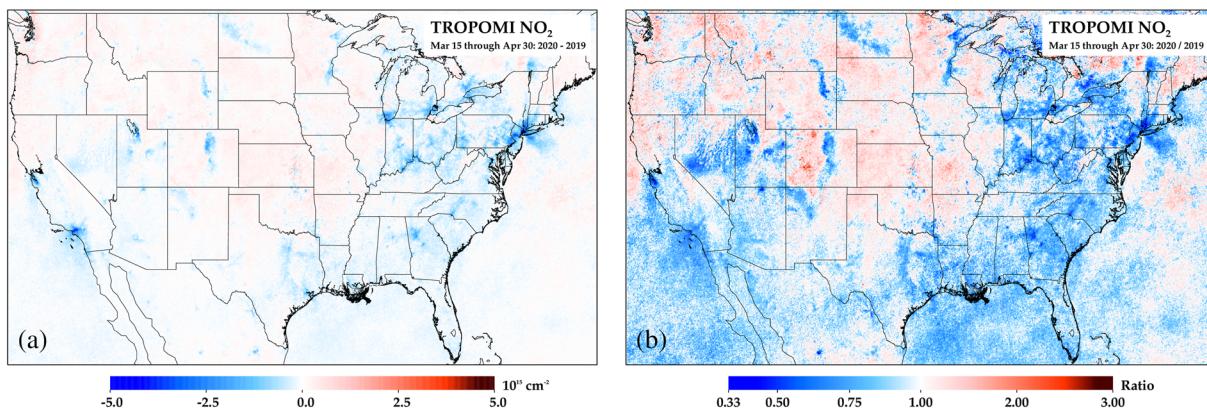

In Method 1, we compare an average of 15 March to 30 April 2020 to the same timeframe of 2019. In Figure 2, we show difference and ratio plots between these 2 years (i.e., Method 1). The largest decreases in NO<sub>2</sub> are near the major cities in North America. We also find regional decreases in the eastern North America. Conversely, the central and northwestern United States have seen little change between years, which is likely due to the high fraction of NO<sub>2</sub> attributed to biogenic sources and long-range transport. We also observe substantial decreases near retired electricity generating units in the western United States (Storrow, 2019).

In Figure 3, we demonstrate Method 2. Here, we show the 2019 and 2020 28-day running TROPOMI NO<sub>2</sub> medians after accounting for solar zenith angle, day-of-week patterns, and two meteorological factors: wind speed and wind direction. A 28-day period is chosen so as to best average out any random fluctuations not

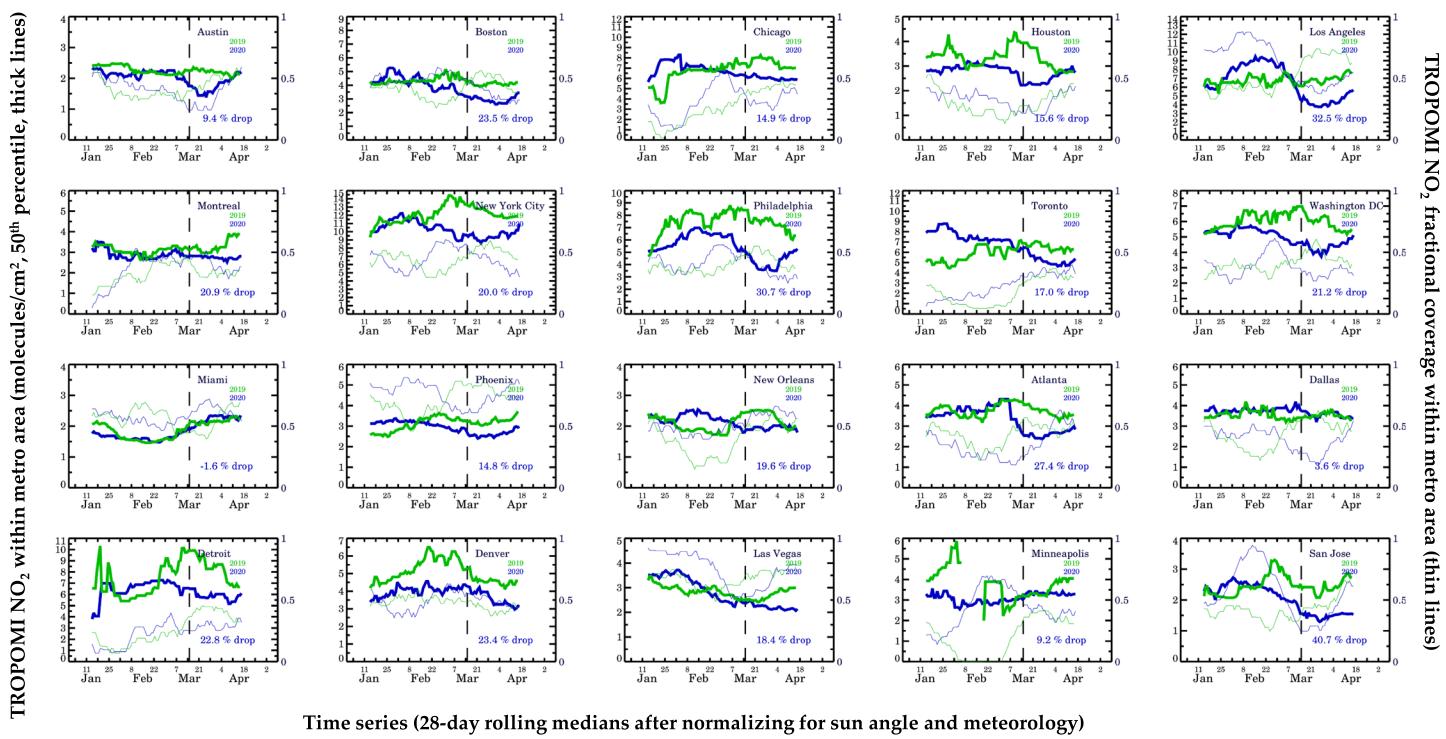

**Table 1**  
*Percentage Drop in Column NO<sub>2</sub> as Observed by TROPOMI*

City name	Reference case Method 0	Account for solar zenith angle only		Account for solar zenith angle and meteorology		Median of methods 1–3
		Method 1	Method 2	Method 3		
San Jose	65.2%	43.4%	40.7%	43.5%	42.5%	<b>43.4%</b>

associated with meteorological influences, such as missing data or real changes in NO<sub>x</sub> emissions due to temperature changes, but there may have been some fluctuations that cannot be averaged out. In Figure 3, the January values are uniformly lower than their true values (Figure S5) because we are normalizing to April meteorological conditions (i.e., solar zenith angle is lower in April as compared to January). In New York City, we calculate a 20.0% drop in NO<sub>2</sub> due to COVID-19 precautions. We find that there is no difference between Method 2—which accounts for meteorology—and Method 1—which only accounts for solar zenith angle. This suggests that varying meteorological conditions in New York City, while different between years, may not have had a strong biasing effect. However, in Washington D. C., we find favorable conditions in 2020 as compared to 2019 because we observe substantially different

**Figure 2.** TROPOMI NO<sub>2</sub> differences between 2019 and 2020, using 15 March to 30 April 2020 as the post-COVID-19 period. Plots are showing (a) the absolute difference and (b) the ratio between years.

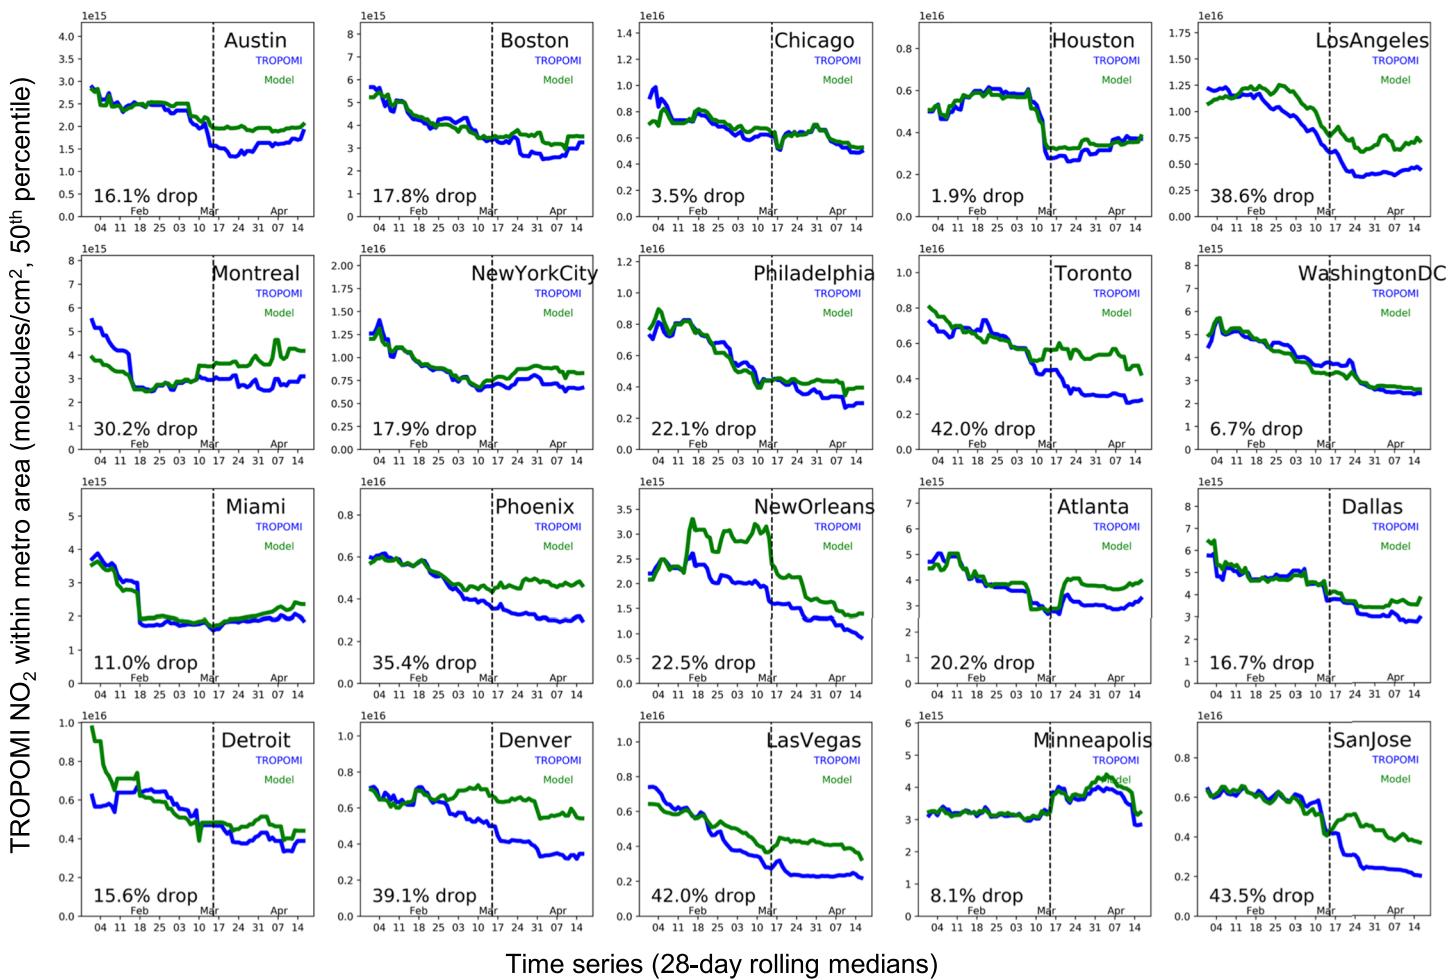

**Figure 3.** Trends in TROPOMI NO<sub>2</sub> since 1 January in 2019 and 2020 after accounting for meteorological variability and solar zenith angle. The thick lines represent the 28-day rolling median value (50th percentile) in a 0.4° × 0.4° box centered on the city center for the largest cities (New York City, Los Angeles, Chicago, Toronto, and Houston) and 0.2° × 0.2° box in all other cities. The thin lines represent the fractional coverage (0–1) in the coincident spatiotemporal domain.

NO<sub>2</sub> drops before (31.4%) and after (21.2%) correcting for the meteorology. These results are corroborated by the wind speed and direction (Figure S6). In 2019, winds were on average southwesterly, while in 2020, winds had more of a northwesterly and therefore cleaner component. Of all cities analyzed, we find that Miami had the most favorable conditions for low NO<sub>2</sub> in 2020 as compared to 2019; in 2020, winds were stronger from the south—in this case a cleaner air mass—than in 2019, which had relatively stagnant winds. Conversely, in Montreal, New Orleans, and Las Vegas, meteorological conditions appeared to be unfavorable in 2020 as compared to 2019.

Meteorological factors that we do not account for in Method 2 are a difference in the number of cloudy scenes and the amount of snow cover between years. In particular, the northern United States had more snow cover in late February and early March in 2019 than in 2020 (Figure S7). In Figure 3, we also show the fractional coverage of the metropolitan area during the 28-day period. For example, in New York City, there was ~0.6 fractional coverage in early March 2020, while in 2019 there was only ~0.3 fractional coverage during the same timeframe. As a result, some of the higher values during this timeframe may be related to fewer valid pixels in outlying areas, which retain snow for longer, and perhaps a snow-related reflectivity artifact even though pixels over snow cover are predominantly removed. This is also why some other snow-prone cities like Chicago, Philadelphia, Toronto, Detroit, Denver, and Minneapolis show large variability preceding March. Beginning in mid-March, snow cover was largely gone in most U.S. cities during both years.

In Figure 4, we demonstrate Method 3, in which we account for meteorology and chemical interactions using a chemical transport model. We create a theoretical TROPOMI column NO<sub>2</sub> using ECCC's regional operational air quality forecast model (Moran et al., 2009; Pendlebury et al., 2018), which accounts for typical seasonal emission changes but not for any impacts due to the COVID-19 lockdowns; this helps provide expected NO<sub>2</sub> levels with a business as usual scenario. Around mid-March there is often a divergence between the expected and observed NO<sub>2</sub> in the major cities. Using this method, largest NO<sub>2</sub> reductions

**Figure 4.** Trends in TROPOMI NO<sub>2</sub> since 1 January 2020. The actual observed columns are shown in black, while the “expected” columns—using GEM-MACH to infer NO<sub>2</sub> in the absence of lockdowns—is shown in blue. The lines represent the 28-day rolling median value (50th percentile) in a 0.4° × 0.4° box centered on the city center for the largest cities (New York City, Los Angeles, Chicago, Toronto, and Houston) and 0.2° × 0.2° box in all other cities.

due to COVID-19 precautions are in Toronto, San Jose, and Las Vegas. Similar to Method 2, we find that NO<sub>2</sub> changes are generally smaller in the Northeastern United States and Florida as compared to Method 1 after accounting for meteorology. In 15 of the 20 studied cities, we find that Methods 2 and 3, which utilize independent meteorological data sets, show similar biasing effects of meteorology (favorable vs. unfavorable) when compared to Method 1.

#### 4. Conclusions and Discussion

We estimate that NO<sub>2</sub> adjusted for seasonality and meteorology temporarily dropped between 9–43% in North American cities due to COVID-19 precautions, with a median drop of 21.6% before and after COVID-19 physical distancing. If the solar zenith angle is not accounted for, then the median NO<sub>2</sub> drop is 39.9%; this represents the true change of NO<sub>2</sub> in cities, but is not particularly helpful if parsing out emissions changes. Our reported median drop of 21.6% after accounting for meteorology is marginally lower than the 22.9% in a simple year-to-year comparison, which suggests that 2020 meteorology was slightly favorable for lower NO<sub>2</sub>, although these effects are most pronounced in the Northeastern United States and Florida.

Here we demonstrate two methodologies, Methods 2 and 3, to account for time-varying effects of meteorology on NO<sub>2</sub> concentrations. Although the NO<sub>2</sub> concentration is also function of collocated chemical constituents, such as OH, VOCs, and O<sub>3</sub>, which also vary by year, the numbers reported here are closer to the true

change in  $\text{NO}_x$  emissions than  $\text{NO}_2$  changes in the absence of accounting for meteorology. There are two main advantages for using Methods 2 and 3 to assess rapid changes in  $\text{NO}_x$  as compared to a year-to-year comparison of the same month or seasonal period. Year-over-year technological improvements in the North America are generally causing  $\text{NO}_x$  emissions to decrease over time (Goldberg, Lu, Oda, et al., 2019; Nopmongcol et al., 2017; Silvern et al., 2019; Zhang et al., 2018), although we find a statistically insignificant  $\text{NO}_2$  increase of 0.6% in our cities between 2019 and 2020 in the January–February average. Accounting for year-over-year changes would be more important if comparing 2020 values to years preceding 2019. There are two U.S. cities, Denver and Philadelphia, which have consistently lower values in 2020 than in 2019 preceding March, using Method 2. While it is conceivable that there may have been policies in these two cities that yielded significantly lower  $\text{NO}_x$  emissions in 2020 versus 2019 preceding March, Method 3 does not corroborate this and further, we do not think the evidence is strong enough to conclude this given the uncertainty related to meteorological conditions unaccounted for, such as snow cover differences between years.

A deficiency of our method is our reliance on a single satellite instrument and algorithm. It is known that the operational TROPOMI  $\text{NO}_2$  algorithm underestimates tropospheric vertical column  $\text{NO}_2$  in urban areas due to its reliance on a global model to provide shape profiles for the air mass factor (AMF); investigating the effects of the AMF bias on trends will be the subject of future work. Also, there may be a clear-sky bias (Geddes et al., 2012) associated with TROPOMI retrievals, but the results presented here are generally consistent with studies using ground monitors over the coincident region (Bekbulat et al., 2020) and the reported  $\text{CO}_2$  emissions reductions due to COVID-19 precautions (Le Quéré et al., 2020).

The estimates of  $\text{NO}_2$  changes using our methods appear to be reasonable given a quick bottom-up emissions calculation. Initial statistics indicate vehicle miles traveled dropped by ~40% in April 2020 and that many industrial sources dropped modestly ~5–25% due to lockdown exemptions,  $\text{NO}_x$  reductions between 10% and 35% would be expected. San Jose, Los Angeles, and Toronto appear to have reductions at the high end of this range, while Miami, Minneapolis, and Dallas have values near the lowest end; further work will look into why these cities have reductions on the ends of the spectrum. Rapid assessments of  $\text{NO}_2$  changes—after normalized for seasonal and meteorological factors—can be used to highlight locations that may have had greater changes in activity and better understand the sources contributing to adverse air quality in each city.

## Data Availability Statement

TROPOMI  $\text{NO}_2$  data can be freely downloaded from the European Space Agency Copernicus Open Access Hub or the NASA EarthData Portal (<http://doi.org/10.5270/S5P-s4ljg54>). The 100-m wind and 2-m surface temperatures from the ERA5 reanalysis can be freely downloaded from the Copernicus Climate Change (C3S) climate data store (CDS) (<http://doi.org/10.24381/cds.adbb2d47>) The intermediary data used to generate all figures can be found at <http://doi.org/10.6084/m9.figshare.12721724>. The submitted manuscript has been created by UChicago Argonne, LLC, Operator of Argonne National Laboratory (“Argonne”). Argonne, a U.S. Department of Energy Office of Science laboratory, is operated under Contract DE-AC02-06CH11357.

## Acknowledgments

This work has been supported by NASA through a Rapid Response grant, a Health and Air Quality (HAQ) grant (Award 80NSSC19K0193), and two Atmospheric Composition Modeling and Analysis Program grants. The work has also been supported by the Department of Energy, Office of Fossil Energy. We would also like to acknowledge valuable comments and input during the manuscript preparation from Joanna Joiner and Lok Lamsal of NASA Goddard, Joel Dreessen of Maryland Department of the Environment, Lucas Henneman of Harvard University T.H. Chan School of Public Health, A.R. “Ravi” Ravishankara of Colorado State University, and Michael Moran of Environment and Climate Change Canada.
