## Summary

**Background** Metformin use is associated with reduced cancer risk in epidemiological studies and has preclinical anti-cancer activity in ovarian cancer models. The primary objective of this phase I study was to determine the recommended phase II dose (RP2D) of metformin in combination with carboplatin/paclitaxel in patients with ovarian cancer. Secondary objectives were to describe safety and pharmacokinetics. **Methods** In this single-center trial the RP2D of metformin in combination with carboplatin area under the concentration-time curve (AUC) 6 and paclitaxel 175 mg/m<sup>2</sup> every 3 weeks (q3w) in patients with advanced epithelial ovarian cancer was determined using a 3 + 3 escalation rule at three fixed dose levels: 500 mg three times daily (tds), 850 mg tds and 1000 mg tds. Metformin was commenced on day 3 of cycle 1 and continued until 3 weeks after the last chemotherapy administration. The RP2D was defined as the dose level at which 0 of 3 or ≤ 1 of 6 evaluable subjects experienced a metformin-related dose-limiting toxicity (DLT). Safety was assessed according to CTCAE v4.0. Plasma and serum samples for pharmacokinetic (PK) analyses were collected during treatment cycles 1 and 2. **Results** Fifteen patients with epithelial ovarian cancer and an indication for neo-adjuvant ( $n = 5$ ) or palliative ( $n = 10$ ) treatment were included. No DLTs were observed. Three patients discontinued study treatment during cycle 1 for other reasons than DLT. Six patients were treated at the RP2D of metformin 1000 mg tds. The most frequent low-grade toxicities were anemia, hypomagnesemia and diarrhea. Grade 3 adverse events (AEs) occurred in ten patients, most common were leucopenia ( $n = 4$ ), thrombocytopenia ( $n = 3$ ) and increased GGT ( $n = 3$ ). There were no grade 4 AEs. Metformin increased the platinum (Pt) AUC ( $\Delta 22\%$ ,  $p = 0.013$ ) and decreased the Pt clearance ( $\Delta -28\%$ ,  $p = 0.013$ ). Metformin plasma levels were all within the therapeutic range for diabetic patients (0.1–4 mg/L). **Conclusion** The RP2D of metformin in combination with carboplatin and paclitaxel in advanced ovarian cancer is 1000 mg tds. This is higher than the RP2D reported for combination with targeted agents. A potential PK interaction of metformin with carboplatin was identified.

## Introduction

Epithelial ovarian cancer has the highest mortality of all gynecological cancers [1]. The disease is often diagnosed at a late stage because symptoms only develop once the disease has spread throughout the abdominal cavity. First line therapy for advanced disease consists of complete debulking surgery in combination with platinum-based chemotherapy [2]. Initial complete response to therapy can be achieved. However, the majority of patients ultimately develop recurrent disease, with over 50% of women diagnosed with epithelial ovarian cancer eventually dying of their disease [3]. Novel targets are needed in ovarian cancer and targeting metabolic reprogramming is of interest [4, 5]. Mutations in the key tumor suppressor gene and metabolic regulator p53 are the most frequent genetic abnormality occurring in ovarian cancer [6–8]. Furthermore, the mammalian target of rapamycin (mTOR) pathway is overactivated in approximately 70% of ovarian cancers and regulates protein translation of cell growth regulators such as cyclin D1, hypoxia inducible factor 1 $\alpha$  (HIF1 $\alpha$ ) and MYC, all essential for survival under cellular stress [9–11].

Metformin is a biguanide widely used in patients with type 2 diabetes mellitus (T2DM). It improves glycemic control by decreasing insulin resistance, reducing hepatic gluconeogenesis and inhibiting gastro-intestinal glucose resorption [12]. In cancer cells, metformin inhibits mTOR through activation of AMP-activated protein kinase (AMPK) resulting in reduced cellular proliferation [13]. In addition, metformin reduces cellular respiration by inhibiting complex 1 of the mitochondrial respiratory chain limiting the cancer cell's metabolic plasticity [14–16]. Metformin-treated cancer cells compensate for suppression of oxidative phosphorylation by enhancing glycolysis. This metabolic conversion appears to be p53-dependent [17]. Therefore, in the absence of functional p53, as is usually the case in high grade serous ovarian cancer (HGSOC), cancer cells might be unable to compensate for metformin-induced suppression of oxidative metabolism [18]. In ovarian cancer cell lines and xenograft models, metformin treatment indeed inhibits cell growth, induces apoptosis, inhibits angiogenesis and metastatic spread, potentiates effectivity of platinum treatment and reverses chemotherapy resistance [19–24]. Metformin use has been associated with a reduced ovarian cancer risk and reduced (ovarian) cancer-specific mortality in diabetic patients, compared to non-use and use of other hypoglycemic drugs [25–27].

Taken together, the body of preclinical and epidemiological evidence suggests a potential role for metformin in the treatment of advanced ovarian cancer, especially in combination with carboplatin [28]. Therefore, we conducted a phase I dose-escalation trial to establish the recommended phase II dose (RP2D) for further evaluation of the effects of metformin treatment in combination with carboplatin in advanced ovarian cancer.

## Methods

### Patient population

Adult patients with advanced stage (FIGO III-IV), histologically confirmed epithelial ovarian cancer eligible for carboplatin/paclitaxel chemotherapy, either in the neoadjuvant or palliative setting, were eligible for this study. Patients were required to have an ECOG-performance status of 0–2, adequate blood counts, hepatic and renal function (eGFR  $\geq$ 60 ml/min, calculated by the Cockcroft-Gault equation) and provide written informed consent for trial participation. Patients that had used metformin within 4 weeks of study enrolment were excluded, as were patients with a known hypersensitivity to the study drugs. No patients with diabetes mellitus were included. Patients with symptomatic central nervous system (CNS) metastases or peripheral neuropathy  $\geq$  CTCAE v4.0 grade 2, serious active infections or other unstable medical conditions were also excluded. Detailed in- and exclusion criteria are listed in Supplementary Table 1.

### Study design

A phase I dose-escalation trial was performed in a single tertiary center in the Netherlands. In addition to standard carboplatin/paclitaxel chemotherapy, metformin was administered in escalating doses according to a 3 + 3 design. Three patients were included per metformin dose level cohort (Table 1). In case any of these patients experienced a DLT, the cohort would be expanded to six patients. If  $\leq$ 1 of these six patients experienced a DLT, escalation to the next dose level was permitted. The maximum administered dose (MAD) was defined as the dose level at which  $\geq$ 2 patients experienced a DLT. The RP2D was defined as one dose level below the MAD. If the MAD was reached at the starting dose level, three to six patients would be treated at dose level ‘-1’ and in absence of DLT this would be the RP2D. In case no DLT was seen at the highest planned dose level this would be the RP2D. Additional patients were recruited into the recommended phase II dose level to include at least six patients. Safety was assessed for all patients entering the trial and receiving at least one dose of metformin. Toxicity was graded using CTCAE v4.0 [29], and dose-limiting toxicities were assessed until the end of cycle 2. A DLT was defined as a toxicity related to metformin, fulfilling one of the criteria in Supplementary Table 2. Any AE that occurred after start of study treatment or worsened during study treatment was defined as a treatment-emergent adverse event (TEAE).

### Study treatment

Patients received carboplatin AUC = 6 and paclitaxel 175 mg/m<sup>2</sup> as a 3-h infusion on day 1 of every 3-week cycle. A

**Table 1** Dose levels and dose-escalation schedule for metformin

Dose level	Dose of metformin given orally (total daily dose)	Minimum number of patients
-1	500 mg bd (1000 mg)	(3, if DLT at level 1)
1	500 mg tds (1500 mg)	3
2	850 mg tds (2250 mg)	3
3	1000 mg tds (3000 mg)	3

BD two times daily, DLT dose-limiting toxicity, TDS three times daily

maximum of 6 cycles were administered, with the exception of patients whose CA-125 had not normalized but was still declining during cycle 6 of palliative treatment. These patients were permitted a maximum of 3 extra cycles. Dose modifications or delays of carboplatin and paclitaxel chemotherapy were executed according to standard clinical practice. Metformin was commenced on day 3 of cycle 1, to allow for pharmacokinetic (PK) analyses of carboplatin and paclitaxel in the absence of metformin. Within every dose level cohort, the dose of metformin was gradually increased during cycle 1, starting at 500 mg bd and increasing by one dose level every 3 days to the target dose level (Table 1). Intra-patient dose-escalation of metformin results in better tolerance in diabetic patients [30, 31]. The highest planned metformin dose level was 1000 mg tds, corresponding to the maximum recommended dose for treatment of T2DM [30]. Metformin treatment was discontinued 3 days before a planned CT-scan or surgery and resumed afterwards using the aforementioned dose-escalation scheme. CT-scans and measurements of ca-125 for evaluation of response to treatment were performed according to standard practice.

### Pharmacokinetic analysis

To assess the influence of metformin on the PK parameters of carboplatin and paclitaxel, these were evaluated in cycle 1 (without metformin) and cycle 2 (with metformin). To determine the complete concentration-time curve, a 9-sample design was used for carboplatin for which plasma samples were drawn after 30 min, 1 h, 1.5 h, 2 h, 3.5 h, 5.5 h, 9.5 h, 24 h ( $\pm 2$  h) and 72 h ( $\pm 2$  h) after administration of carboplatin. For paclitaxel, four of these time points were used, namely 30 min, 3.5 h, 24 h ( $\pm 2$  h) and 72 h ( $\pm 2$  h) after paclitaxel administration. The following parameters of carboplatin and paclitaxel PK were compared using the PK modeling software MWPharm version 3.82 (Mediware, Groningen, Netherlands): maximum concentration (C<sub>max</sub>), time to reach maximum concentration (T<sub>max</sub>), AUC, half-life (t<sub>1/2</sub>), total body clearance and apparent volume of distribution (V<sub>d</sub>).

Metformin was analyzed at the Department of Clinical Pharmacy and Pharmacology of the University Medical Center Groningen using a validated liquid chromatography-tandem mass spectrometry (LC-MS/MS) method. Samples were diluted using a solution containing 2H-labeled

metformin. The lower limit of quantitation (LLOQ) was 0.1 mg/L and the upper limit of quantitation (ULOQ) was 100 mg/L. The coefficient of variation was less than 4.4% over the entire working range. Platinum (Pt) was analyzed using a validated ICP-MS method. The LLOQ was 1 microg/L and the ULOQ was 3000 microg/L. The coefficient of variation was less than 4.7% over the entire working range. Paclitaxel was analyzed at the Netherlands Cancer Institute Amsterdam using a validated LC-MS/MS method [32]. The concentration range was between 0.5 and 500 microg/L. Samples with concentrations above the ULOQ were diluted and reanalyzed. Inter-assay accuracy and precision were tested at four concentration levels and were within 10% and less than 10%, respectively. All analytical methods were compliant with the EMA guidelines for bio-analytical method validation (<https://www.ema.europa.eu/en/bioanalytical-method-validation>). PK profiles of carboplatin and paclitaxel were determined during cycle 1 and cycle 2. The AUC was calculated until the last time-point measured. Microsoft Excel 2010 was used to carry out the numerical integration ( $\Delta t = 1$  min) to calculate the AUC. Pt levels during and after infusion were calculated according to a 3-compartment PK model using the KinFit module in MWPharm [33].

### Statistical analysis

Baseline characteristics and incidence of AEs were summarized using descriptive statistics. For the PK analyses, intra-patient comparisons were performed using the Wilcoxon signed rank test for AUC, V<sub>d</sub> and clearance of carboplatin and paclitaxel. All *p* values were calculated using IBM SPSS Statistics for Windows version 23, assuming non-parametric distribution. *P* < 0.05 was considered to indicate a statistically significant difference.

## Results

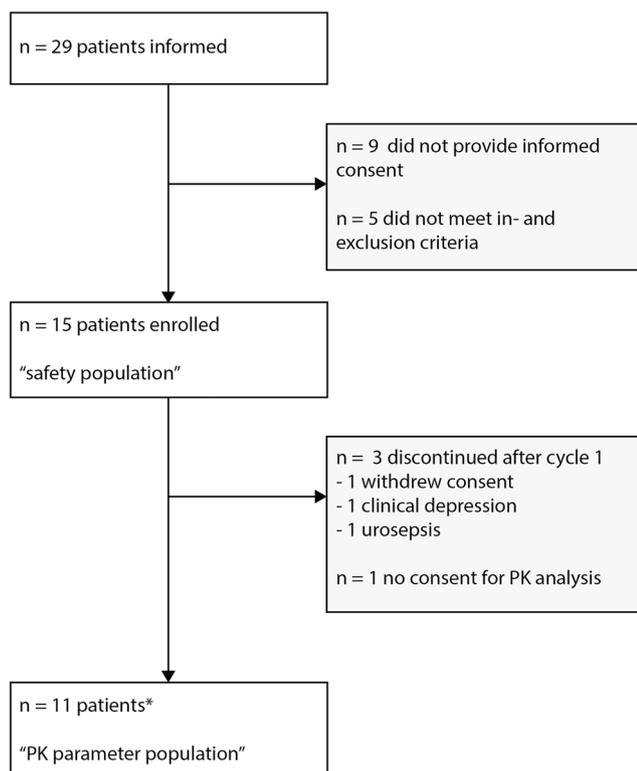

### Characteristics of the study cohort

29 patients were informed about the trial. Nine patients declined and five did not meet the in- and exclusion criteria. Fifteen eligible patients were enrolled in the trial and received  $\geq 1$  dose of metformin (*n* = 5 neo-adjuvant and *n* = 10

palliative setting), this population was used for the safety assessment (Fig. 1). The baseline characteristics of these 15 patients are shown in Table 2. Three patients discontinued study treatment during cycle 1 for other reasons than DLT: one patient withdrew consent, and two patients experienced a serious AE (SAE) unrelated to metformin treatment but resulting in study discontinuation (one patient with a serious depression and one patient with a urosepsis). One patient did not provide consent for PK-analysis and for one patient plasma samples were not drawn at the correct times to allow a valid Pt AUC calculation. The population for PK analysis of carboplatin and paclitaxel therefore consisted of the 10 and 11 patients respectively for whom valid and evaluable PK parameters were derived during cycle 1 and cycle 2 of treatment.

### MTD and DLTs

No DLTs were observed for metformin. Six patients were treated at the 1000 mg tds metformin dose level. Safety data showed that most common low-grade toxicities were anemia, hypomagnesemia and diarrhea. Grade 3 treatment-emergent adverse events (TEAEs) occurred in nine patients, most commonly leucopenia ( $n = 4$ ), thrombocytopenia ( $n = 3$ ) and increased GGT ( $n = 2$ ). There were no grade 4 TEAEs. All grade

**Fig. 1** Consort diagram of patient flow through the study. \* For one patient plasma samples were not drawn at the correct times to allow for a valid Pt AUC calculation. PK of carboplatin was therefore assessed in 10 patients.

AUC 48 h	mg/L* <i>h</i>	82.8 (14.2)	91.8 (35.0)	0.028
AUC 48 h corrected for dose adjustment	mg/L* <i>h</i>	82.8 (14.2)	101 (44.7)	0.013

Pharmacokinetic parameters of platinum (carboplatin) when administered as combination chemotherapy with paclitaxel and with addition of metformin ( $n = 10$  patients)

<sup>a</sup>With the KinFit analysis, it was determined that a three-compartment model fit the platinum levels best based on the improved *p*-values of the fits compared to a two-compartment model. No significant difference in volume of distribution was found in any of the three separate compartments.

Platinum AUCs of cycle 2 were corrected for carboplatin dose adjustment from cycle 1 to cycle 2 in 3 patients (dose reduction for reason of thrombocytopenia), assuming a linear relationship between dose and AUC. AUC area under the concentration-time curve, CL clearance, IQR inter quartile range, Vd total volume of distribution

**Fig. 2** Platinum AUC, clearance and total volume of distribution without (cycle 1) and with metformin (cycle 2), calculated from measurement of platinum in plasma samples in 10 patients in three dose cohorts of metformin (metformin 500 mg bd  $n = 2$ , 850 mg tds  $n = 3$ , 1000 mg tds  $n = 5$ ). The lines between the two boxplots indicate the intra-individual changes of platinum AUC, clearance and total volume of distribution ( $n = 10$  patients). Platinum AUCs of cycle 2 were corrected for carboplatin dose adjustment from cycle 1 to cycle 2 in 3 patients (dose reduction for reason of thrombocytopenia), assuming a linear relationship between dose and AUC

3 TEAEs and grade 1–2 TEAEs occurring in  $\geq 10\%$  of patients are listed in Table 3.

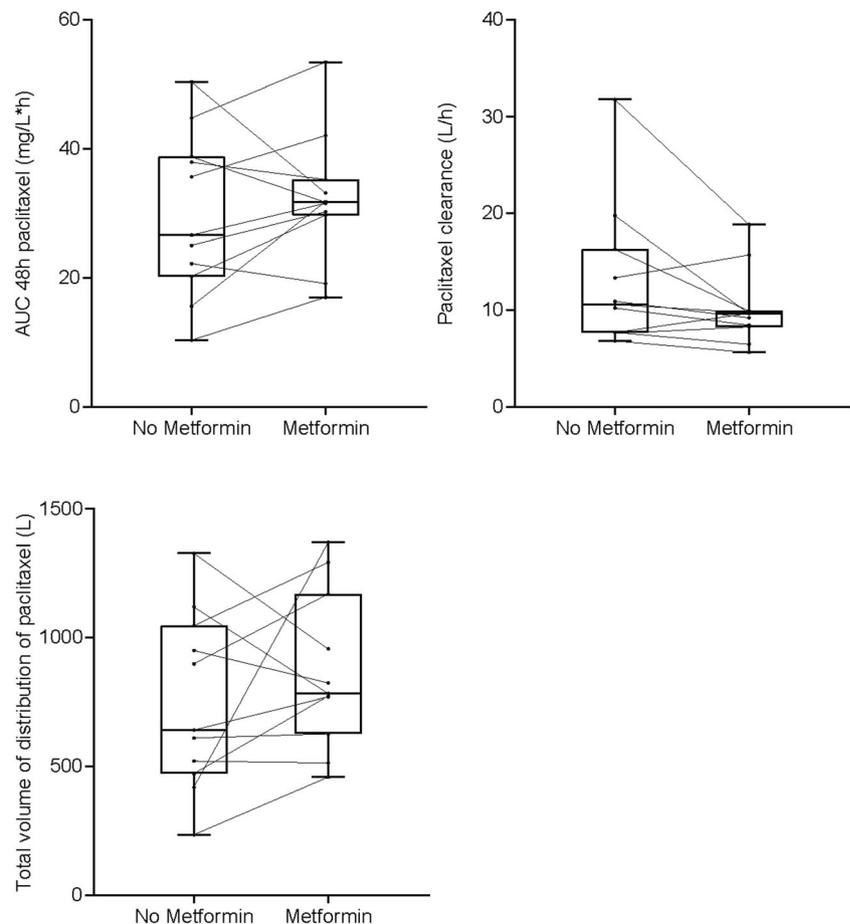

Twelve patients completed all planned carboplatin cycles. Three patients stopped paclitaxel treatment early; one patient after cycle 4 due to myelosuppression and two patients did not receive the last paclitaxel cycle due to neuropathy. In three patients the carboplatin dose was reduced due to thrombocytopenia, in one patient the dose was reduced by two levels. Paclitaxel dose was reduced by one level in eight patients, due to chemotherapy-related myelosuppression ( $n = 3$ ) or neuropathy ( $n = 5$ ). Seven patients required one or more dose delays (one  $n = 2$ ; two  $n = 3$ ; four  $n = 2$ ). Dose delays were due to chemotherapy-related hematological toxicity in six patients and a viral infection in one patient.

## Pharmacokinetics

Platinum PK analyses were performed in 10 patients. The AUC was calculated for  $t = 0$  to  $t = 48$  h, because in two patients the 72 h sample was missing. Median PK parameters of Pt are shown in Table 4. Carboplatin AUCs in cycle 2 were corrected for carboplatin dose adjustment from cycle

1 to cycle 2 in three patients (dose reduction due to thrombocytopenia), assuming a linear relationship between dose and AUC, to assess the effect of metformin on Pt AUC. PK analysis showed a metformin induced increase in the AUC of Pt (82.8 mg/L\*h vs. 101 mg/L\*h,  $\Delta$  22.0%,  $p=0.013$ ) and a decrease in the Pt clearance (3.39 L/h vs. 2.44 L/h,  $\Delta$ -28%,  $p=0.013$ ). There were no differences in Pt AUC 48 h between dose groups; however the small group sizes hamper a firm conclusion. A decrease of 20.5% in median total volume of distribution (Vd) of Pt was found when co-administrated with metformin (484 L vs. 385 L,  $p=0.037$ ) (Fig. 2). When patients were ranked based on carboplatin AUC and clearance, there was no correlation between these parameters and occurrence of known carboplatin toxicities such as thrombocytopenia and hypomagnesemia. Moreover, there was no correlation between metformin induced changes in carboplatin pharmacokinetics and toxicity. There were no differences in paclitaxel AUC, clearance or Vd between cycle 1 without metformin and cycle 2 of treatment with metformin (Fig. 3, Supplementary Table 3). All measured metformin levels were within the therapeutic range of 0.1–4 mg/L for diabetic patients) [34, 35].

**Fig. 3** Paclitaxel AUC, clearance and total volume of distribution without (cycle 1) and with metformin (cycle 2), calculated from measurement of paclitaxel in plasma samples in 11 patients in three dose cohorts of metformin (metformin 500 mg bd  $n=3$ , 850 mg tds  $n=3$ , 1000 mg tds  $n=5$ ). The lines between the two boxplots indicate the intra-individual changes of carboplatin AUC, clearance and total volume of distribution ( $n=11$  patients). Paclitaxel AUC of cycle 2 was corrected for paclitaxel dose adjustment from cycle 1 to cycle 2 in 1 patient (dose reduction for reason of leukopenia), assuming a linear relationship between dose and AUC

## Evaluation of response to treatment

Response assessment was not an endpoint in this study and was performed according to standard clinical practice. Treatment efficacy parameters for individual patients are listed in Supplementary Table 4.

## Discussion

The recommended phase II dose (RP2D) of metformin in combination with carboplatin and paclitaxel in our study was 1000 mg tds (3000 mg/day).

This RP2D is higher than in other early phase trials where metformin was combined with other anti-cancer therapy. Overlapping gastro-intestinal toxicities of metformin with, for example, mTOR-inhibitors and 5-FU based chemotherapy may have led to lower tolerability of combination therapy in these trials. Furthermore, relatively fit patients were included in our study; 67% had an ECOG-PS of 0 and 33% an ECOG-PS of 1. Metformin tolerability as monotherapy and in combination with anti-cancer therapy is improved when inpatient dose-escalation schemes are used [36–39]. The dose-

escalation scheme used in our study, likely contributed to the relatively high RP2D (3000 mg/day). The characteristics of previous trials can be found in supplementary Table 5 [36–48].

The combination of metformin with carboplatin and paclitaxel was tolerable and no dose-limiting toxicities occurred. Diarrhea is a well-known side effect of metformin, occurring in 20% of metformin treated diabetic patients leading to discontinuation in 5% of patients [49, 50]. Diarrhea occurred in eight patients in our study (53%), all grade 1–2. Although this is comparable to rates observed in other metformin combination studies it must be considered that diarrhea, even at low grades, can have a serious impact on health-related quality of life, and reduce treatment adherence. Hypomagnesemia is reported in 18% of type 2 diabetes mellitus patients receiving metformin [51], and even more frequently in patients receiving carboplatin (up to 46%) [52]. We therefore expected to observe an increased frequency of hypomagnesemia. Hypomagnesemia indeed occurred in 12 of 15 patients (80%) in our trial. However, in the majority of patients this was mild (11 patients grade 1–2) and all patients were treated with oral supplementation only. Other frequently occurring adverse events were related to myelosuppression, with frequencies not higher than expected for carboplatin and paclitaxel chemotherapy.

Metformin increased the Pt AUC by 22% and reduced Pt clearance by 28%. Due to the small number of patients per dose group, it was not possible to determine whether metformin had a dose-dependent effect on Pt AUC and clearance. There were no other obvious factors explaining the difference in Pt AUC and Pt clearance between cycle 1 and cycle 2. GFR did not change significantly, changes in albumin levels were not considered to be of influence because carboplatin does not bind to protein *in vitro* [53] and corrections for body weight changes were incorporated in the calculation of the carboplatin doses in cycle 1 and cycle 2.

The metformin-induced reduction in renal clearance of Pt could be due to a direct effect of metformin on the tubular resorption of Pt, via its copper-binding properties [54, 55]. Copper transporters 1 and 2 (CTR1 and CTR2) regulate both copper-transport and transport of carboplatin as well as cisplatin into the cell [56, 57]. Copper-deficiency can be induced by metformin binding to copper which may result in upregulation of CTR1 as a compensatory mechanism [58]. Upregulation of CTR1 in kidney tubular cells may result in improved retention of carboplatin resulting in decreased clearance. Intracellular copper deficiency in cancer cells may also enhance carboplatin uptake due to upregulation of copper transporters [59]. Five patients with platinum resistant HGSOC were treated with carboplatin in combination with the copper chelator trientine yielding a partial response in one patient and stable disease in three patients [60]. Metformin has indeed been shown to reverse platinum-

resistance of ovarian cancer cells through various mechanisms, but copper transporters have not been evaluated in these models [61, 62]. The majority of preclinical studies on anti-cancer effects of metformin used higher concentrations of metformin than those that can be achieved in patients with diabetes [63]. However, metformin has been shown to accumulate in tumor tissue, potentially due to the acidic tumor microenvironment, which could well result in intratumoral concentrations in the ranges studied preclinically [64, 65].

In conclusion, our study showed that the addition of metformin to carboplatin/paclitaxel in advanced ovarian cancer is feasible and well tolerated, with a RP2D of 1000 mg tds. A potential PK interaction of metformin with carboplatin was identified.
