Prognosis

Left atrial function

ABSTRACT

Objectives: Left atrial (LA) function is an important marker of hemodynamic status in cardiac amyloidosis (CA), and its characterization may provide relevant prognostic information. We sought to assess the prevalence and prognostic impact of LA dysfunction by cardiac magnetic resonance (CMR) in patients with CA.

Methods: We performed CMR in 80 consecutive patients with CA, including 38 with AL (47%) and 42 with ATTR (53%). LA function was assessed by acquiring short axis cine steady-state free precession (SSFP) covering the entire chamber. The atrial emptying fraction (AEF) was calculated as the ratio between the difference of LA maximal and minimal volume to LA maximal volume, expressed as percentage. Severe atrial dysfunction was defined as $AEF \leq 14\%$.

Results: Mean AEF was 18% (13–35%). Overall, $AEF \leq 14\%$ was present in 19 patients (24%), including 21% of those in sinus rhythm (SR) with no history of atrial fibrillation (AF). After a median of 3 years (IQR 2–4), 36 patients (44%) died of cardiac causes. Patients with $AEF \leq 14\%$ showed increased cardiac mortality, with an independent OR of 4.2 (95 IC 2.1–8.2, $P < 0.0001$). Of note, $AEF \leq 14\%$ was the stronger independent predictor of cardiac death. Patients in SR with $AEF \leq 14\%$ had worse outcome than those with AF. **Conclusions:** Severe impairment of LA contractile function was present in three-quarters of patients with CA, and was prevalent irrespective of CA etiology, both in the presence and absence of AF. Severe LA dysfunction was associated with an independent 4-fold increase in risk for cardiac death at three years.

1. Introduction

Cardiac amyloidosis (CA) is characterized by extracellular accumulation of fibrillary proteins within the myocardium, leading to progressive infiltration and functional impairment [1]. CA begins with a subclinical stage characterized by mild and non-specific cardiac symptoms [2]. Progression of amyloid deposition causes marked thickening of the cardiac walls leading to subsequent stages of heart failure with preserved systolic function (HFpEF) and different grades of diastolic dysfunction. The end-stage of CA is characterized by congestive HF with biventricular systolic

impairment, atrial fibrillation (AF) or sinus node dysfunction and atrioventricular block [3].

While the ventricular manifestations of CA dominate the clinical picture, the disease is known to affect the heart as a whole, including the left atrium (LA), interatrial septum and valvular apparatus. Amyloid deposition has been documented in the atrial walls and may create dysfunction [4]. LA remodeling and functional impairment, although different in etiology and molecular substrates, is a well-established epiphenomenon of many cardiac diseases, including pathophysiologic models resembling CA, such as hypertrophic cardiomyopathy (HCM). In HCM, both LA size and systolic function represent important predictors of outcome [5]. However, whether this concept may be applied to CA is still unresolved. The issue has a number of potential implications in clinical practice, ranging from screening and stratifying for disease severity to evaluating likelihood of AF. Cardiac magnetic resonance

(CMR) is today the gold standard for the evaluation of LA size and function. The present study aimed to exploit the potential of CMR in CA patients to 1) evaluate the prevalence of LA dysfunction through the analysis of LA volume\time curve, both in patients in sinus rhythm and AF, and 2) evaluate its independent clinical and prognostic.

2. Methods

We enrolled 80 consecutive patients (mean age 70 ± 12 years, 56 males) with an established diagnosis of CA: 38 patients with systemic AL amyloidosis (47%); 13 with genetic amyloidosis due to ATTR mutations (16%); 29 with wild type ATTR amyloidosis (37%). Diagnosis of AL amyloidosis was confirmed by biopsy of abdominal fat pad or of an involved organ. Amyloid deposits demonstrated typical Congo Red birefringence under polarized light and were characterized as AL type by immunohistochemistry on optic or immunoelectron microscopy or proteomics analysis according to the time of diagnosis. A monoclonal light chain of the same isotype (κ or λ) as that found in the amyloid deposits needed to be detected in serum and/or urine by immunofixation and by circulating FLC quantitation. A diagnosis of ATTR was made after evidence of documentation of Congo-red staining and apple-green birefringence under cross-polarized light in at least one involved organ followed by TTR deposits typing by immunohistochemistry on optic or immunoelectron microscopy or proteomics analysis according to the time of diagnosis in a positive tissue biopsy; (b) non-invasive documentation of intense cardiac uptake (visual score 2 or 3) on bone tracer scintigraphy with ^{99m}Tc -HMDP in the absence of either an abnormal serum free light chain ratio or a monoclonal protein in the serum or urine by immunofixation [6]. Diagnosis of CA was confirmed by myocardial biopsy (Congo-red staining combined with polarized light) and/or by the presence of CMR morphologic and post-contrast criteria of CA [7] or cardiac ^{99m}Tc -HMDP retention. The study was approved by the institutional ethical committee, and all subjects gave their written informed consent.

All patients underwent a thorough clinical, biohumoral, electrocardiographic and echocardiographic evaluation at enrollment. Presence and the severity of dyspnea was classified by New York Heart Association (NYHA) functional class. Biomarkers included serum creatinine, troponine I and plasma NT-proBNP assay. Patients with contraindications to CMR and those with an estimated glomerular filtration rate (eGFR) < 30 ml/min, by Cockcroft Gault formula were excluded from the study.

2.1. CMR protocol

CMR was performed with a dedicated 1.5-T (Signa Artist, General Electric Healthcare, Milwaukee, Wisconsin) with a 16-channel cardiac phased array coil. Short-axis cine images were acquired orthogonal to main LV axis covering both LV and LA, using a steady-state free precessing FIESTA (fast imaging employing steady-state acquisition) pulse sequence with the following parameters: 30 phases, slice thickness 8 mm, no gap, 8 views per segment, number of excitation 1, field of view 40 cm, phase field of view 1, 224×224 matrix, voxel dimensions $1.78 \times 1.78 \times 8$ mm, reconstruction matrix 256×256 , 45° flip angle, repetition time/echo time equal to 3.5/1.5, and a bandwidth of 125 KHz. After cine imaging, 0.2 mmol/kg Gadoteridol (Prohance, Bracco Imaging) were administered and late gadolinium enhancement (LGE) images acquired approximately 10 after the administration of the contrast medium in a full set of short-axis views in the same plane of cine images. The following parameters were used: field of view 35–40 cm, slice thickness 8 mm, no gap between each slice, repe-

tion time 4.6 ms, echo time 1.3, 20° flip angle, matrix 224×224 , reconstruction matrix 256×256 , number of excitations 1. A modified Look-Locker Imaging (MOLLI) pulse sequence with 3(3)3(3)5 pattern was used to evaluate native T1 in 3 (basal, middle and apical) short axis slices.

2.2. Image analysis and definition of atrial emptying fraction (AEF)

Analysis of CMR images was performed, using a commercially available research software package (CMR42, Circle). Endocardial and epicardial contours of LV and RV myocardium were traced in the end-diastolic and end-systolic phases. End-diastolic and end-systolic volume indexes, biventricular mass and mass index were measured as previously described [8]. The presence of typical LGE pattern for CA was evaluated by three expert level-III EACVI accredited observers, blinded to each other [9].

Parameters of LA function were evaluated as previously reported [8]. Briefly, LA endocardial contours were automatically traced in every cine frame to obtain volumetric data of all cardiac phases. Manual correction was performed when needed. Volumetric data were plotted against time (in ms) generating a LA volume over time (V/t) curve (Fig. 1). Through the analysis of the atrial V/t curves, atrial emptying volume was measured as the difference between the maximal and minimal atrial volumes. The atrial emptying fraction (AEF) was then measured as the ratio between atrial emptying volume and maximal atrial volume, expressed in %. The atrial reservoir, conduit and booster volumes were measured in ml. As reported in the previously mentioned study [8] in healthy controls AEF was $> 36\%$ and this was considered the cut-off for preserved LA function. Using this threshold, patients were divided in those with preserved and those with impaired LA function ($\text{AEF} \leq 36\%$). Patients with impaired LA function, were further divided in 3 groups based on tertiles of AEF found in our cohort: severe ($\text{AEF} \leq 14\%$), moderate ($>14\%$ to $\leq 20\%$), and mild dysfunction ($>20\%$ – $\leq 36\%$).

2.3. Clinical follow-up and study end-point

All patients were followed-up after CMR. A clinical questionnaire was compiled by an expert physician during periodic ambulatory visitations in each hospital, by contacting their relatives by telephone, by a general practitioner, or by consulting the office of vital statistics at the patient's place of residence. The end-point of the study was death due to cardiac causes (heart failure or sudden cardiac death).

2.4. Statistical analysis

Values are presented as the mean \pm SD or as the median and interquartile range (IQR) for variables with normal and non-normal distributions, respectively. Values with non-normal distribution according to the Kolmogorov-Smirnov test were logarithmically transformed for parametric analysis. Qualitative data are expressed as percentages. Categorical variables by the Chi-square or by the Fisher exact test. Continuous variables were compared by the ANOVA with Bonferroni correction when needed, or with Wilcoxon non-parametric test as appropriate. ROC curve analysis was used to found the more accurate threshold of AEF for predicting cardiac death. The Kaplan-Meier time-to-event method was employed to calculate and compare longitudinal curves between groups. Univariate and Multivariate COX regression analysis (stepwise) was used to explore the impact of each significant variable to predict the occurrence of cardiac death). The risk of multicollinearity among the covariates was evaluated by the variance inflation factor (VIF). VIF values were < 10 for all the variable included in

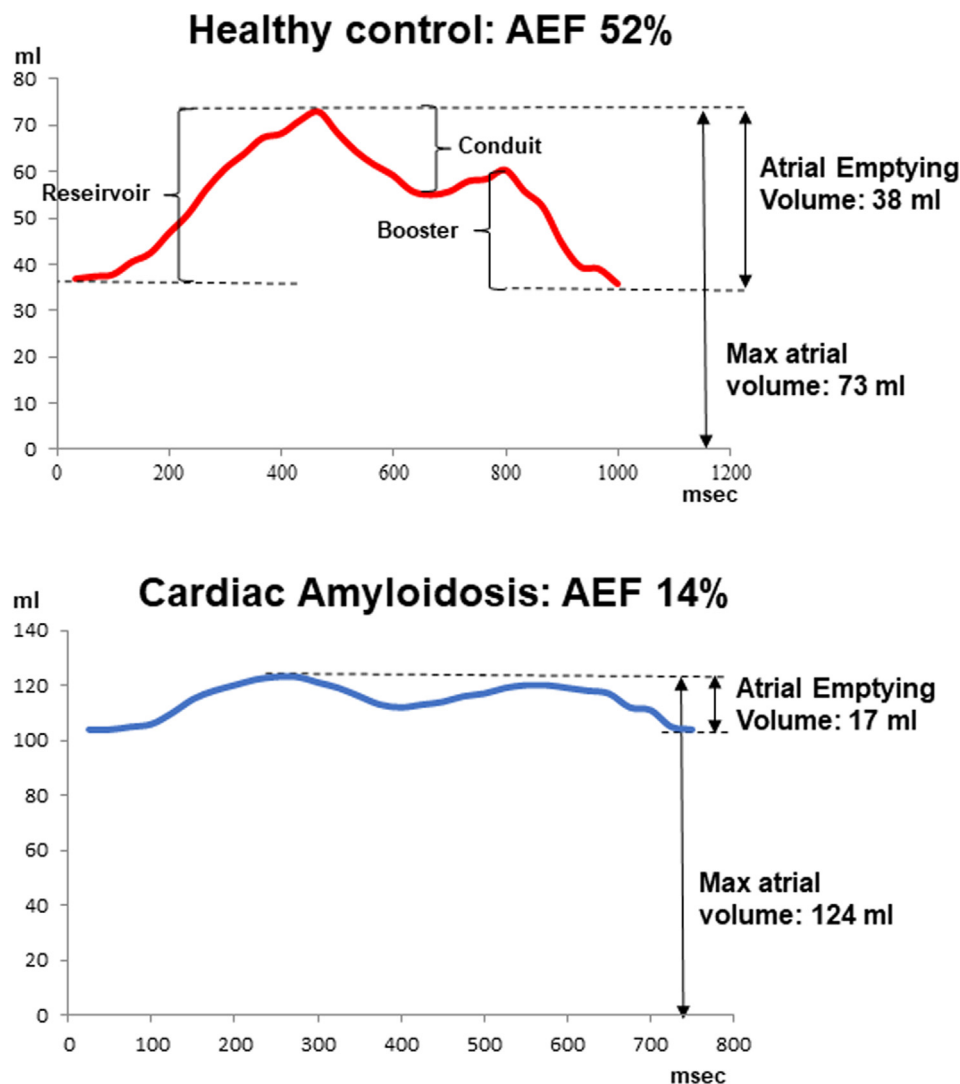

Fig. 1. Left atrial Volume/Time curves: Examples of left atrial volume/time curve in a healthy control, upper panel and in a patient with cardiac amyloidosis.

the multivariable models, indicating low risk of multicollinearity. A p -value < 0.05 was considered statistically significant.

3. Results

A total of 80 patients with mean age 70 ± 12 years, 56 males (69%) were enrolled in the study, including 57 patients (71%) in SR and 23 (29%) in AF. Of these 80 patients, 19 had severe LA dysfunction ($AEF \leq 14\%$), 21 moderate ($AEF > 14\%$ to $\leq 20\%$), and 20 mild dysfunction ($AEF > 20\%$ – $\leq 36\%$); the remaining 20 patients had normal AEF values (Table 1). Notably, $AEF \leq 14\%$ was found in 12 of the 57 (21%) patients in sinus rhythm. Patients with severe LA dysfunction ($AEF \leq 14\%$) had higher NT-pro-BNP values, higher wall thickness and atrial volume than those with preserved LA function. An inverse relation was found between AEF and NT-pro-BNP ($R^2 0.24$, $p = 0.015$). Patients with aTTR amyloidosis were older (64 ± 12 vs 76 ± 10 years, $p < 0.001$), had higher wall thickness (14 ± 4 vs 17 ± 5 mm, $p = 0.007$), higher LV mass index (88 ± 27 vs 121 ± 38 g/m², $p < 0.001$) and greater atrial maximal volume (120 ± 33 vs 140 ± 42 ml/m², $p < 0.02$) than those with AL. However, AEF was not significantly different between AL and aTTR.

3.1. Clinical Follow-up

During a median follow up of 3 (2–5) years, 36 patients died (44%) of cardiac causes. At baseline, patients with cardiac death, compared to survivors, had higher TnI-HS values 95 vs 52 pg/dl; $p < 0.05$, lower RVEF (54% vs 60%; $p < 0.05$), higher LA maximal (146 vs 120 ml; $p < 0.05$) and minimal volume (124 vs 90 ml; $p < 0.005$), lower LA reservoir (18 vs 28 ml; $p < 0.005$) and booster volumes (12 vs 18 ml; $p < 0.005$) and lower AEF (14 vs 24; $p < 0.001$). At ROC curve analysis, AEF predicted cardiac death with an AUC of 0.72 (95% CI 0.60–0.82; $p = 0.0002$). The best AEF threshold for cardiac death prediction was $\leq 14\%$ (sensitivity 60%, specificity 86%). The relation between AEF and the maximal atrial volume is showed in Fig. 2. Kaplan Meier survival analysis identified impaired survival in patients with $AEF \leq 14\%$ compared to patients with $AEF > 14\%$ (Log rank $p < 0.0001$) as depicted in Fig. 3 (left panel). At univariate Cox regression analysis, NYHA class, NT-proBNP, troponin I, RVEF, maximum atrial volume, AEF and $AEF \leq 14\%$ were associated with cardiac death (Table 2). Multivariable Cox regression analysis was performed in two different models, the first including AEF as continuous variable, the second with $AEF \leq 14\%$ as dichotomous parameter. In the first model NYHA class and AEF were independent predictors of cardiac death,

Table 1
Prevalence and clinical correlates of left atrial (LA) systolic dysfunction in 80 patients with cardiac amyloidosis.

¹ significant p value vs severe LA dysfunction.

² significant p value vs Moderate LA dysfunction.

³ significant p value vs Mild LA dysfunction.

⁴ significant p value vs Preserved LA function.

Fig. 2. Relation between the atrial emptying fraction (AEF) and the maximal atrial volume: A significant inverse relation was found between AEF and the maximal atrial volume ($r = -0.61$, $p < 0.0001$), but some patients had low AEF with only mild atrial dilation. In left panels patients were divided by the type of amyloidosis (AL, mutated-aTTR, wild type-aTTR). In right panel, patients were divided by cardiac death or not.

in the second model NYHA class and $AEF \leq 14\%$ were independent predictors.

3.2. Sinus rhythm vs atrial fibrillation

Among patients in SR, Kaplan Meier survival analysis showed that the presence of $AEF \leq 14\%$ was associated to worse prognosis than those with $AEF > 14\%$ (Log rank < 0.0001 , Fig. 3, right panel). In contrast, among patients in AF, no significant difference in survival was found between $AEF > 14\%$ and $AEF \leq 14\%$. Interestingly,

patients in SR and $AEF \leq 14\%$ had higher risk of cardiac death than those with AF: 1-year risk of cardiac death, respectively 42% (95% CI 40–43) vs 17% (95% CI 16–18), $p < 0.0001$; 3-year risk, respectively 75% (95% CI 72–78) vs 42% (95% CI 40–43), $p < 0.0001$.

4. Discussion

The main findings of the present study can be summarized as follows: a) left atrial dysfunction is common in CA patients, and can be severe even in the presence of stable SR; b) when severe,

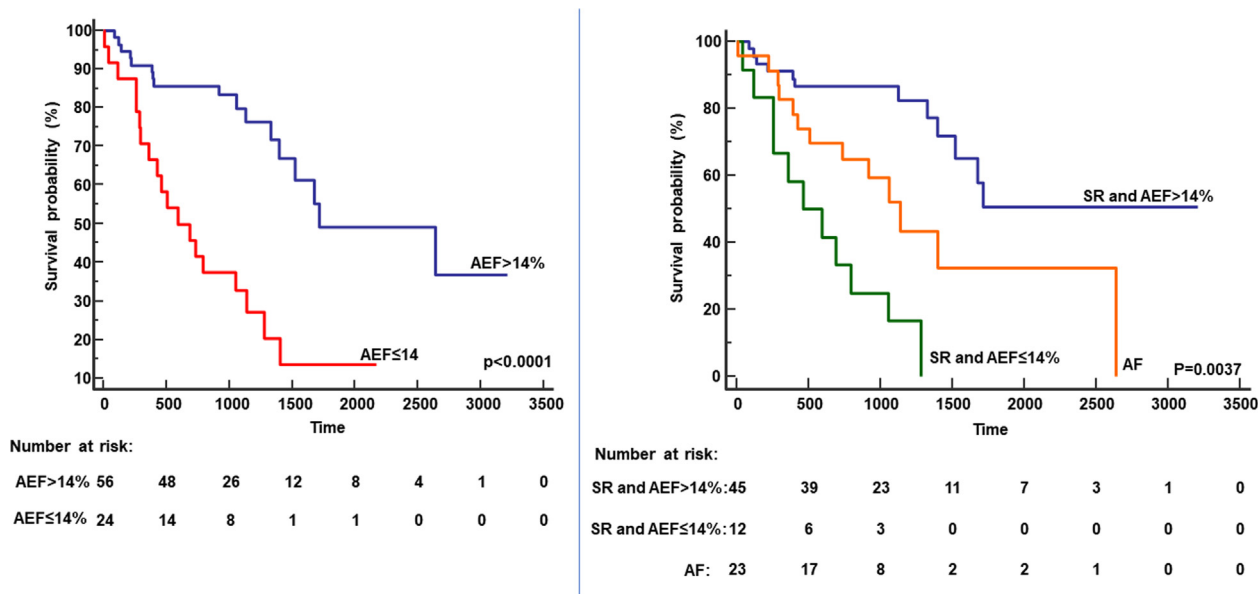

Fig. 3. Prognostic differences between patients with and without atrial dysfunction. In left panel, Kaplan Meier curve demonstrating that patient with impaired left atrial function with atrial emptying fraction (AEF) ≤ 14% had worse prognosis than those with better function. In right panel, Kaplan Meier curve demonstrating that patient with atrial fibrillation had worse prognosis than those with sinus rhythm and atrial emptying fraction (AEF) > 14%, but the worst prognosis is showed in patient with sinus rhythm and AEF ≤ 14%.

i.e. AEF ≤ 14%, atrial dysfunction is associated with a > 4-fold increase in cardiac mortality, representing a powerful independent predictor of risk; c) the prognosis of CA patients in SR with

AEF ≤ 14% is worse than that of patients in AF. Severe LA dysfunction, defined as AEF ≤ 14% was a strong independent predictor of cardiac death. Patients with AEF ≤ 14% had a 32% risk at 1 year and a 61% risk at 3 years. The identification of AEF by CMR is a simple, accurate and reproducible parameter that can facilitate risk stratification and prognosis assessment in patients with AL and ATTR CA. Furthermore, phasic measurement of LA function using feature-tracking CMR add important information regarding LA fibrosis and provide additional insight for procedural outcomes and stroke risk stratification [23]. In HF patients, Pellicori et al [21] found that left atrial function measured by CMR was an important marker of cardiac dysfunction and cardiovascular outcome. In that study, AEF was associated with increasing plasma concentrations of NT-proBNP and a higher incidence of AF and was a predictor of adverse outcome independently of other parameters of cardiac dysfunction. Mohty et al [22] observed an association of AEF with severity of cardiac involvement, functional status and presence of LGE in patients with AL CA.

LA is a “victim” of CA for a number of reasons. First, the deposition of amyloid proteins causes an increase in LV stiffness and diastolic dysfunction that determines LA dilatation, and ultimately precipitates AF and electromechanical dysfunction. Second, amyloid directly affects the LA wall reducing atrial contractility and contributing to the impairment of LV filling. Henein et al. analyzed LA strain by 2D echocardiography in 46 patients with CA [16]. They found that, despite normal chamber size, LA myocardial deformation function was depressed, suggesting that infiltration with amyloid fibrils could limit LA distension and primarily affecting the atrial booster phase.

Notably, although severe atrial dysfunction was more prevalent (48%) among CA patients in AF, it was far from rare among in sinus rhythm (involving one in five or 21%). While patients in SR and preserved atrial function expectedly showed more favorable prognosis than those in AF, patients with SR and severe atrial dysfunction had the worst outcome of all. Although the small sample size warrants caution in its interpretation, this finding suggests that LA dysfunction per se carries sufficient hemodynamic burden to cause clinical deterioration without the mediation of AF; this may also reflect the

fact that loss of atrial contribution in these stages of CA is irrelevant and does not carry adverse consequences when lost to AF: The other explanation is that severe atrial dysfunction in SR might be a marker of severe atrial amyloid deposition inducing atrial standstill with preserved electrical conduction, in a sort of regional electromechanical dissociation reflecting particularly severe cardiac involvement. This observation deserves further investigation as it largely counters what is seen in other forms of heart failure and cardiomyopathies including HCM. Finally, severe atrial dysfunction in the presence of SR has important management implications, including a potentially high cardioembolic risk even in the absence of AF. The fact that we did not observe stroke or other embolic complications does not exclude this possibility, as shown in previous studies on CA patients in sinus rhythm [18,19,20].

Some study limitations should be mentioned. First, the study population patients was relatively small (n = 80) and allowed limited power for subanalyses (including different CA etiologies). Second, we did not employ dedicated software for atrial function assessment such as, feature tracking. The choice to evaluate atrial function using only atrial volume was aimed at obtaining an easily reproducible parameter available with every clinical CMR scanner without the need for complex and expensive post-processing software.

5. Conclusions

Severe impairment of LA contractile function was present in three-quarters of patients with CA, and was prevalent irrespective of CA etiology, both in the presence and absence of AF. Severe LA dysfunction was associated with an independent 4-fold increase in risk for cardiac death at three years. AEF is easily obtainable and should be considered routinely in CA patients undergoing CMR.
