ABSTRACT

Objectives To examine the long-term outcomes for patients hospitalised with chronic diseases at age 30, 40 or 50 years.

Design Nationwide, population-based cohort study.

Setting All Danish hospitals, 1979–1989, with follow-up through 2014.

Participants Patients hospitalised during the study period with one, two or three or more chronic diseases and age-matched and sex-matched persons from the general population without chronic disease leading to hospitalisation: age-30 group: 13 857 patients and 69 285 comparators; age-40 group: 24 129 patients and 120 645 comparators; and age-50 group, 37 807 patients and 189 035 comparators.

Main outcome measures Twenty-five-year mortality risks based on Kaplan-Meier estimates, years-of-life-lost (YLLs) and mortality rate ratios based on Cox regression analysis. YLLs were computed for each morbidity level, as well as in strata of income, employment, education and psychiatric conditions.

Results Twenty-five-year mortality risks and YLLs increased steadily with increasing number of morbidities leading to hospitalisation and age, but the risk difference with general population comparators remained approximately constant across age cohorts. In the age-30 cohort, the risk differences for patients compared with comparators were 35.0% (95% CI 32.5 to 37.5) with two diseases and 62.5% (54.3% to 70.3%) with three or more diseases. In the age-50 cohort, these differences were, respectively, 48.4% (47.4 to 49.3) and 61.7% (60.1% to 63.0%). Increasing morbidity burden augmented YLLs resulting from low income, unemployment, low education level and psychiatric conditions. In the age-30 cohort, YLLs attributable to low income were 2.4 for patients with one disease, 6.2 for patients with two diseases and 11.5 for patients with three or more diseases.

Conclusions Among patients with multiple chronic diseases, the risk of death increases steadily with the number of chronic diseases and with age. Multimorbidity augments the already increased mortality among patients with low socioeconomic status.

INTRODUCTION

Multimorbidity, or the coexistence of two or more chronic conditions within the same individual,¹ is common among young and

Strengths and limitations of this study

- This nationwide, population-based cohort study examined the long-term mortality risks among patients of age 30, 40 or 50 years with and without hospital-diagnosed chronic disease.
- The study furthermore examined how number of chronic diseases impacts mortality and how socioeconomic factors and other psychiatric disease impacts these risks.
- The setting with long-term follow-up and accurate linkage within a uniform healthcare system eliminated selection and referral biases.
- Data on chronic and psychiatric diseases arose from inpatient hospitalisations and thus did not include conditions diagnosed and treated in the outpatient setting.
- Patients were identified based on 19 selected chronic diseases included in the Charlson Comorbidity Index, but other chronic conditions not listed here could potentially affect long-term outcomes.

middle-aged adults.² A Scottish cross-sectional study established that despite a strong association of multimorbidity with increasing age, adults aged 65 years or younger account for most of these patients in absolute numbers.² Multimorbidity is associated with fractionated healthcare and adverse health outcomes such as poor survival and reduced quality of life.^{3–5}

Strong evidence exists that multimorbidity is associated with premature death; however, most previous studies examining this association have focused on older adults.^{3 6–10} For example, in a recent meta-analysis of evidence pooled from 26 studies, risk of death was increased approximately twofold among multimorbid patients over age 60 years compared with those without multimorbidity.³ In contrast, the long-term prognosis of young and middle-aged adults age 50 years or younger who have multimorbidity remains poorly understood. The lack of focus on this population is worrisome, considering their potentially long life expectancy and the huge

personal and societal consequences of multimorbidity in this age group.^{2 11} Furthermore, data indicate a strong socioeconomic gradient in the onset of multimorbidity, particularly among young and middle-aged adults,^{2 12} with little information about how this gradient affects long-term prognosis.

To address these evidence gaps, we used nationwide health and administrative registries with virtually complete individual-level linkage and follow-up to examine 25-year mortality risks and expected years of life lost (YLLs) in three cohorts of patients aged 30, 40 and 50 years hospitalised with one or more chronic diseases.

METHODS

Design and setting

We conducted a nationwide, population-based cohort study in Denmark covering 1979–1989, allowing for a 25-year follow-up period through 2014. The Danish National Health Service provides universal, tax-supported healthcare for all Danish residents to both general practitioners and hospital care.¹³ Patient data are linkable at the individual-level across health and administrative registries through a unique 10-digit identifier, assigned by the Civil Registration System (CRS) to all residents at birth or on immigration.¹⁴ The CRS is updated daily concerning changes in vital status and migration for the entire Danish population.

Patient cohorts

We used the Danish National Patient Registry (DNPR) to construct three cohorts of different ages at baseline: we identified those ages 30, 40 or 50 years with a primary or secondary inpatient hospital diagnosis of at least one condition included in the Charlson Comorbidity Index (CCI).¹⁵ We categorised the overall morbidity burden according to the number of diagnosed conditions (1, 2 or ≥ 3). Patients with at least two conditions were defined as having multimorbidities. The baseline was set as the date a patient reached age 30, 40 or 50 years. The cumulative source population during the inclusion period was 898 266 for people aged 30 years; 871 658 for people aged 40 years; and 627 826 for people aged 50 years.

The DNPR has recorded non-psychiatric inpatient hospitalisations since 1977.¹⁶ Records of hospitalisations in the DNPR include one primary and one or more secondary diagnosis, coded according to the *International Classification of Diseases*, Eighth Revision, between 1977 and 1994 and 10th Revision thereafter. The CCI is a commonly used index to identify comorbidities and comprises a wide range of diseases, including cardiovascular, metabolic, hepatic and renal diseases, malignancies, dementia, peptic ulcer and AIDS (online supplemental table S1).¹⁵ Hospital diagnosis codes of CCI conditions have high validity in the DNPR, with positive predictive values for all CCI conditions exceeding 90% compared with medical records.¹⁷

General population comparison cohorts

We used the CRS to construct three general population comparison cohorts.¹⁴ For this purpose, we matched, with replacement, up to five persons from the general population to each member of the patient cohorts on date of birth and sex.¹⁸ Persons were ineligible if they had one or more primary or secondary inpatient hospital diagnoses of any CCI conditions recorded in the DNPR any time before or at baseline. Diagnoses made after baseline were ignored.

Mortality

The primary outcome was time to death during 25 years of follow-up. Data on all-cause mortality were extracted from the CRS.

Covariables

To examine the impact of socioeconomic factors, we gathered information on socioeconomic factors 2 years before baseline: income level (low, intermediate, high and very high), employment status (early retirement, unemployed and employed) and education level (primary school, youth education/high school and higher education) from the Integrated Database for Labor Market Research.¹⁹ We also gathered information on prevalent psychiatric conditions at baseline (schizophrenia, bipolar disorder/depression, schizotypal disorder, personality disorder and other mental illness) from the Psychiatric Central Research Registry (PCRR).²⁰ The PCRR contains data on all inpatient psychiatric admissions since 1969.

Statistical analysis

We characterised patients and their matched general population comparators according to age, sex, calendar year, morbidity burden, individual chronic diseases included in the CCI, income level, employment status, educational achievement and psychiatric conditions. We followed cohort members from baseline until death, emigration or 31 December 2014, whichever occurred first. Separately for each age cohort, we used the complement of the Kaplan-Meier estimator to compute and illustrate 25-year mortality risks for patients, stratified by their morbidity burden and general population comparators.

As an additional method to assess survival in the patient and the general population cohorts, we computed expected YLLs as the mean survival difference between the two, that is, the difference in the area between the mean Kaplan-Meier survival curves.²¹ YLLs were computed for each morbidity level, as well as in strata of income, employment and education, and for each psychiatric condition, without and with stratifying by morbidity level. Ninety-five per cent CIs were computed using bootstrapping on each of the matched pairs using 100 replicates.

As a measure of the mortality rate ratio, we computed HRs of death and 95% CIs by means of stratified Cox proportional hazards regression within the sex-matched and age-matched strata, comparing the patient cohorts with the general population comparison cohorts.

Table 1 Characteristics of Danish patients with one or more chronic diseases leading to hospitalisation by age 30, 40 or 50 years and age-matched and sex-matched individuals from the general population without chronic disease during 1979–1989

CCI, Charlson Comorbidity Index.

The regression was done separately in each morbidity subgroup. In multivariable analyses, we adjusted for income level, employment status and education level. Because the proportionality assumption was violated, we applied a piecewise Cox regression, computing HRs within 0–1 year, >1–5 years, >5–10 years, >10–20 years and >20–25 years.

All statistical analyses were conducted using the SAS statistical software package, V.9.4. Diagnosis codes are provided in online supplemental table S1.

Patient involvement

No patients were involved in setting the research question or the outcome measures, nor were they involved in developing plans for design or implementation of the study. No patients were asked to advise on interpretation or writing up of results. There are no plans to disseminate the results of the research to study participants or the relevant patient community.

RESULTS

We identified 13 857 patients and 69 285 age-matched and sex-matched general population comparators who were age 30 years; 24 129 patients and 120 645 age-matched and sex-matched comparators who were age 40 years; and 37 807 patients and 189 035 age-matched and sex-matched comparators who were age 50 years (table 1). The sexes were approximately equally distributed in each cohort. The prevalence of multimorbidity increased slightly with age. The most frequently hospital-diagnosed conditions were any tumour, peptic ulcer, chronic pulmonary disease and type 1 and 2 diabetes. Socioeconomic status was generally lower in the patient cohorts, and

across all age cohorts, low income, unemployment and early retirement, and less educational achievement was more frequent among patients than among general population comparators. Similarly, psychiatric conditions, such as personality disorder and other mental illness, were more common among the patients than among the comparators.

Absolute mortality risks

We observed 2999 deaths in the age-30 group, 8988 in the age-40 group and 23 427 deaths in the age-50 group. The 25-year mortality risk increased steadily with increasing number of morbidities leading to hospitalisation and age (figure 1). Among patients with one disease, the 25-year mortality risks were 19.4% (95% CI 18.7% to 20.1%) in the age-30 group, 34.4% (95% CI 33.7% to 35.0%) in the age-40 group and 58.6% (95% CI 58.1% to 59.2%) in the age-50 group. These risks increased respectively to 68.6% (95% CI 60.3% to 76.6%), 82.3% (95% CI 78.0% to 86.3%) and 92.4% (95% CI 90.6% to 93.9%) among patients with three or more diseases at baseline. However, the mortality risk differences with matched comparators from the general population remained largely similar across age cohorts. For the age-30 patients at baseline, the risk differences with comparators were 13.3% (95% CI 12.8% to 13.8%) with one disease, 35.0% (95% CI 32.5% to 37.5%) with two diseases and 62.5% (95% CI 54.3% to 70.3%) with three or more diseases. For the age-40 patients, the risk differences with matched comparators were 21.3% (95% CI 20.9% to 21.7%) with one disease, 46.8% (95% CI 44.9% to 48.6%) with two and 69.2% (95% CI 65.1% to 73.0%) with three or more. Finally for the age-50 group, the risk differences

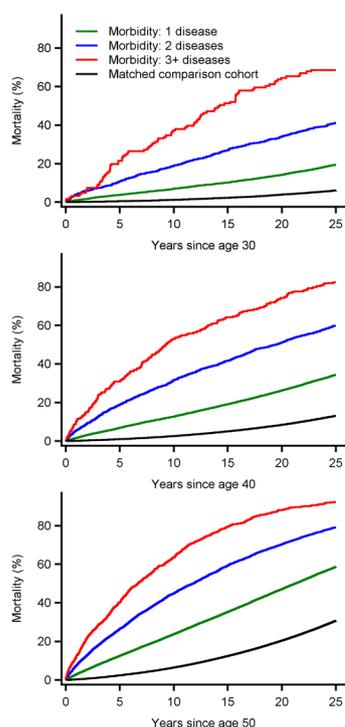

Figure 1 Twenty-five-year mortality risks for patients with one or more chronic diseases when they reached age 30, 40 or 50 years, stratified by number of chronic conditions and age-matched and sex-matched individuals from the general population without chronic disease during 1979–1989 in Denmark.

from matched comparators were 28.0% (95% CI 27.6% to 28.3%), 48.4% (95% CI 47.4% to 49.3%) and 61.7% (95% CI 60.1% to 63.0%) with one two, and three or more diseases, respectively.

Years of life lost

We calculated expected YLLs by comparing the mean survival difference between the patient and general population cohorts. In line with the absolute mortality risks, expected YLLs during 25 years of follow-up increased with baseline age and with number of morbidities. For patients in the 30-year age group, the expected YLLs were 1.7 (95% CI 1.6 to 1.8), 5.2 (95% CI 4.7 to 5.6) and 10.4 (95% CI 8.7 to 12.1) with one, two and three or more diseases, respectively. For those in the 50-year group, the corresponding YLLs were 4.6 (95% CI 4.5 to 4.7), 9.3 (95% CI 9.1 to 9.6) and 13.4 (95% CI 12.9 to 13.9) (table 2).

YLLs were greater among patients with low versus high income, for those on early retirement versus being employed and for those with lower versus higher education level (table 2). For example, YLLs for patients who were aged 30 years and with low income were as high as or higher than those for patients with very high income who were 10 years older. For psychiatric conditions, YLLs were substantial for the patient groups (eg, with schizophrenia,

the YLLs were 3.6 (95% CI 1.8 to 5.5) in the age-30 cohort and 6.1 (95% CI 5.0 to 7.2) in the age-50 cohort).

YLLs in association with lower socioeconomic status and psychiatric conditions were more pronounced with increasing morbidity burden, regardless of age (table 2). For example, in the age-30 cohort, YLLs because of low income were 2.4 (95% CI 2.2 to 2.6) for patients with one disease, 6.2 (95% CI 5.3 to 7.2) for patients with two diseases and 11.5 (95% CI 8.2 to 14.8) for patients with three or more diseases. Similar trends were observed for most other socioeconomic factors and psychiatric conditions.

Relative mortality risks

Compared with sex-matched and age-matched comparators from the general population, the relative risk of death during the first year was approximately 20–100 fold in patients with multimorbidity (table 3). Although the HRs decreased during follow-up, values ranging from approximately 2–10, depending on baseline age, persisted among patients surviving at least 20 years. HRs tended to decrease with increasing baseline age, irrespective of number of morbidities and follow-up period. Adjustment for socioeconomic factors did not change the unadjusted estimates materially.

DISCUSSION

In this nationwide, population-based cohort study comprising patients age 30, 40 and 50 years, the 25-year mortality risk grew with increasing number of morbidities leading to hospitalisation and with age. Although the mortality risk difference with persons from the general population increased among patients with more chronic conditions, it remained approximately constant across age cohorts. Increasing number of morbidities was linked to higher YLLs from low income, unemployment, low education level and psychiatric conditions.

Our study should be viewed in light of several factors. Our setting with long-term follow-up and accurate linkage within a uniform healthcare system eliminated selection and referral biases. However, data on chronic and psychiatric conditions arose from inpatient hospitalisations and thus did not include conditions diagnosed and treated in the outpatient setting, including by general practitioners. Presumably, this selection yielded higher mortality risk estimates than would have resulted with inclusion of outpatient diagnoses. It is possible that general population comparators were, in fact, living with chronic conditions not leading to hospitalisation. This potential source of misclassification could have biased the HRs downwards. Furthermore, we identified and categorised patients based on 19 selected chronic diseases included in the CCI, and other chronic conditions not listed here could potentially affect prognosis. In addition, prognoses associated with several of the included conditions, including myocardial infarction, stroke, some cancers, AIDS and leukaemia have

Table 2 Expected years of life (EYL) and EYL lost during 25 years of follow-up for patients with one or more chronic diseases leading to hospitalisation by age 30, 40 or 50 years and age-matched and sex-matched individuals from the general population without chronic disease, by number of conditions and by socioeconomic factors and psychiatric conditions, overall and by number of chronic diseases

*Years of life lost were calculated as the difference in the area between the mean Kaplan-Meier survival curve in the patient and the general population cohorts.

improved considerably since the start of study period as a consequence of medical, diagnostic and treatment advances.^{7 22}

Several previous studies have linked multimorbidity with increased mortality among older adults.^{3 6–10} A meta-analysis including 26 studies of patients age 60 years or older reported an HR of 1.7 for patients with at least two diseases and 2.7 for those with at least three compared with people without multimorbidity.³ Similarly, the Emerging Risk Factor Collaboration found a 4–7 fold increased risk of death among patients (mean age: 53 years) with cardiometabolic multimorbidity compared with a reference group without multimorbidity.⁶ In line with our study, a number of previous groups used the CCI to identify multimorbidity, either with^{7 8} or without^{9 10} an index disease. For example, Schmidt *et al*⁷ found a 2.5-fold higher 5-year mortality rate among stroke patients with a weighted CCI score of 3+ compared with stroke patients with a weighted CCI score of 0.

In contrast to most previous literature on multimorbidity, we examined the prognosis in young and middle-aged adults under aged 50 years. In line with current understanding,² we found a steep socioeconomic gradient in YLLs attributable to multimorbidity, with YLLs because of low socioeconomic status increasing with the number of prevalent diseases. Although we compiled data on socioeconomic factors 2 years before baseline, reverse causality remains possible.²³ Given that YLLs for patients who were 30 years old and in the low-income category were as high as or higher than YLLs for very high-income patients a decade older, reducing disparities in healthcare is obviously crucial. We did not examine associations of modifiable risk factors linked to socioeconomic status, such as tobacco smoking, excessive alcohol consumption, poor diet, high body mass index, hypertension and hyperlipidaemia.²⁴ We also could not evaluate whether socioeconomic status itself was acting directly through complex mechanisms involving upstream factors²⁵. Both of these questions require further investigation.

Our study also evaluated YLLs in relation to psychiatric conditions, a poorly understood area in relation to somatic multimorbidity, particularly in young and middle-aged adults. Psychiatric conditions increase in prevalence with increasing burden of physical ill health.² Our findings that YLLs attributable to psychiatric conditions increased with an increasing number of prevalent diseases indicates an unmet need among those with these psychiatric conditions.

Healthcare systems lack an optimal infrastructure to properly care for patients with multimorbidity. Although these patients may be in contact with health services more frequently than those who have a single disease, management of multimorbidity is usually fragmented, as medical professionals are becoming increasingly specialised in single diseases or organs.^{2 26} Thus, improving coordination of care is a great challenge, particularly in light of the demographic changes that will lead to increasing numbers of patients with multiple conditions.²

Table 3 HRs comparing patients with one or more chronic diseases by age 30, 40 or 50 years with age-matched and sex-matched individuals from the general population without chronic disease, by follow-up time and number of chronic diseases

*Adjusted for socioeconomic factors (income level, employment status and education level).
PY, person years.

In conclusion, young and middle-aged patients hospitalised with one or more chronic diseases had increased mortality risk during 25 years of follow-up, compared with age-matched and sex-matched persons from the general population without chronic disease. The risk of death grew steadily with the number of chronic diseases and with age. Multimorbidity also added to the increased mortality among patients with low socioeconomic status.

Contributors AGO, NS and HTTS designed the study. EH-P and HTTS collected the data. NS and AGO reviewed the literature. AGO, NS and HTTS directed the analyses, which were carried out by BD. All authors participated in the discussion and interpretation of results. NS and AGO organised the writing and wrote the initial draft. All authors critically revised the manuscript for intellectual content and approved the final version. HTTS is the guarantor.

Funding This work was supported by a grant from The Lundbeck Foundation (grant no. R248-2017-521). The sponsor had no role in study design, data collection, analysis or interpretation of the data, writing of the manuscript or in the decision to submit the paper for publication. All authors had full access to the study data and had final responsibility for the decision to submit for publication.

Competing interests None declared.

Patient and public involvement Patients and/or the public were not involved in the design, or conduct, or reporting, or dissemination plans of this research.

Patient consent for publication Not required.

Provenance and peer review Not commissioned; externally peer reviewed.

Data availability statement No data are available.
