Photocatalytic CO₂ Reductions Catalyzed by *meso*-(1,10-Phenanthroline-2-yl)-Porphyrins Having a Rhenium(I) Tricarbonyl ComplexYusuke Kuramochi*^[a, b] and Akiharu Satake*^[a, b]

Abstract: We have prepared Zn and free-base porphyrins appended with a *fac*-Re(phen)(CO)₃Br (where phen is 1,10-phenanthroline) at the *meso* position of the porphyrin, and performed photocatalytic CO₂ reduction using porphyrin–Re dyads in the presence of either triethylamine (TEA) or 1,3-dimethyl-2-phenyl-2,3-dihydro-1*H*-benzo[*d*]imidazole (BIH) as an electron donor. The Zn porphyrin dyad showed a high turnover number for CO production compared with the free-base porphyrin dyad, suggesting that the central Zn ion of porphyrin plays an important role in suppressing electron

accumulation on the porphyrin part and achieving high durability of the photocatalytic CO₂ reduction using both TEA and BIH. The effect of acids on the CO₂ reduction was investigated using the Zn porphyrin–Re dyad and BIH. Acetic acid, a relatively strong Brønsted acid, rapidly causes the porphyrin's color to fade upon irradiation and dramatically decreases CO production, whereas proper weak Brønsted acids such as 2,2,2-trifluoroethanol and phenol enhance the CO₂ reduction.

Introduction

Artificial photosynthesis has received much attention because of its great potential for solving environmental challenges such as global warming and ocean acidification, as well as the shortage of fossil fuels. Because sunlight is mainly composed of visible light and the photon flux is low, a photosensitizer is an essential component for efficient collection of visible light in a solar energy conversion system.^[1] In natural photosynthesis, a network of chlorophylls efficiently captures even dilute photons from the sun and transfers the absorbed solar energy to produce energy-rich compounds.^[2] As synthetic chlorophyll analogues, porphyrin derivatives have been actively studied to elucidate the high efficiency of energy and electron transfer processes in photosynthetic systems^[3,4] and have been used as photosensitizers in photoredox reactions^[5–9] be-

cause of their absorption bands in the visible region [e.g., $\epsilon_{423\text{nm}} \approx 540\,000\text{ M}^{-1}\text{ cm}^{-1}$ for zinc tetraphenylporphyrin (ZnTPP)].^[10]

Dyads combining porphyrin and the Re diimine tricarbonyl complex have been developed for photocatalytic CO₂ reduction.^[11–15] Inoue and co-workers reported that the photocatalytic CO₂ reduction using a dyad, in which a Zn porphyrin and a Re(bpy)(CO)₃Br (where bpy is 2,2'-bipyridine) complex were connected via an amide-bridged linker, gave CO in the presence of triethylamine (TEA) as an electron donor. The reaction quantum yield (Φ_{CO}) strongly depended on the excitation wavelength, showing 10% and 0.64% on exciting at 364 and 428 nm, respectively.^[11] Perutz and co-workers reported that a saturated methylene spacer in the amide-bridge linker of the dyad significantly improved the CO production to reach a turnover number (TON_{CO}) of 260 by irradiation at $\lambda > 520\text{ nm}$ in the presence of triethanolamine (TEOA) as the electron donor.^[12a] Tschierlei, Schwalbe, and co-workers reported that the dyad, in which a Zn porphyrin and a Re(bpy)(CO)₃Cl were linked via a π -conjugated moiety, gave CO with a TON_{CO} value of 13 using 5 vol% TEA as the electron donor by irradiation at $\lambda > 375\text{ nm}$.^[13a] The dyads using Fe, Co, Cu, and Pd porphyrin instead of Zn porphyrin did not show catalytic activity for the CO₂ reduction. Moore, Schwalbe, and co-workers reported that the rigid xanthene-bridged dyad of a Zn porphyrin and a Re(bpy)(CO)₃Cl showed a TON_{CO} of 5.7 or 195 using either 5 vol% TEA or a mixture of 20 vol% TEOA and 1,3-dimethyl-2-phenyl-2,3-dihydro-1*H*-benzo[*d*]imidazole (BIH) by irradiation at $\lambda > 450\text{ nm}$. The dyad of a free-base porphyrin instead of the Zn porphyrin showed no activity for a photocatalytic CO₂ reduction using 5 vol% TEA.^[13b] Tamiaki and co-workers reported that irradiation at $\lambda > 540\text{ nm}$ of a dyad composed of a chloro-

phyll and a $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ complex, gave CO with a TON_{CO} of 18 using a mixture of 17 vol% TEOA and 0.1 M BIH.^[14]

We have recently reported that the dyad of a Zn porphyrin and $\text{Re}(\text{phen})(\text{CO})_3\text{Br}$ (where phen is 1,10-phenanthroline), in which the Re complex is directly connected at the 2-position of the phen moiety to a *meso*-position of the porphyrin, named as **ZnP-phen=Re** (Scheme 1), showed a TON_{CO} larger than 1300 by irradiation at $\lambda = 420$ nm using BIH as an electron donor^[13b,15–17] and phenol (PhOH) as a proton source.^[15] However, in the previous work, only photocatalytic CO_2 reduction using BIH as the electron donor, PhOH as the proton source, and the dyad in which the porphyrin center was a Zn ion, was investigated, and other applicable ranges and conditions were not examined. In the current work, we report three main experiments that supplement our earlier study. First, to investigate the role of the central Zn ion of the porphyrin in the photocatalytic CO_2 reduction, we prepared a dyad consisting of a free-base porphyrin and a *fac*- $\text{Re}(\text{phen})(\text{CO})_3\text{Br}$, named as **H₂P-phen=Re** (Scheme 1), and compared its catalytic activity with that of **ZnP-phen=Re**. Second, to check whether the photocatalytic reaction proceeds with an electron donor other than BIH, we performed photocatalytic CO_2 reduction using TEA as the electron donor, which has been more often used in the porphyrin=Re complex dyad systems. Third, we investigated the effect of proton sources (Brønsted acids) and metal cations in the photocatalytic CO_2 reduction using the system of **ZnP-phen=Re** and BIH.

Scheme 1. Synthetic routes to **ZnP-phen=Re** and **H₂P-phen=Re**.

Results and Discussion

Syntheses and structures of the dyads

The synthetic procedures are shown in Scheme 1. The dyads, **ZnP-phen=Re** and **H₂P-phen=Re**, were synthesized by the reactions of the corresponding porphyrins^[15] with 1 equiv of $\text{Re}(\text{CO})_5\text{Br}$, respectively. Use of an excess amount (4 equiv) of $\text{Re}(\text{CO})_5\text{Br}$ caused a low yield (<10%) of the target dyad accompanied with unidentified species that were decomposed in silica-gel column chromatography. The crude products obtained by the reactions with 1 equiv of $\text{Re}(\text{CO})_5\text{Br}$ were recrystallized from CHCl_3 /ethanol/hexane to afford the pure dyads,

ZnP-phen=Re and **H₂P-phen=Re**, each of which shows a single spot on silica-gel thin layer chromatography (TLC). The chemical compositions of the dyads were identified by elemental analysis.

¹H NMR spectra of the purified **ZnP-phen=Re** and **H₂P-phen=Re** in CDCl_3 are shown in Figure 1. The signals were assigned with a combination of a 2D NMR (¹H-¹H correlation spectroscopy (COSY); Figures S3 and S8 in Supporting Information). The spectrum of **H₂P-phen=Re** shows an inner NH proton signal at -2.51 ppm, which is a characteristic signal for free-base porphyrin. Both spectra of **ZnP-phen=Re** and **H₂P-phen=Re** show that one β proton appears at the higher magnetic field, 8.4 and 8.2 ppm, compared with the other seven β protons for **ZnP-phen=Re** and **H₂P-phen=Re**, respectively. In addition, six doublet ($J=8$ Hz) signals are observed on the *ortho* protons of the phenylene groups. The above observations indicate that both **ZnP-phen=Re** and **H₂P-phen=Re** have A- and A'-type structures in Figure S9; that is, facial structures. Judging from the facts that the anisotropic magnetic field of the carbonyl group shifts the β_3 proton to the low magnetic field and the β_2 proton to the high magnetic field (Figure S10, top view) and from the correlations in the ¹H-¹H COSY, the β protons shifting to higher magnetic fields at 8.4 and 8.2 ppm were assigned to be β_7 protons. The characteristic β_7 protons are magnetically shielded by the nearby Br atom. The formation of the A- and A'-type isomers (Figure S9) is supported by three signals of CO carbons at different positions on the ¹³C NMR spectra (Figure S5) and the pattern of the CO stretching bands on the infrared (IR) spectra (Figure S11).^[15] The free energies of formation of the Zn porphyrin isomers were estimated with density functional theory (DFT) calculations, and showed that the A-type isomers were more stable than the B- and C- type isomers that have *trans*(CO) structures (Figure S12).

Figure 1 shows the broadened peaks (half maximum of the peak: 5–7 Hz) of the phenylene protons at 8.0–8.3 ppm in **H₂P-phen=Re** compared with the other β and phen peaks (1–3 Hz), whereas all the peaks including the phenylene protons have similar widths of 2–3 Hz in **ZnP-phen=Re**. The conformational flexibility of the porphyrin skeleton is known to depend on the atom(s) coordinated to the central core and increases according to the following order in solution: $\text{Zn}^{\text{II}} < \text{Pd}^{\text{II}}$ and $\text{Cu}^{\text{II}} < \text{free base} < \text{Ni}^{\text{II}}$.^[18] This order is consistent with the degree of distortion of the porphyrin skeleton from planarity in the crystal structures.^[18] Thus, it is thought that the broad peaks observed for the phenylene protons in **H₂P-phen=Re** originate from the flexibility of the free-base porphyrin.

H₂P-phen=Re complexes sometimes show low reproducibility in the ¹H NMR signals even when samples showing a single spot at the same position on the silica-gel TLC are used (Figure S7). We encountered poor reproducibility even using the same sample. Judging from the peak shapes of phen and β -pyrrole, aggregations seem to be ruled out. The ¹H NMR signals of **ZnP-phen** and **ZnP-phen=Re** in CDCl_3 were significantly affected by the presence of $[\text{D}_4]\text{MeOH}$ (Figures S1 and S2), and a small amount of ethanol was observed at about 1.2

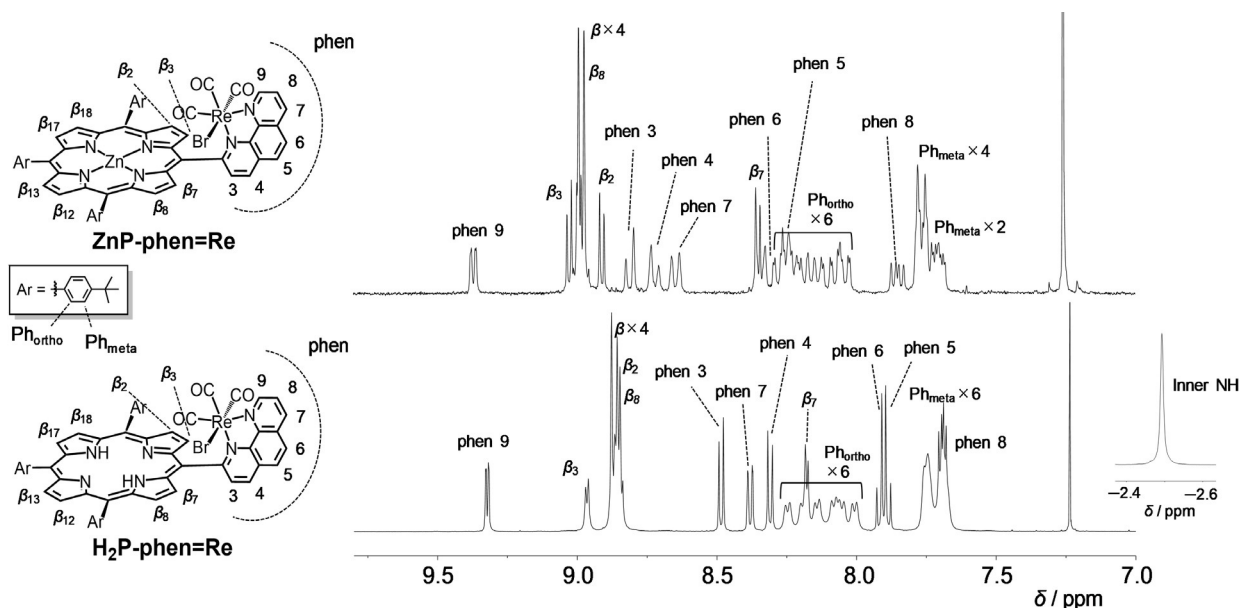

Figure 1. ^1H NMR spectra of ZnP-phen=Re (top, 300 MHz) and $\text{H}_2\text{P-phen=Re}$ (bottom, 500 MHz) in CDCl_3 . The top Figure corresponds to Figure S7 in ref. [15].

and 3.7 ppm in the ^1H NMR spectra of $\text{H}_2\text{P-phen=Re}$ (Figure S7a and b, insets).^[19] Thus, a trace amount of ethanol, which was used as a solvent for recrystallization and was included as a stabilizer in the chloroform used for sample transfer, might be the cause of the low reproducibility in the ^1H NMR spectrum.

Photophysical and electrochemical properties

The ultraviolet–visible (UV/Vis) absorption spectra of the porphyrins were measured in *N,N*-dimethylacetamide (DMA), which is a suitable solvent for photocatalytic CO_2 reduction using the Re complex.^[20] DMA is known to act as an axial ligand for Zn porphyrin and causes a red shift in UV/Vis absorption spectra.^[21] The absorption spectrum of ZnP-phen in

DMA was red-shifted compared with that in CHCl_3 (Figure S13), indicating that DMA coordinates the Zn porphyrins not only in ZnP-phen , but also in ZnP-phen=Re . Porphyrin has intense absorption bands in the visible region. The absorption coefficients of the Soret bands for ZnP-phen and ZnP-phen=Re ($\epsilon > 200\,000\ \text{M}^{-1}\ \text{cm}^{-1}$) are larger by a factor of more than 10 than that of a Ru^{II} tris-diimine complex, $[\text{Ru}(\text{dmb})_3]^{2+}$ ($\text{dmb} = 4,4'$ -dimethyl-2,2'-bipyridine; Figure 2a), which is widely used as a photosensitizer in many photocatalytic reactions including CO_2 reduction.^[17,22] In addition, the porphyrins have relatively intense absorption peaks of the Q-bands at more than 540 nm ($\epsilon > 15\,000\ \text{M}^{-1}\ \text{cm}^{-1}$), where the Ru tris-diimine complexes have almost no absorption bands. The Soret band of ZnP-phen=Re is significantly broader than that of ZnP-phen , indicating strong electronic interaction between the Zn porphyrin

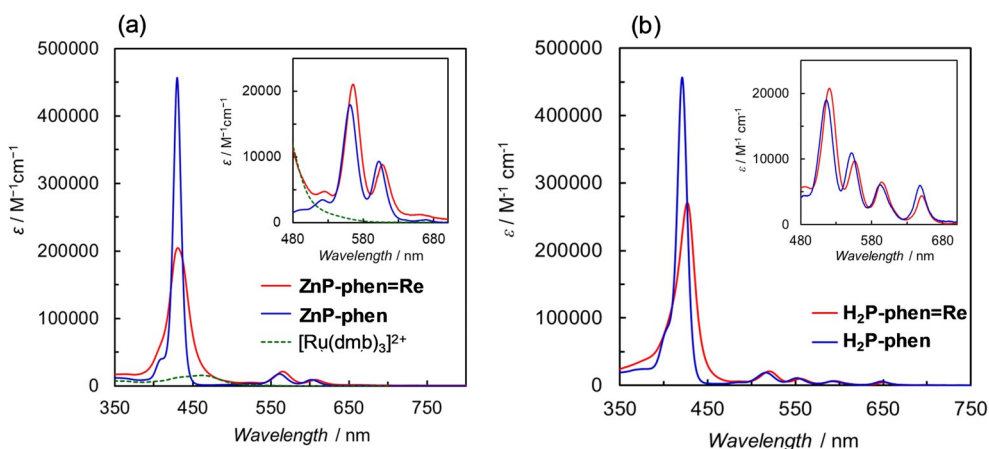

Figure 2. UV/Vis absorption spectra of (a) ZnP-phen , ZnP-phen=Re and $[\text{Ru}(\text{dmb})_3]^{2+}$ ($\text{dmb} = 4,4'$ -dimethyl-2,2'-bipyridine), and (b) $\text{H}_2\text{P-phen}$ and $\text{H}_2\text{P-phen=Re}$ in DMA. The insets show the magnifications of the Q-band region. The spectra of ZnP-phen and ZnP-phen=Re correspond to Figure 2 in ref. [15].

and the Re complex.^[15] $\text{H}_2\text{P-phen}=\text{Re}$ also shows a broader Soret band than that of $\text{H}_2\text{P-phen}$ (Figure 2b). In general, monomeric Zn and free-base *meso*-tetraarylporphyrins have no strong absorption band between 450 and 500 nm. However, the dyads of $\text{ZnP-phen}=\text{Re}$ and $\text{H}_2\text{P-phen}=\text{Re}$ have sufficient absorption by broadening the Soret bands, giving the potential to use a much wider wavelength range of visible light (450–500 nm) for photocatalytic reactions.

The redox potentials of the dyads and the corresponding parts in Ar-saturated DMA were obtained with cyclic voltammetry (CV, Figure 3) and differential pulse voltammetry (DPV, Figure S15). The anodic signals of $\text{H}_2\text{P-phen}$ and ZnP-phen appeared at -1.2 and -1.4 V, respectively, on the reversed scans after sweeping more negative potentials, indicating that the C=C bond hydrogenated species were formed by two-electron reduction.^[23] By contrast, the anodic become reversible on sweeping right after the first reduction waves, indicating that the one-electron reduced species of the porphyrins are stable in DMA. The first reduction potential of $\text{ZnP-phen}=\text{Re}$ appeared at -1.71 V, which is almost the same with that of *fac*- $\text{Re(phen)(CO)}_3\text{Br}$ (-1.72 V), indicating that the one-electron species localizes the electron on the Re part. By contrast, the first reduction signal of $\text{H}_2\text{P-phen}=\text{Re}$ appeared at -1.48 V, similar to that of $\text{H}_2\text{P-phen}$ (-1.52 V), indicating that the one-electron species localizes the electron on the porphyrin part. The reduction potentials evaluated from the electrochemical measurements correlated with the lowest unoccupied molecular orbital (LUMO) levels estimated from the DFT calculations; in particular, between $\text{ZnP-phen}=\text{Re}$ coordinated by DMA and $\text{H}_2\text{P-phen}=\text{Re}$ (Figure 4). In $\text{ZnP-phen}=\text{Re}$ (Figure 4, left and center), the highest occupied molecular orbital (HOMO)

level was significantly increased by the DMA coordination (180 mV), but the LUMO level was only slightly increased (50 mV). This reflects that the LUMO mainly distributes not on the porphyrin, but on the Re part in $\text{ZnP-phen}=\text{Re}$.

The first reduction signals of $\text{ZnP-phen}=\text{Re}$ and $\text{H}_2\text{P-phen}=\text{Re}$ appeared at similar potentials to those of *fac*- $\text{Re(phen)(CO)}_3\text{Br}$ and $\text{H}_2\text{P-phen}$, respectively. By contrast, the second signals were shifted to the negative side by more than 100 mV compared with the mononuclear units, indicating that there are strong electronic interactions between the porphyrin and the Re complex parts in the dyads.

The fluorescence of ZnP-phen and $\text{H}_2\text{P-phen}$ was almost completely quenched by introducing the Re complex parts in DMA (Figure S16). It has been reported that the fluorescence quenching in $\text{ZnP-phen}=\text{Re}$ originates not from the intramolecular electron transfer from the Zn porphyrin part to the Re part, but from spin-orbit coupling imposed by the large Re atom to induce a rapid intersystem crossing (ISC) on the porphyrin.^[15] The fluorescence quenching in $\text{H}_2\text{P-phen}=\text{Re}$ also comes from the rapid ISC induced by the Re atom, because the intramolecular electron transfer from the free-base porphyrin part to the Re part is a very endothermic reaction (Figure S17). $\text{ZnP-phen}=\text{Re}$ showed phosphorescence from Zn porphyrin in Ar-saturated DMA even at room temperature because of the rapid ISC caused by the large Re atom.^[15] However, we could not observe phosphorescence of $\text{H}_2\text{P-phen}=\text{Re}$ under the same conditions. Quimby and Longo reported that no phosphorescence of free-base TPP could be unambiguously detected in methylcyclohexane-isopentane glass even at 77 K, and estimated that the phosphorescent quantum yield of free-base TPP is less than 1/100 that of ZnTPP.^[10b] Thus, no detectable phosphorescence of $\text{H}_2\text{P-phen}=\text{Re}$ could originate from the much lower phosphorescent ability of the free-base porphyrin.

Figure 3. CVs of the dyads, porphyrins and *fac*- $\text{Re(phen)(CO)}_3\text{Br}$ (0.5 mM) in Ar-saturated DMA with 0.1 M $n\text{Bu}_4\text{NPF}_6$ as a supporting electrolyte. Scan rate = 100 mVs^{-1} .

Photocatalytic CO_2 reductions using TEA as the electron donor

TEA is a weaker reductant and is more often used as an electron donor than BIH in porphyrin–Re complex dyad systems.^[11–13] Photocatalytic CO_2 reductions were performed using TEA as the electron donor and either $\text{ZnP-phen}=\text{Re}$ or $\text{H}_2\text{P-phen}=\text{Re}$ as a photocatalyst. In addition, as a control experiment, the reaction using a mixed system of ZnTPP and *fac*- $\text{Re(phen)(CO)}_3\text{Br}$ was also conducted. The photocatalytic CO_2 reduction using the dyads gave CO selectively and the time profiles of the CO production under irradiation at 420 nm are shown in Figure 5a. Irradiation under Ar atmosphere instead of CO_2 gave only H_2 without formation of CO. The TON_{CO} for $\text{ZnP-phen}=\text{Re}$ reached a value of 23 after 60 h and the CO production still continued even after 60 h. The value of $\text{TON}_{\text{CO}} > 25$ was the highest in the reported dyads composed of a porphyrin and a Re complex in close proximity.^[13]

$\text{ZnP-phen}=\text{Re}$ has a broadened Soret band compared with the Zn porphyrins without the Re unit. The selected wavelength of 450 nm in Figure 5b is generally the foot of the Soret band of monomeric Zn porphyrin but the photocatalytic

Figure 4. Energy level diagrams and frontier orbitals of **ZnP-phen=Re** without (left) and with (center) the axial-coordinated DMA and **H₂P-phen=Re** (right). The structures are optimized at the B3LYP/LANL2DZ/6-31G(d) level using PCM with the default parameter for DMA (isovalue = 0.02).

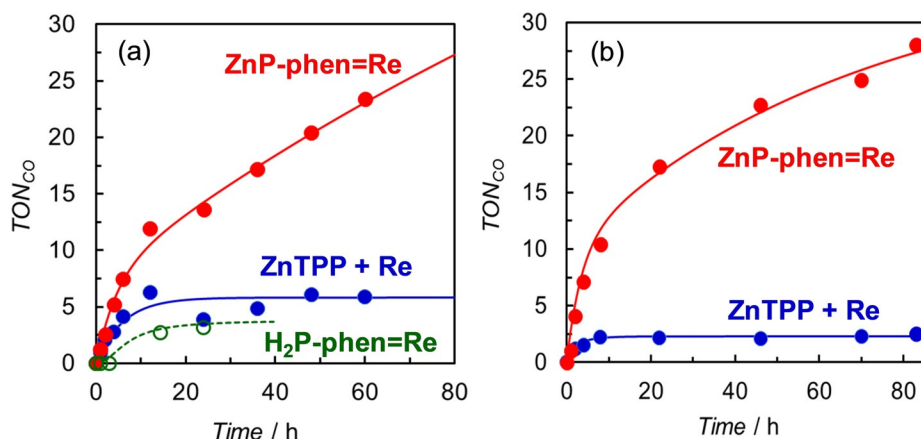

Figure 5. Time dependences of CO formation during irradiation of 2.0 mL of CO₂-saturated DMA solutions containing 5 vol% TEA in the presence of **ZnP-phen=Re** (0.05 mM), **H₂P-phen=Re** (0.05 mM) or a mixed system of ZnTPP (0.05 mM) and *fac*-Re(phen)(CO)₃Br (0.05 mM); irradiation was performed at (a) 420 nm (30 mW) and (b) 450 nm (40 mW).

reaction of **ZnP-phen=Re** proceeds efficiently. Contrary to the behavior of a monomeric Zn porphyrin such as ZnTPP, in **ZnP-phen=Re** there is high absorbance even at 450 nm because of the broad Soret band caused by the strong electronic interaction between the porphyrin and the Re complex. Based on their power (30 and 40 mW), the photon number of the 450 nm lamp was estimated to be about 1.4 times that of the 420 nm lamp, and the initial reaction rate of **ZnP-phen=Re** in Figure 5a (5.2 for 4 h) is approximately 1.4 times that in Figure 5b (7.1 for 4 h). Thus, **ZnP-phen=Re** could efficiently use all the irradiated photons with the wavelength where mono-

meric Zn *meso*-tetraarylporphyrins do not have enough absorption.

In contrast to **ZnP-phen=Re**, the CO productions for **H₂P-phen=Re** and the mixed system stop by 10 h and the TON_{CO} values are low. The colors of solutions of both **H₂P-phen=Re** and the mixed system changed into pale-yellow by 10 h. The rapid color fading is due to hydrogenation of more than two pyrrole C=C bonds of the porphyrin. The complete bleaching of porphyrin absorption by hydrogenation has been observed in the photocatalytic CO₂ reduction using the amide-bridged dyads.^[12] By contrast, the solution color of **ZnP-phen=Re**

gradually changed from dark-green to green during the irradiation, but the green color was maintained even after 10 h. The UV/Vis absorption spectral change of **ZnP-phen=Re** during the irradiation showed a decrease of the Q-band of the Zn porphyrin at 565 nm and appearance of a new peak at 629 nm with an isosbestic point (Figure S18). The new peak was assigned to the Zn chlorin formed by hydrogenation of only one pyrrole C=C bond of the porphyrin.^[12] The Zn chlorin of the dyad was not hydrogenated further and acted as the photosensitizer after 10 h irradiation (Figure 5), whereas **H₂P-phen=Re** and the mixed system lose the photocatalytic ability upon further hydrogenation.

Photocatalytic CO₂ reductions using BIH as the electron donor

Figure 6 shows the time profiles of the CO production in the photocatalytic CO₂ reductions using BIH as the electron donor. In all the reactions using the dyads, only CO was observed as a reduction product of CO₂ in both without and with PhOH. Control experiments for the dyad systems showed no detectable CO in the absence of any one of the components, the Re catalyst, light or CO₂. A trace amount of CO was observed by using *fac*-Re(phen)(CO)₃Br in the absence of porphyrin (TON_{CO} = ca. 2 after 24 h). The values of TON_{CO} in the photocatalytic CO₂ reduction using the dyads reached values more than an order of magnitude larger than with TEA as the electron donor.

In the absence of PhOH, the TON_{CO} for **ZnP-phen=Re** reaches a value of more than 500 (blue open circles), while the mixed system of ZnTPP and *fac*-Re(phen)(CO)₃Br hardly gave CO (TON_{CO} ≈ 6, green open squares) because ZnTPP in the mixed system was rapidly bleached during irradiation at 420 nm.^[15] The CV graphs showed that the two-electron-reduced porphyrin species readily caused hydrogenation of the porphyrin skeleton to form chlorin or phlorin,^[12,23] whereas the one-electron-reduced species of Zn porphyrin was stable in *N,N*-dimethylacetamide (Figure 3). Thus, a higher durability in

ZnP-phen=Re would result from suppression of more than two-electron accumulation on the porphyrin part. As indeed, the photocatalytic CO₂ reduction upon irradiation at 560 nm, whose photoinduced electron transfer was slower than that upon irradiation at 420 nm due to the low absorption cross section of Zn porphyrin at 560 nm, gave a linear increase of CO production until all BIH in the system was consumed even in the absence of PhOH (Figure S19).

In our previous report, it was shown that the phosphorescence from the Zn porphyrin in **ZnP-phen=Re** is efficiently quenched by BIH under Ar atmosphere, indicating that the photoinduced electron transfer from BIH to the excited porphyrin in **ZnP-phen=Re** occurs via the excited triplet state (T₁) (Scheme 2).^[15] The long-lived excited state of T₁ allows an efficient electron transfer with a high Stern–Volmer constant $K_{SV} = 180\,000\text{ M}^{-1}$ in the bimolecular reaction between **ZnP-phen=Re** and BIH. The reduction in the excited Zn porphyrin part by BIH is followed by the intramolecular electron transfer from the reduced Zn porphyrin to the Re complex. In the initial stage, the reduction of the Re tricarbonyl Br complex induces dissociation of the Br ligand, an event that starts the catalytic CO₂ reduction.^[17] The photocatalytic CO₂ reduction using **ZnP-phen=Re** does not show an induction period for the CO production (Figure 6b), indicating that an efficient electron transfer to the Re tricarbonyl Br complex occurs. By contrast, the catalysis using **H₂P-phen=Re** in the absence of PhOH gave an induction period, indicating that intramolecular electron transfer from the reduced free-base porphyrin to the Re tricarbonyl Br complex is inefficient. The inefficient electron transfer would cause electron accumulation on the porphyrin part, resulting in a low TON_{CO} for **H₂P-phen=Re**. This is supported by the lower LUMO of the free-base porphyrin than of the Zn porphyrin (Figure 4) and the energy diagram in which the electron transfer from the one-electron reduced free-base porphyrin to the Re part is thermodynamically unfavorable (Figure S20).

The addition of PhOH, which is a proton source that can promote the reaction with CO₂ on the Re complex,^[24,25] improves not only the reaction rate, but also the durability of the

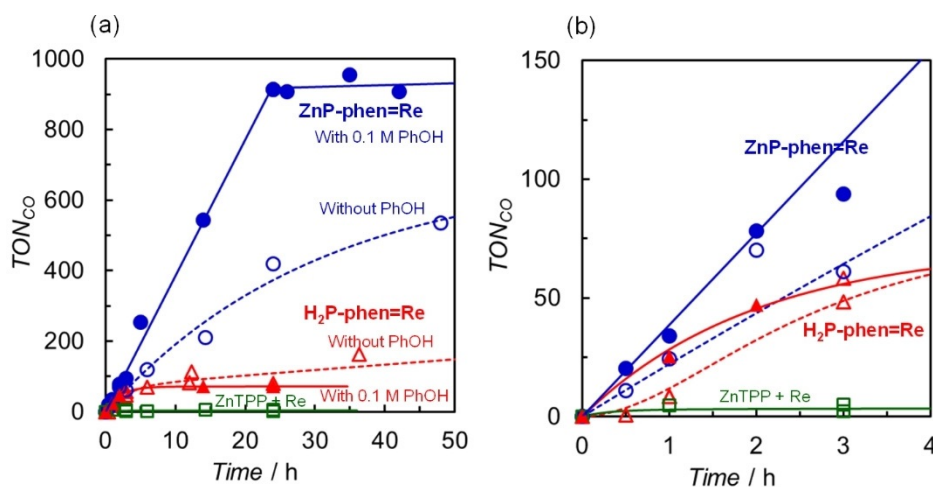

Figure 6. Time dependences of CO formation during irradiation at 420 nm in 2.0 mL of CO₂-saturated DMA solutions containing 0.05 mM BIH in the presence of 0.05 mM **ZnP-phen=Re** and 0.05 mM **H₂P-phen=Re**, with 0.1 M PhOH (filled) and without PhOH (open), and a mixed system of 0.05 mM ZnTPP and 0.05 mM *fac*-Re(phen)(CO)₃Br without PhOH; (a) 0–50 h and (b) 0–4 h. The plots for **ZnP-phen=Re** and the mixed system correspond to Figure 3 in ref. [15].

Scheme 2. A plausible reaction mechanism in **MP-phen=Re** ($M = \text{Zn}, 2\text{H}$).^[15,24]

photocatalytic CO_2 reduction in **ZnP-phen=Re** (Figure 6a). The CO production linearly increased to a TON_{CO} value of about 1000, where all BIH was consumed. The addition of PhOH (H^+) promotes CO_2 conversion into CO on the Re complex, suppressing electron accumulation of **ZnP-phen=Re** (Scheme 2). The efficient electron transfer from BIH to the long-lived T_1 of the Zn porphyrin provided a high reaction quantum yield for the CO production reaching 8% upon both excitations to the S_2 ($\lambda_{\text{ex}} = 420 \text{ nm}$) and the S_1 ($\lambda_{\text{ex}} = 560 \text{ nm}$).^[15] The reaction quantum yield was almost independent of BIH concentration ($> 10 \text{ mM}$, Figure S21). While the addition of PhOH did not contribute to improvement in the durability in **H₂P-phen=Re**, the initial rate of CO production was enhanced (Figure 6b). The initial rate ($< 1 \text{ h}$) of **H₂P-phen=Re** in the presence of PhOH is comparable to that of **ZnP-phen=Re**. Considering that the quenching of the excited singlet state (S_1) of free-base porphyrin of **H₂P-phen** by BIH was not efficient ($\eta_{\text{q}} = 0.69$ using $[\text{BIH}] = 0.05 \text{ M}$ and $K_{\text{SV}} = 44 \text{ M}^{-1}$ in Figure S22) and the fluorescence of **H₂P-phen=Re** was almost completely quenched, the photoinduced electron transfer from BIH to **H₂P-phen=Re** would also occur via the T_1 of the free-base porphyrin.

As described above, a proton source can enhance the photocatalytic CO_2 reduction using **ZnP-phen=Re**. The effects of several proton sources (Brønsted acids) having different acidities and of metal cations were examined.^[26] Water ($\text{p}K_{\text{a(DMSO)}} = 31.4$ in DMSO), methanol (MeOH, $\text{p}K_{\text{a(DMSO)}} = 29.0$ in DMSO), 2,2,2-trifluoroethanol (TFE, $\text{p}K_{\text{a(DMSO)}} = 23.5$ in DMSO), PhOH ($\text{p}K_{\text{a(DMSO)}} = 18.0$ in DMSO), and acetic acid (AcOH, $\text{p}K_{\text{a(DMSO)}} = 12.3$ in DMSO) were selected as the Brønsted acids.^[27] $\text{Mg}(\text{OTf})_2$ and $\text{Ce}(\text{OTf})_3$ were selected as the metal cations. Figure 7a shows the effects of various acids on the turnover frequencies of CO and H_2 up to 2 h. The time dependence of CO formation

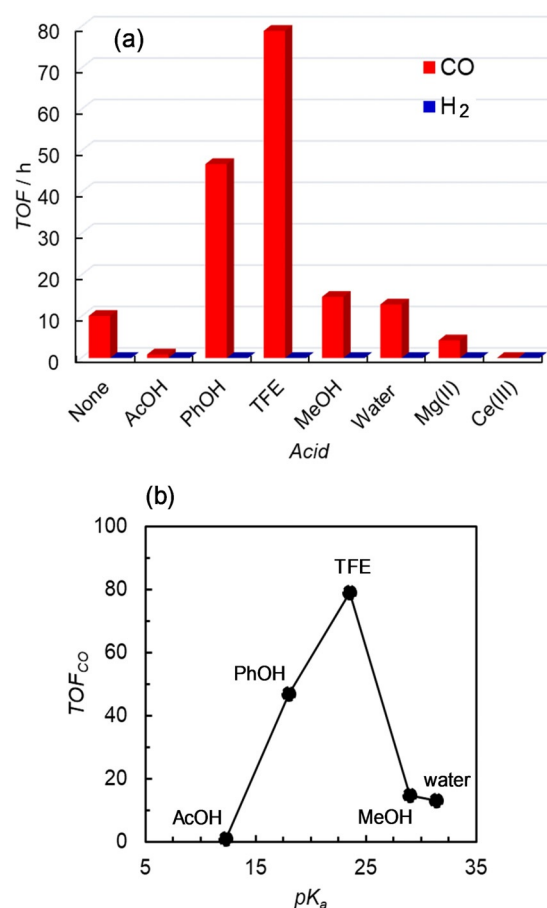

Figure 7. (a) Turnover frequencies (TOFs) of CO and H_2 during the irradiation at 420 nm up to 2 h in CO_2 -saturated DMA solutions containing 0.05 M BIH and 0.05 mM **ZnP-phen=Re** in the presence of acids (0.1 M). (b) $\text{p}K_{\text{a}}$ -dependence of the TOF of CO of the photocatalytic CO_2 reduction in the presence of Brønsted acids. The $\text{p}K_{\text{a}}$ used were the values in DMSO.^[27]

up to 15 h in the presence of the acids is shown in Figure S23. The TON_{CO} at 15 h is larger for TFE than PhOH, while the linearity of the CO production is better for PhOH than TFE. No formation of H_2 was observed even in the presence of AcOH, which induced H_2 production in the electrochemical CO_2 reduction using the Re-bpy complex.^[24] The addition of AcOH gives a colorless clear solution rapidly (2 h), indicating that the formation of the Re hydride complex induces the hydrogenation of the porphyrin skeleton instead of hydrogen production. MeOH and water show slight increases in CO production, whereas TFE and PhOH significantly enhanced the catalysis. In contrast, addition of the metal cations suppressed the CO formation. In particular, a trivalent cation, Ce^{3+} , completely deactivated the photocatalysis to produce no reduction products. It is speculated that the adduct of Ce^{3+} with the Re- CO_2 species is too stable, suppressing the formation of the Re-CO species. The plots of turnover frequencies for the CO production against $\text{p}K_{\text{a(DMSO)}}$ are shown in Figure 7b, indicating that the proper acidity is important for increasing the CO production in the photocatalytic CO_2 reduction. The trend of the initial reaction rates (TFE > PhOH > $\text{H}_2\text{O} \approx \text{MeOH}$) is in agreement with the trend of the simulated reaction rates in the electrochemical CO_2 reduction using the Re-bpy complex reported by Carter et al. (Figure 4 in ref. [28]).

Ishitani and co-workers reported that TEOA plays an important role not only in promoting the deprotonation of the oxidized BIH to suppress the back-electron transfer from the one-electron reduced photosensitizer to the oxidized BIH, but also in trapping CO_2 by forming the $\text{Re}(\text{bpy})(\text{CO})_3(\text{CO}_2\text{-TEOA})$ species.^[17,29] The effects of amines (TEOA and TEA) on the photocatalytic CO_2 reduction system were examined here using **ZnP-phen=Re** and BIH (Figure S24). The time-course dependences for CO formation did not show improvement in the catalysis by the addition of amine, suggesting that neither the deprotonation of the oxidized BIH nor the CO_2 trapping would be the rate-determining step in the reaction conditions.

Conclusions

We have previously reported that **ZnP-phen=Re** acts as a good photocatalyst in the photocatalytic CO_2 reduction using BIH as the electron donor. In this work, we demonstrated that **ZnP-phen=Re** also acted as a good photocatalyst even when TEA, a weaker electron donor, was used. The photocatalytic CO_2 reaction selectively gave CO as the product whose TON_{CO} reaches at least 25 and still continued CO production after irradiation for 60 h. To investigate the effect of the central Zn ion of porphyrin in the catalysis, a dyad composed of free-base porphyrin and *fac*-Re(phen)(CO)₃Br, **H₂P-phen=Re**, was synthesized. The durability of **H₂P-phen=Re** was lower than that of **ZnP-phen=Re**, reflecting ease of decomposition of the porphyrin skeleton by hydrogenation of the C=C bonds. The ease of decomposition is explained by the energy diagram (Figure S20), in which the electron-transfer process from the one-electron reduced porphyrin to the Re part is thermodynamically unfavorable for **H₂P-phen=Re**. Thus, the relationship of the redox potentials between the porphyrin and Re parts is impor-

tant for developing a highly durable catalyst. The effect of acid on the reaction using **ZnP-phen=Re** and BIH was investigated. PhOH and TFE enhanced the CO, but the stronger AcOH acid and a trivalent metal cation almost completely deactivated the catalysis.

Acknowledgements

This work was supported by ENEOS Hydrogen Trust Fund. We thank Prof. Akihiko Kudo (Tokyo University of Science) for help with capillary electrophoresis analyses.
