

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Research paper

Impact of the coronavirus disease 2019 pandemic on critical care healthcare workers' depression, anxiety, and stress levels

ABSTRACT

Aim: The aim of the study was to determine levels of depression, anxiety, and stress symptoms and factors associated with psychological burden amongst critical care healthcare workers in the early stages of the coronavirus disease 2019 pandemic.

Methods: An anonymous Web-based survey distributed in April 2020. All healthcare workers employed in a critical care setting were eligible to participate. Invitations to the survey were distributed through Australian and New Zealand critical care societies and social media platforms. The primary outcome was the proportion of healthcare workers who reported moderate to extremely severe scores on the Depression, Anxiety, and Stress Scale-21 (DASS-21).

Results: Of the 3770 complete responses, 3039 (80.6%) were from Australia. A total of 2871 respondents (76.2%) were women; the median age was 41 years. Nurses made up 2269 (60.2%) of respondents, with most (2029 [53.8%]) working in intensive care units. Overall, 813 (21.6%) respondents reported moderate to extremely severe depression, 1078 (28.6%) reported moderate to extremely severe anxiety, and 1057 (28.0%) reported moderate to extremely severe stress scores. Mean \pm standard deviation values of DASS-21 depression, anxiety, and stress scores amongst woman vs men was as follows: 8.0 ± 8.2 vs 7.1 ± 8.2 ($p = 0.003$), 7.2 ± 7.5 vs 5.0 ± 6.7 ($p < 0.001$), and 14.4 ± 9.6 vs 12.5 ± 9.4 ($p < 0.001$), respectively. After adjusting for significant confounders, clinical concerns associated with higher DASS-21 scores included not being clinically prepared ($\beta = 4.2$, $p < 0.001$), an inadequate workforce ($\beta = 2.4$, $p = 0.001$), having to triage patients owing to lack of beds and/or equipment ($\beta = 2.6$, $p = 0.001$), virus transmission to friends and family ($\beta = 2.1$, $p = 0.009$), contracting coronavirus disease 2019 ($\beta = 2.8$, $p = 0.011$), being responsible for other staff members ($\beta = 3.1$, $p < 0.001$), and being asked to work in an area that was not in the respondents' expertise ($\beta = 5.7$, $p < 0.001$).

Conclusion: In this survey of critical care healthcare workers, between 22 and 29% of respondents reported moderate to extremely severe depression, anxiety, and stress symptoms, with women reporting higher scores than men. Although female gender appears to play a role, modifiable factors also contribute to psychological burden and should be studied further.

1. Introduction

Coronavirus disease 2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2, emerged in Wuhan, China, late in 2019 and rapidly spread globally, currently with more than 100 million confirmed infections and more than two million deaths (as of January 27, 2021).¹ Healthcare workers (HCWs) responding to pandemics serve the needs of the community and place themselves at risk of physical and psychological harm.^{2–4} They are directly and indirectly exposed to death, grief, injury, loss, significant stressors, lack of appropriate equipment, difficult ethical decisions, moral injury, long hours, physical hardship, extended separation from family and friends, and the risk of becoming infected themselves.² The previously reported emotional impacts of pandemics (Middle Eastern Respiratory Syndrome [MERS], severe acute respiratory syndrome [SARS], H1N1 influenza) can be significant and include feelings of fear, stigmatisation, isolation, and post-traumatic stress symptoms^{5–10} which have been reported to impact HCWs out to 2 years.¹¹

There is limited information about how to best ameliorate these emotional impacts and support the wellbeing of staff during a pandemic as most research occurs after the event. It has been suggested that the emotional response of HCWs can be influenced by the level of exposure, perceived social support, level of supervision in the disaster, and individual factors such as personal coping style, underlying psychopathology, and socio-economic factors.^{12–14} Implementing structured wellbeing programs before, during, and after a disaster can reduce negative psychological reactions and promote growth, mastery, and self-efficacy after the experience.^{15–17}

To inform guidelines for structured psychological and wellbeing supports for frontline critical care HCWs, we aimed to measure the psychological burden in the early stages of the COVID-19 pandemic using the Depression, Anxiety, and Stress Scale-21 (DASS-21) and understand the factors that are associated with higher and lower scores.

2. Methods

2.1. Study design and participants

The survey was approved as a quality assurance project and exempt from full review by Human Research Ethics Committee, Children's Health Queensland, Australia. An invitation to complete an online survey was distributed via five Australian and New Zealand critical care networks, social media, and investigator contacts with a request to forward to their respective networks. The online survey using SurveyMonkey (SurveyMonkey Inc., San Mateo, California) was open for 1 month (April 1–30, 2020). We did not capture a denominator as a snowball distribution method was used. The survey was aimed at all HCWs in critical care settings including medical, nursing, and allied health staff. This included educators, researchers, and students redeployed to work outside their normal clinical areas such as in emergency departments, intensive care, high-dependency units, anaesthetic departments, and operating

theatres. Completion of the survey was voluntary and considered implied consent from the respondents. All data collected were anonymous.

2.2. Pandemic incidence during the survey

During the survey period, the global incidence of confirmed cases of COVID-19 increased from just more than 930,000 on the 1st of April 2020 to more than 3.25 million by the 30th of April 2020. The highest burden globally was in China, Italy, the United Kingdom (UK), and the United States of America. At the time of the survey, Australia's case numbers increased from 4862 to 6766, China's case numbers increased from 82,361 to 83,596, Italy's case numbers increased from 110,574 to 205,463, the UK's case numbers increased from 29,865 to 172,481, and the United States of America's case numbers increased from 214,194 to 1.073 million between the 1st and 30th of April 2020.¹

2.3. Outcomes and data collected

The primary outcome was the proportion of critical care HCWs who reported moderate to extremely severe symptom scores on the DASS-21. Secondary outcomes were to determine the factors associated with increased or reduced DASS-21 scores. Both primary and secondary outcomes were analysed by gender to understand if any gendered impacts of the COVID-19 pandemic exist.¹⁸

The DASS-21 is an abbreviated version of the empirically developed DASS.¹⁹ It was chosen for its validity for use on multiple populations.²⁰ This validated instrument comprises three subsections of seven questions that evaluate states of depression, anxiety, and stress with an individual scale range of 0–21 and a total score range of 0–63. Respondents were asked to read each statement and rate on a scale of 0 to 3 the degree to which the statements applied to themselves over the past week, with 0 meaning did not apply, 1 meaning applied some degree or some of the time, 2 meaning applied a considerable degree or good part of the time, and 3 meaning applied very much or most of the time. These constructs are interrelated, and the combined score can be used to screen for general psychological distress.^{19,20}

For the purposes of this survey, the respondents were self-reporting the degree to which the statements applied to them during the past week. The resultant score within each subsection highlights the severity of symptoms the respondent had at the time of the survey. The DASS-21 was not being used as a diagnostic tool for depression, anxiety, and/or stress, and the reported levels within this article refer to symptom severity.

A 13-item pandemic specific questionnaire was developed by the multidisciplinary authors, with an understanding of possible concerns and wellbeing of potential respondents (Survey provided in eSupp). These items included the phase of the pandemic, prior disaster preparedness training, the main source of COVID-19 information, how much information on COVID-19 was being received, support in the workplace, main concerns about caring for patients with COVID-19, if they were expected to perform duties outside of their usual scope of practice, essential training

Data are presented as n (%) or median (interquartile range). HDU, high-dependency unit; GP, General Practice.

requirement, impact on sleep, personal growth, and commitment to working during a pandemic. Demographic items (gender, age, living arrangements, highest education level), country, workplace (area of work, role), employment status (full-time, part-time, or casual), years of clinical and critical care experience, and hospital type were also collected. One open-ended question was asked regarding what could assist the respondent's wellbeing. Owing to the numbers responding and the richness and depth of comments, these data will be reported in a separate article.

2.4. Statistical analysis

Means \pm standard deviations (SDs) were reported for continuous data, and numbers and proportions were reported for categorical data. DASS-21 scores were doubled for analysis for comparability with the full DASS scores, according to the developer's recommendations.²⁰ Scores were categorised for each metric as follows: (i) for depression: normal, scores 0–9; mild, 10–13; moderate, 14–20; severe, 21–27; and extremely severe, 28 and above; (ii) for anxiety: normal, 0–7; mild, 8–9; moderate, 10–14; severe, 15–19; and extremely severe, 20 and above; and (iii) for stress: normal, 0–14; mild, 15–18; moderate, 19–25; severe, 26–3; and extremely severe, 34 and above. The results were further dichotomised into normal/mild or moderate to extremely severe. The DASS-21 was reported as a mean \pm SD score and numbers and proportions for all respondents and by gender. DASS-21 scores were also matched to Australian population norms by age and gender using the means described by Crawford et al.²¹ to determine individual percentile ranks (interquartile range [IQR]) within the general population.

The reliability of the three scales was assessed by examination of internal consistency (Cronbach's alpha coefficient). A value of 0.75 or higher was considered indicative of good reliability.²²

To estimate the relative association between respondent and workplace characteristics and the DASS-21 score, univariate linear regression was performed and presented as a beta (β) coefficient with 95% confidence intervals (presented in the figures). These factors included gender, age, home arrangement, level of education, area of practice in the hospital (emergency, intensive care, operating theatre, or other), professional role (nursing, medical, allied health, or other), provision of care to adults and/or paediatrics, clinical experience, critical care experience, rurality of practice, current COVID status, prior disaster preparedness training, amount of information received, and amount of support received (table 2). Characteristics associated with the DASS-21 with a *p*-value <0.2 were entered into a predictive multivariable linear regression model using forward and backward elimination to achieve the optimal Akaike information criterion. The final characteristics were evaluated with the respondents' concerns to determine the impact of each concern on psychological outcomes.

All statistical analyses were conducted using R (version 4.0.2; R Foundation for Statistical Computing, Vienna, Austria). Two-tailed *P* values <0.01 were deemed significant.

3. Results

Over the month of April 2020, a total of 3992 responses were received. Of these, 222 did not complete the survey and were excluded from the analysis. (table 1 reports respondent characteristics by completions vs noncompletions.) Table 1 outlines all respondent demographics and clinical information. Of the 3770 completed surveys, 80.6% (3039) were from Australia. Most had a graduate diploma and/or certificate (1277 [33.9%]) and bachelor's degree (1232 [32.7%]). The majority were women (2871 [76.2%]), the median (IQR) age was 41 (33–50) years, 1814 (48.1%) participants lived at home with a partner and children/dependants, and 1373 (36.4%) participants lived with a partner and/or housemates. Nurses accounted for 2269 (60.2%) of the respondents. Most respondents treated adult patients (2479 [67.3%]) in tertiary hospitals (2148 [57.7%]), in intensive care units (2029 [53.8%]), and in emergency departments (1104 [29.6%]).

Responses specific to COVID-19 are shown in Table 2. Most respondents were identified as being in the prephase or early phase of the COVID-19 pandemic (3435 [91.1%]). The primary source of COVID-19 information was from local health management (1017 [28.4%]), health authorities (863 [24.1%]), and social media/websites (812 [22.6%]), with 1205 (33.6%) respondents reporting that the amount of information received was comprehensive and 1149 (32.1%) reporting that it was too much. The most common primary concern for respondents was virus transmission to family (1060 [29.6%]). Despite this concern, the respondents were strongly committed to working in the hospital during the pandemic (3137 [83.0%]) and strongly agreed they could grow professionally and personally as a result of the COVID-19 pandemic (2663 [70.6%]).

3.1. Depression, anxiety, and stress

The DASS-21 subscales had high internal consistency, with Cronbach's alpha for depression, anxiety, and stress subscales to be 0.88, 0.89, and 0.90, respectively.

Overall, the mean of each subscale was within the normal range (Table 3). Prevalence of any severity of symptoms of depression, anxiety, and stress in the sample was 33.0% (1244/3770), 36.6% (1380/3770), and 41.2% (1552/3770), respectively. The number of respondents reporting moderate to extremely severe depression symptoms was 813 (21.6%), 1078 (28.6%) reported moderate to extremely severe anxiety, and 1057 (28.0%) reported moderate to extremely severe stress. Mean \pm SD values of DASS-21 depression, anxiety, and stress scores amongst women vs men were 8.0 ± 8.2 vs 7.1 ± 8.2 ($p = 0.003$), 7.2 ± 7.5 vs 5.0 ± 6.7 ($p < 0.001$), and 14.4 ± 9.6 vs 12.5 ± 9.4 ($p < 0.001$), respectively (Table 3).

For the age- and gender-matched Australian population percentile analysis, the depression median percentile rank was 74

SD, standard deviation; DASS-21, Depression, Anxiety, and Stress Scale-21.

(IQR = 55–89), the median anxiety percentile rank was 75 (IQR = 53–92), and the median stress percentile rank was 76 (IQR = 54–91). Overall reported psychological symptoms of distress amongst respondents revealed a percentile rank of 78 (IQR = 60–92), suggesting that more than half of all respondents had similar psychological distress as the top (i.e., worst) quartile of the Australian population.

Factors that were associated with reduced DASS-21 scores and symptoms of distress on multivariable regression included male gender ($\beta = -5.4$, $p < 0.001$), older age (>65 years, $\beta = -16.5$, $p < 0.001$) compared with younger age (20–29 years), living at home with children ($\beta = -3.3$, $p = 0.003$) compared with living alone, and being an allied health professional ($\beta = -5.0$, $p = 0.003$) (Fig. 1).

Factors that increased DASS-21 scores included living in Europe or North America compared with Australia ($\beta = 6.3$, $p < 0.001$; $\beta = 8.2$, $p < 0.001$, respectively), working in anaesthetic departments/operating theatres ($\beta = 4.9$; $p = 0.001$), being in the early phase ($\beta = 3.24$, $p = 0.001$) or peak of the pandemic ($\beta = 9.2$, $p = 0.001$), receiving too much information ($\beta = 7.4$, $p < 0.001$) compared with an adequate level, and not feeling well supported in the work environment ($\beta = 21.3$, $p < 0.001$) compared with adequate support (Fig. 1).

After adjusting for significant confounders, the clinical concerns associated with higher DASS-21 scores included not being clinically

prepared ($\beta = 4.2$, $p < 0.001$), an inadequate workforce ($\beta = 2.4$; $p < 0.001$), having to triage patients owing to lack of beds and/or equipment ($\beta = 2.6$, $p < 0.001$), contracting COVID-19 ($\beta = 2.7$, $p < 0.001$), being responsible for other staff members ($\beta = 3.1$, $p < 0.001$), and being asked to work in an area that was not in the respondents' expertise ($\beta = 5.7$, $p < 0.001$) (Fig. 2).

4. Discussion

4.1. Statement of principle findings

This survey of critically care HCWs in the early phases of the COVID-19 pandemic found that between one-fifth and one-third of respondents reported moderate to extremely severe depression, anxiety, and stress symptoms, with higher mean scores reported for women than for men. Modifiable factors associated with higher DASS-21 scores including receiving too much information and not feeling well supported in the work environment. The primary concerns for respondents were work related (not being clinically prepared, having to triage patients and equipment, being responsible for other staff members, working outside their area of expertise) and virus related (being infected by the virus and the risk of transmitting the infection to family and friends).

Fig. 1. Factors associated with lower or higher DASS-21 scores. Blue represents factors that significantly reduced DASS-21 scores, whereas red represents factors that significantly increased DASS-21 scores. Grey represents factors that did not achieve statistical significance. Estimate represents change in the DASS-21 score. Significance is established at $p < 0.01$. CI, confidence interval; HDU, high-dependency unit; ICU, intensive care unit; DASS-21, Depression, Anxiety, and Stress Scale-21; COVID, coronavirus disease.

4.2. Comparison with other studies

In this study, one-fifth to one-third of the respondents reported moderate to extremely severe symptom levels of depression, anxiety, and stress. In a recent study of HCWs working in three provinces of China during the acute outbreak of COVID-19, 14.8% and

12.3% of respondents reported moderate to severe depression and anxiety, respectively.²³ Our reported numbers for moderate to severe anxiety and depression are higher (21.6% and 28.6%, respectively). This could possibly be related to the different validated instruments used to assess anxiety and depression, cultural differences, or to the type of HCW, given our sample was critical care

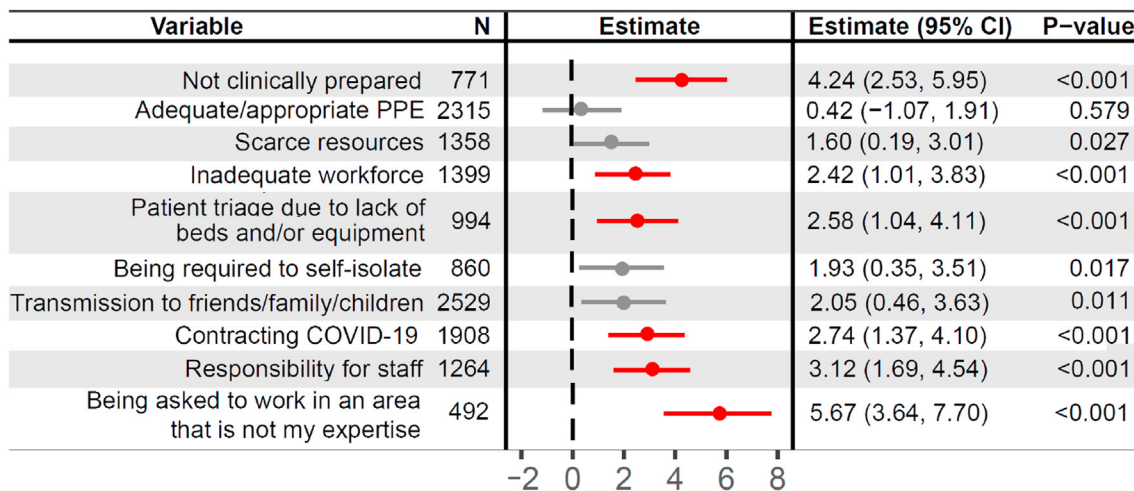

Fig. 2. Clinical concerns and association with the DASS-21 score. Clinical concerns adjusted for country, age, gender, home arrangement, location of practice, professional role, COVID status, amount of information, and support received. Red represents factors that significantly increased DASS-21 scores. Grey represents factors that did not achieve statistical significance. Estimate represents change in the DASS-21 score. Significance is established at $p < 0.01$. CI, confidence interval; N, number of respondents; DASS-21, Depression, Anxiety, and Stress Scale-21; COVID, coronavirus disease.

health professionals as opposed to HCWs working in other departments. The difference could also be attributed to this survey being conducted in April and receiving mostly Australian respondents, whereas the survey was performed in Wuhan, China, the location of the source of COVID-19, and two other Chinese provinces and was conducted in January/February. It is possible the high proportion of respondents experiencing moderate to severe physiological symptoms seen in our sample was related to anticipatory anxiety resulting from media reports, societal lockdown, reported rates of death in the public and in HCWs globally, and the speed of the spread of COVID-19 from China to other countries. The reports of overwhelmed healthcare systems, particularly intensive care units, may explain the higher levels of depression, anxiety, and stress symptoms reported in our survey than in the study conducted in China.

Lai et al.²³ also reported more adverse psychological symptoms in women than in men, and this finding concurs with our study findings. Reports from the UK²⁴ and Australia²⁵ identify that women have a higher prevalence of diagnosed mental illness than men. Our findings may be related to general population prevalence of psychological symptoms or report that women are more likely to self-report psychological problems than men. Interventions to support HCWs need to address these gender differences to ensure that all HCWs are adequately supported.

More than half of the women responding to our survey were nurses ($n = 2269$; 60.2%). In a survey of psychosocial effects of the 2003 SARS outbreak in hospital staff in Toronto, the authors found that being a nurse was significantly associated with emotional distress.²⁶ Similarly, in a study on HCWs working in an emergency department in Hong Kong during the SARS outbreak, nurses scored higher for psychological distress than other healthcare professionals.²⁷ These findings may not be isolated to working during pandemics. A small study ($n = 102$) of Australian nurses working across multiple areas measured depression, anxiety, and stress using the DASS-42, with similar scores seen in our study.²⁸ Nonetheless, the findings in our cohort are still important as nurses consistently reported higher DASS-21 scores. Concerns related to not being clinically prepared, working outside of one's area of expertise, and being responsible for other staff members were major components of pandemic surge planning.^{29,30} Nurses comprise the majority of the healthcare workforce, particularly during the management of pandemics. Managers and administrators should be cognisant that the decisions to redeploy HCWs to new areas, be responsible for junior or inexperienced staff members, or be expected to work out of their trained scope of practice may have major psychological impacts. Strategies, such as those outlined in COVID-19 guidelines,^{29,30} should be instigated to ensure HCWs are optimally prepared and supported to mitigate potential negative impacts.

4.3. Limitations

The key limitation of this survey was the convenience sampling method and uncontrolled distribution strategy; therefore, a denominator could not be captured to provide a response rate, and generalisability is limited. The rationale for using snowball sampling was to distribute the survey to as many frontline critical care workers as possible and be able to report results in a timely fashion to enable institutions and guideline developers to use the results to assist in recommendations and interventions for critical care HCWs. We recognise that without a response rate, it is difficult to determine the representativeness of the sample to critical care HCWs. Response bias is likely to be in a survey of this nature, with those experiencing no emotional distress and similarly with those experiencing high levels of emotional distress less likely to

respond. The results of higher levels of depression, anxiety, and stress may not be unexpected, given the unique global situation and the impact and exposure of media coverage of this pandemic. The methods used in this study are also a potential limitation in that we have only captured a snapshot of each respondent's experience. Repeated surveys and longitudinal and qualitative studies would enable a complete understanding of the long-term impact of the COVID-19 pandemic on critical care HCWs. The pandemic-specific questions were not tested for content validity, but the multidisciplinary authors were able to draw on their current experiences, strengthening the appropriateness of the questions. The strengths of this study include the large number of responses from the critical care community, which has enabled useful analysis and insights into the concerns, preparedness, and wellbeing of critical care HCWs globally. We used a valid and reliable instrument to determine levels of depression, anxiety, and stress among the respondents. We also prespecified a gender-disaggregated analysis, which is considered best practice,¹⁸ and in the case of our study, we highlighted the gender-associated impacts of the early phase of the pandemic on women and men working as health professionals in critical care areas.

4.4. Future direction

Further work on the potential benefits of preparing for the pandemic and external disasters and conducting wellbeing programs for HCWs, particularly women and nurses, is important. High levels of stress has been associated with poor performance, absenteeism, and burnout, which may lead to additional strain on an already stressed healthcare system during a pandemic.^{29,30} Managers and administrators should be cognisant of how they deliver information to HCWs and develop appropriate support and training, particularly for less experienced HCWs and those expected to work out of their usual scope of practice. Institutions should emphasise simulation and disaster preparedness training along with provision of equipment to simplify and enable HCWs to perform their work with as little additional stress as possible. Strategies to enhance resilience and work engagement may secure the longevity of HCWs and maintain and improve patient safety and outcomes.^{31,32}

5. Conclusion

In this survey of critical care HCWs in the early phase of the COVID-19 pandemic, between 22% and 29% of respondents reported moderate to extremely severe depression, anxiety, and stress symptoms, with women experiencing higher scores for all three subdomains than men. Modifiable factors associated with higher DASS-21 scores included receiving too much information and not feeling well supported in the work environment. The primary concerns for the respondents were related to the working environment and risk of infection to themselves or family and friends. Although female gender appears to play a role, modifiable factors also contributed to psychological burden and should be studied further.
