ABSTRACT

Objective To identify knowledge of breast cancer (BC) symptoms, time taken to consult a doctor and factors contributing to delays in medical help-seeking.

Design A cross-sectional study of Omani women diagnosed with BC.

Setting The two main teaching hospitals in Oman: Royal Hospital and Sultan Qaboos University Hospital.

Participants Adult Omani women recently diagnosed with BC.

Tools The Breast Module of the Cancer Awareness Measure and the International Cancer Benchmarking Partnership questionnaire were used to collect data.

Results A total of 300 women with BC participated (response rate: 91.0%). The mean age at diagnosis was 43.0±12.50 years and 33.5% were diagnosed at stage III or IV. Although most women (74.4%) recognised breast/armpit lumps to be a symptom of BC, less than half identified other symptoms, including breast/armpit pain (44.0%), changes in the position of the nipple (36.2%), redness (31.7%), fatigue (26.3%), weight loss (23.4%) and loss of appetite (20.8%). While most (91.6%) were aware that BC could be cured if detected early, only 66.4% sought medical help within a month of developing symptoms. Initial responses to symptoms included informing husbands (40.2%) or family members (36.5%). Barriers to seeking medical help included feeling scared (68.9%) and worried about what the doctor might find (62.8%). Highly educated women were more likely to recognise the following as BC symptoms: changes in nipple position (OR: 0.16, 95% CI 0.03 to 0.81), breast pain (OR: 0.10, 95% CI 0.01 to 0.86) and unexplained weight loss (OR: 0.18, 95% CI 0.04 to 0.88) (all $p < 0.05$).

Conclusions Although many Omani women with BC were aware of the importance of early diagnosis, most demonstrated inadequate knowledge of symptoms, did not prioritise seeking medical help and reported emotional barriers to help-seeking. More educational measures are needed to improve symptom recognition and address help-seeking barriers to minimise delays in diagnosis.

BACKGROUND

Worldwide, breast cancer (BC) accounts for 10% of all cancers diagnosed annually and approximately 15% of all cancer deaths

Strengths and limitations of this study

- This is the first study conducted in Oman to explore time taken to seek medical help and barriers to seeking medical help among women diagnosed with breast cancer (BC).
- Although women were aware of the importance of early detection of BC and that delays in seeking medical help could lead to complications, most presented at relatively advanced stages, with the cause for delay usually being due to the patients themselves.
- The initial response on first noticing possible BC symptoms was to inform husbands and family members rather than seeking medical help.
- The possibility of recall and response bias could not be ruled out due to the use of self-reported questionnaire measures for data collection.
- While the Arabic version of the final questionnaire was assessed for reliability, the validity of this measure was not determined.

among women.¹ Despite efforts to improve the early detection of BC, nearly one-third of women worldwide have either regional or distant metastasis at the time of diagnosis.² In the Gulf Cooperation Council (GCC) region, BC is the most commonly diagnosed cancer among women, accounting for 13%–35% of all cancers; moreover, approximately half of patients with BC are under 50 years of age at the time of diagnosis, with a median age of 49–52 years compared with 63 years in Western countries.³ In addition, approximately 58.0% of women in GCC countries present with advanced stages of BC at diagnosis (45% with regional metastasis and 12.8% with distant metastasis).⁴

Nonetheless, there is a high chance of a cure if BC is detected early and adequately treated; for example, women who begin

treatment within 3–5 months of developing symptoms have significantly worse survival rates compared with those who seek medical help in <3 months.^{5,6} Delays in cancer diagnosis can occur at any time between the first symptom being noticed and the start of treatment.⁷ The most common cause of delay is usually because patients do not correctly identify cancer symptoms or act on them to seek medical help.^{8,9} Low awareness of BC symptoms, lack of access to care, unavailability or non-participation in BC screening, fatalism, negative perceptions of BC and cultural beliefs are all factors which contribute to delays in seeking medical help on the part of patients.^{2,8,10–12}

The Pathways to Treatment model is a framework which defines the various temporal stages which occur between the onset of recognisable symptoms and the start of treatment and is often used to contextualise the various processes involved in symptom appraisal and help-seeking behaviours.¹³ The model is based on the notion that the process of general healthcare-seeking is complex and influenced by a mixture of physical, social and psychological factors. Key time points along the diagnostic pathway include the detection of initial bodily changes (symptoms), the perception of such changes as abnormal (symptom appraisal), the development of perceived reasons to consult with a doctor, the decision and action of consulting the doctor, and finally the diagnosis and start of the treatment.¹³

In Oman, BC is the most commonly diagnosed cancer and accounts for 12.79% of all cancers and 21.2% of cancers affecting women.¹⁴ Recently, the incidence of BC has almost doubled from 13.6 cases per 100 000 women in 1996 to 26.9 in 2015.¹⁴ Like other GCC countries, the majority of women diagnosed with BC in Oman are younger (median age: 49 years) and present at advanced stages (ie, stages III and IV), with a low 5-year survival rate (63%).¹⁵ Several factors contribute to delays in cancer diagnosis in Oman, including the lack of a national screening programme, social stigma, the influence of family, spouses and friends in treatment decision-making, and the prevalence of traditional medicine and medical tourism.^{8,16–18} Identifying specific factors which contribute to delays in BC diagnosis is crucial to help improve patient outcomes. The aim of this study was therefore to identify knowledge of BC symptoms, time taken to seek medical help and barriers to medical help-seeking among Omani women diagnosed with BC.

METHODS

Study setting

This cross-sectional study was carried out between November 2018 and April 2019 at the National Oncology Centre of the Royal Hospital (RH) and the Oncology Unit of the Sultan Qaboos University Hospital (SQUH), both of which are located in Muscat, the capital city of Oman. These hospitals represent the two primary oncology centres in Oman and provide comprehensive treatment (including surgery, chemotherapy and radiotherapy)

and palliative care to patients diagnosed with all types of cancer, including BC.¹⁹ The majority of patients diagnosed with BC at other regional hospitals of Oman are referred to either RH or SQUH for treatment.

Sample size estimation and recruitment

According to previous data from the National Cancer Registry from 1999 to 2015, the number of patients with BC in 2018 and 2019 was estimated to be 271 based on a linear prediction model.¹⁴ Thus, Omani women diagnosed with BC at RH or SQUH during the year prior to data collection were targeted for inclusion in the current study, as having been diagnosed more than a year previously could have resulted in recall bias.

A total of 330 adult Omani women aged ≥ 18 years and diagnosed with BC within the preceding year at RH or SQUH were identified from the electronic hospital systems and invited to participate in the study. The names of the patients and the date of their next visit to outpatient oncology clinics and day care units or admission to wards were identified. Two different researchers over a period of 6 months were involved in the data collection process in order to increase the number of participants in the study. Also, women who did not respond were contacted again and the date of their next appointment recorded.

Patients were informed that participation in the study was optional and would not affect the medical care they received. Only women who agreed to participate were included in the study. Women who were in obvious distress or pain and those who were admitted due to complications such as febrile neutropaenia were excluded. All participants signed a consent form prior to taking part in the study.

Tool used to measure BC symptom knowledge and barriers to seeking medical help

The Breast Module of the Cancer Awareness Measure (Breast-CAM) was developed by the Cancer Research, King's College London and University College London in the UK and is a valid and reliable instrument for measuring BC awareness in women.^{20,21} It has moderate to good test–retest reliability for most items, with a good discriminatory index of BC knowledge, and can be administered either face-to-face or via telephone interviews.^{20,21} The Breast-CAM was intended to be delivered to women in the community and includes different sections which independently measure and assess the following: knowledge of BC symptoms (ie, changes in the nipple, pain or lumps in the breast or armpit, redness, fatigue, unexplained weight loss and loss of appetite) and barriers to seeking medical help, including emotional (ie, being too embarrassed, scared or worried about what the doctor might find), practical (ie, being too busy to make time, having too many other things to worry about and anticipating difficulties explaining concerns to the doctor) and service-related barriers (ie, difficulties arranging transport or being worried about wasting the doctor's time).²⁰

Tool used to measure time taken to seek medical help

The International Cancer Benchmarking Partnership (ICBP) was initiated by the Department of Health in the UK and was subsequently used as part of a collaborative research project to study international variations in cancer survival between jurisdictions in six countries, including Australia, Canada, Denmark, Norway, Sweden and the UK.⁷ The module seeks to measure the overall time interval between the first possible symptom of cancer and the start of treatment.⁷ This overall interval is then divided into subintervals depending on the factors responsible for the delay, including delays related to the patient's attitudes and help-seeking behaviours (ie, their initial response on first noticing symptoms and the duration of symptoms before contacting the doctor), the diagnostic process (ie, time elapsed to secure an appointment to see the doctor, number of medical visits before receiving a diagnosis, and time elapsed between being referred to hospital and getting an appointment with a specialist) and the treatment or management process (ie, time elapsed between first medical appointment and diagnosis, and between diagnosis and first receiving treatment).⁷ The ICBP questionnaire has been used in several international studies to investigate the root causes of delays in cancer diagnoses.^{22 23}

For the purposes of the current study, the Breast-CAM and ICBP tools were combined into one questionnaire in order to assess knowledge of BC symptoms, time taken to consult a doctor and barriers to seeking medical help among Omani women. Sociodemographic variables in the modules were modified to be relevant to Omani society and the national healthcare system. Both the Breast-CAM and ICBP tools were translated from English to Arabic and then back-translated into English.

The combined questionnaire was completed by two researchers during face-to-face interviews conducted with the participants. In order to ensure the clarity and reliability of the questionnaire, a pilot study was conducted of the first 30 women enrolled in the study. Based on a standardised item analysis, the Cronbach's alpha (α) values of the Arabic versions of the Breast-CAM tool and ICBP questionnaire were 0.88 and 0.85, respectively.

Statistical analysis

Data were analysed using SPSS V.22 software. Descriptive data were presented as numbers and percentages. χ^2 test was used to determine the associations between socio-demographic characteristics and the responses of the participants. A binary logistic regression model was used to adjust for the effect of certain factors, with the findings presented as OR and 95% CI. A p value of <0.05 was considered significant.

Patient and public involvement

Patients and/or the public were not involved in the design, or conduct, or reporting, or dissemination plans of this research.

RESULTS

Characteristics of the participants

A total of 300 women with BC participated in the study out of 333 eligible subjects, resulting in a response rate of 91.0%. The mean age was 47.0±12.2 years (median: 45.0 years, range: 24–84 years). The majority were below the age of 50 years (66.1%) and married (76.2%). Over one-third were residents of Muscat (34.3%) and had no formal education (35.2%). Overall, 81 patients (27.1%) reported having a family history of BC, of which the majority (76.3%) were first-degree or second-degree relatives. The mean age at BC diagnosis was 43.0±12.50 years.

At the time of the interviews, the length of the time since diagnosis was less than 3 months in 15.5% of women. Moreover, 33.5% of women had been diagnosed at late stages (ie, stages III and IV). The women were receiving various treatment modalities at the time of the interviews, including chemotherapy, radiotherapy and hormonal therapy (table 1).

Knowledge of BC symptoms and barriers to seeking medical help

The majority of women were aware that BC could be cured if detected sufficiently early (91.6%) and that delays in seeking medical treatment could adversely affect their health (91.6%). Moreover, the majority were aware that missing or delaying an appointment to visit the doctor could cause delays in treatment (90.2%) and that delays in diagnosis could lead to complications (89.0%). On the other hand, less than half of the women (43.8%) had been aware of BC prior to their diagnosis. Under one-third of the cohort thought that a BC diagnosis could lead to social stigma (24.2%) and that society had an effect in delaying BC treatment (30.2%) (figure 1).

The majority of women (74.7%) were aware that lumps in the breast or armpit could be symptoms of BC. However, less than half were aware that pain in the breast or armpit (44.0%), changes in the position of the nipple (36.2%), redness of the skin of the breast (31.7%), fatigue (26.3%), unexplained weight loss (23.4%) and loss of appetite (20.8%) were possible BC symptoms (figure 2). The most commonly reported barriers to seeking medical help were fear (68.9%), followed by anxiety over what the doctor might find (62.8%), having too many other things to worry about (43.6%), embarrassment (26.0%), being too busy to make time to go to the doctor (19.5%), difficulties arranging transport (13.7%), difficulties explaining their symptoms to the doctor (12.4%) and worry over wasting the doctor's time (8.1%) (figure 3).

Associations between sociodemographic characteristics and responses

The binary logistic regression analysis indicated that women who had no formal education were less likely than those who were highly educated (ie, college and above) to recognise that the following were potential symptoms of BC: changes in the position of the nipple (OR 0.16 (95% CI 0.03 to 0.81), p<0.05), pain in the breast or armpit

BC, breast cancer; OMR, Omani rial.

(OR 0.10 (95% CI 0.01 to 0.86), $p < 0.05$) and unexplained weight loss (OR 0.18 (95% CI 0.04 to 0.88), $p < 0.05$). On the other hand, women educated to the high school level were more likely than college-educated women to recognise that a lump in the breast or armpit (OR 7.28 (95% CI 1.06 to 50.19), $p < 0.05$) and fatigue (OR 3.82 (95% CI 1.08 to 13.58), $p < 0.05$) could be BC symptoms.

Employed women were more likely than unemployed women to recognise that fatigue could be a symptom of BC (OR 4.18 (95% CI 1.34 to 13.05), $p < 0.05$). In addition, women in the lowest income category were more likely than those in the highest category to recognise that pain in the breast or armpit (OR 4.14 (95% CI 1.14 to 15.12), $p < 0.05$) and redness (OR 3.58 (95% CI 1.11 to 11.52), $p < 0.05$) could be BC symptoms (table 2).

Time taken to seek medical help

The initial response of most women on first noticing possible BC symptoms was to inform their husband (40.2%), followed by informing other family members (36.5%) and seeing a doctor at a government hospital (8.4%), local health centre (LHC) (8.1%) or private facility (2.4%); however, few women reported travelling abroad (2.0%), informing friends (1.7%) or using traditional or herbal remedies (0.7%). Of all respondents, less than half (31.2%) decided to see a doctor within the first week of developing possible BC symptoms and 17.7% were able to get an appointment to see a doctor on the

**Figure 1** General knowledge of breast cancer and delays in diagnosis.

Figure 2 Knowledge of specific signs and symptoms of breast cancer.

same day or the next day following their decision to seek medical help.

The majority of women were diagnosed with BC after their first visit to an LHC (67.7%) or to government hospitals (30.1%). Moreover, many women were able to see specialists at government hospitals within less than 1 week of referral (39.5%) and received confirmation of the diagnosis on the same day or the next day following their first appointment (10.4%). Finally, many women (29.9%) were able to receive their first treatment within the first week of their diagnosis (table 3).

Based on an indepth regression analysis, no significant associations were observed between sociodemographic variables and awareness of BC symptoms or help-seeking behaviours (ie, time taken for medical consultation, referral and treatment).

DISCUSSION

To our knowledge, this is the first study conducted in Oman to explore knowledge of BC symptoms, time taken to seek medical help and barriers to seeking medical help among women with BC. The mean age of the women diagnosed with BC in this study was 43 years; this is much lower than the average age reported in developed countries (mean age: 63 years) and slightly below that reported in other Arab countries (mean age: 49–52 years).³ A previous study conducted in Oman shared similar findings in which the mean age of women diagnosed with BC was 47 years, with one-third being under 40 years.¹⁵ The younger age of presentation of women with BC in Oman might be attributable to various factors, including genetic background, the adoption of more ‘Westernised’ lifestyles (including reduced levels of physical activity and higher rates of obesity), a decrease in breast feeding and the presence of potential carcinogens in the local environment.²⁴

Although the vast majority of women in this study were aware of the importance of early detection of BC

Figure 3 Barriers to medical help-seeking.

and that delays in seeking medical help could lead to complications, many nevertheless presented at relatively advanced stages (ie, stage III or IV). Previous studies have reported similar findings.^{15–25} Although a large proportion of women in this study were able to recognise that lumps in the breast or armpit were a possible symptom of BC, the majority were not aware of other symptoms such as fatigue, unexplained weight loss or loss of appetite. Indeed, less than half of the women reported having been aware of or knowledgeable regarding BC prior to their own diagnosis. Researchers have recommended incorporating information regarding cancer risk factors and symptoms into the school curriculum so as to increase cancer knowledge in adulthood.²⁶

Poor awareness of BC symptoms is a predominant reason for delayed presentation to a doctor, particularly if symptoms are atypical in nature.⁹ Most women with BC more commonly recognise obvious symptoms, such as lumps, compared with more ambiguous symptoms, such as tiredness, unexplained weight loss and reduced appetite; in fact, delays in presentation are more likely to occur in BC cases in which the symptoms do not include a breast lump.^{6,11} Furthermore, knowledge of BC symptoms is a prerequisite for prompt help-seeking behaviours, particularly if the symptom is perceived to be serious.²⁷ Uneducated women in our study were less likely to recognise certain BC symptoms, such as changes in the position of the nipple, breast or armpit pain and unexplained weight loss. Similar findings have also been noted among Omani women with ovarian cancer, with more educated women being more likely to recognise specific symptoms compared with those who were less educated.²⁸ Although more educated women in the current study were generally more likely to recognise BC symptoms compared with less educated women, the opposite was true for certain items. Specifically, women educated to the high school level were more likely than those with college degrees to understand that lumps in the breast or armpit or fatigue could be BC symptoms. Similarly, women in the low income group were more likely to understand that pain and redness could be associated with BC compared with those with high income. This contradicts results reported by a previous study.²⁸ Reasons for these surprising findings are not clear and merit further investigation.

More than half of women in our study who sought medical help at LHCs or government hospitals were diagnosed with BC after their first or second visit, indicating that the cause for any delays in diagnosis was likely due to the patients themselves. Other researchers have highlighted that not seeking early medical help is a predictor of delayed diagnosis.^{8,29} Furthermore, the majority of women who were seen at LHCs in the present study were subsequently seen by specialists within 2 weeks of referral, with the BC diagnosis confirmed within another 2 weeks. Once again, this indicates that factors related to the local health system do not seem to play a major role in delaying BC diagnoses in Oman. Referral policies covering specific aspects of patient care are well established to oversee

Table 2 Association between sociodemographic characteristics and knowledge of BC symptoms

Characteristics	Knowledge of BC symptoms, OR (95% CI)

BC, breast cancer.

the transfer of patients from one healthcare setting to another for management.³⁰ Nonetheless, patients with cancer in Oman, much like those in neighbouring GCC countries, often choose to seek medical help abroad (ie, in countries like Thailand or India); this trend can cause delays in diagnosis, with many patients returning home with additional complications.¹⁶

For the majority of women in the current study, their initial response on first noticing possible BC symptoms was to inform their husbands and family members. Becoming aware of possible symptoms of a life-threatening disease is often associated with feelings of emotional distress, anxiety and depression; hence, sharing this information with close family members might offer some emotional relief and support.^{31 32} Indeed, most women in our study prioritised sharing their symptoms with husbands or family members over consulting a doctor. This finding might be related to prevailing sociocultural attitudes which are based on a strong sense of moral responsibility and familial obligation, particularly when it comes to illness.¹⁸ Furthermore, Omani women diagnosed with BC often rely on their families for emotional, physical and financial support, which also plays a role in treatment decision-making.^{17 18} However, the involvement of family members in medical decisions and treatment options can sometimes delay diagnoses, particularly if these individuals encourage patients to seek medical treatment abroad or pursue alternative or traditional remedies.^{8 33}

Although more than half of the women in our study sought medical help within 1 month of developing BC symptoms, many nevertheless presented at an advanced stage by the time they were diagnosed. Various psychosocial and cultural

beliefs have been attributed to the delayed presentation of BC cases.^{16 29 31} A previous study from Oman showed that women with BC experienced severe psychosocial distress, including fear of death, social isolation, anxiety regarding the side effects of treatment and fear that the cancer might spread or interfere with their daily lives.¹⁶ Women who express explicit fears about the consequences of diagnosis and treatment are more reluctant to seek medical help, resulting in a higher chance of delays in diagnosis.¹¹

Similarly, many women in our study reported emotional barriers that might contribute to delays in consulting a doctor, such as being scared, embarrassed or worried about what the doctor might find. Symptom appraisal and perception of their severity are predictors of decisions to seek medical help.²⁹ Indeed, it is difficult to assess delays in BC presentation, diagnosis and treatment objectively due to variations in how people perceive symptoms and define time intervals.³⁴ Although there is growing interest in measuring cancer diagnostic time intervals and examining their effect on outcomes, the pathway from symptoms to diagnosis is a complex process as outlined in the Pathways to Treatment framework.¹³

The decision to consult a doctor and seek medical help often relies on a patient's subjective definition of the 'main' symptoms of cancer, which in itself is often influenced by their pre-existing knowledge and perceptions of symptom severity.³⁵ The presence of chronic diseases or psychological symptoms may also further influence interpretation of these symptoms.¹³ Furthermore, international variations in the investigation and referral of patients with cancer to secondary care for suspected cancer symptoms can play a critical role in diagnostic delays and cancer outcomes; for instance, countries in which healthcare professionals demonstrate a greater readiness to refer or investigate patients with possible cancer symptoms have demonstrated high rates of cancer survival.³⁶

This study has certain limitations. First, many patients in Oman often choose to access healthcare in non-integrated settings, for instance, by attending a mixture of government facilities, private facilities and facilities abroad. Thus, it was difficult in some cases to track the time taken throughout the diagnostic pathway using the three usual component intervals of delay (ie, patient, primary care and secondary care delays). Apart from self-reported information from the patients, there were no other methods available to measure delays in the absence of electronic or written tracking data.

Second, while we recruited Omani women diagnosed with BC within the previous year to satisfy the sample size requirements, the possibility of recall bias cannot be ruled out. Third, although the Arabic version of the combined questionnaire (which incorporated both the Breast-CAM and ICBP tools) was tested for reliability and demonstrated a satisfactory Cronbach's alpha (α) coefficient, we could not guarantee its validity, which was beyond the scope of this research. Fourth, we provided women with a predetermined list of BC symptoms in the Breast-CAM module instead of asking them to demonstrate their own knowledge of such symptoms; this may have obscured our understanding of how knowledge influenced help-seeking behaviours. Finally, we used the Breast-CAM section to measure knowledge of BC symptoms

and barriers to seeking medical help among patients who had already been diagnosed with BC; as this tool was originally designed to be delivered to a community sample, we could not rule out potential bias in that the participants might have more knowledge of BC symptoms compared with other Omani women.

CONCLUSION

Omani women with BC demonstrated low levels of knowledge of BC symptoms and experienced several emotional barriers to seeking medical help; moreover, many were diagnosed at advanced stages. Despite national efforts to increase BC awareness, further educational initiatives are needed. Healthcare professionals should visit schools to raise awareness of BC symptoms and promote early help-seeking behaviours among female students in different regions of Oman. Employing both social and traditional media campaigns in LHCs and hospitals might also help to increase BC knowledge. Finally, healthcare professionals should make more efforts to build a trusting and cooperative relationship with female patients in order to help address emotional barriers to medical help-seeking, thereby encouraging them to disclose potential symptoms and thus reducing delays in diagnosis.
