Edited by Wolfgang Peti

The main protease (3CL M^{pro}) from SARS–CoV-2, the etiological agent of COVID-19, is an essential enzyme for viral replication. 3CL M^{pro} possesses an unusual catalytic dyad composed of Cys^{145} and His^{41} residues. A critical question in the field has been what the protonation states of the ionizable residues in the substrate-binding active-site cavity are; resolving this point would help understand the catalytic details of the enzyme and inform rational drug development against this pernicious virus. Here, we present the room-temperature neutron structure of 3CL M^{pro}, which allowed direct determination of hydrogen atom positions and, hence, protonation states in the protease. We observe that the catalytic site natively adopts a zwitterionic reactive form in which Cys^{145} is in the negatively charged thiolate state and His^{41} is doubly protonated and positively charged, instead of the neutral unreactive state usually envisaged. The neutron structure also identified the protonation states, and thus electrical charges, of all other amino acid residues and revealed intricate hydrogen-bonding networks in the active-site cavity and at the dimer interface. The fine atomic details present in this structure were made possible by the unique scattering properties of the neutron, which is an ideal probe for locating hydrogen positions and experimentally determining protonation states at near-physiological temperature. Our observations provide critical information for structure-assisted and computational drug design, allowing precise tailoring of inhibitors to the enzyme's electrostatic environment.

COVID-19, a deadly disease caused by the novel coronavirus SARS–CoV-2 (severe acute respiratory syndrome–coronavirus 2), is a pandemic of extraordinary proportions, disrupting social life, travel, and the global economy. The development of vaccines and therapeutic intervention measures promises to mitigate the spread of the virus and to alleviate the burdens COVID-19 has caused in many communities in recent months (1–6). SARS–CoV-2 is a single-stranded positive-sense RNA virus with a genome comprised of ~30,000 nucleotides. The viral replicase gene encodes two overlapping polyproteins, pp1a and pp1ab, consisting of individual viral proteins essential for replication (7, 8). Each polyprotein must be processed into indi-

vidual functional proteins, a vital step in the virus life cycle. This is accomplished by a chymotrypsin-like protease, 3CL M^{pro} or main protease, a hydrolase enzyme that cleaves peptide bonds. The proper functioning of 3CL M^{pro} is indispensable for SARS–CoV-2 replication, whereas its inhibition leads to the inability to produce mature infectious virions. Thus, the enzyme is considered a promising target for the design and development of SARS–CoV-2–specific protease inhibitors and for repurposing existing clinical drugs (9–15).

SARS–CoV-2 3CL M^{pro} is a cysteine protease (16, 17) and is catalytically active as a homodimer (Fig. 1). Its amino acid sequence is 96% homologous to the earlier SARS–CoV 3CL M^{pro}, and the catalytic efficiencies of the two enzymes are similar (10, 11, 18–20). The ~34-kDa enzyme has three distinct domains: catalytic domains I (residues 8–101) and II (residues 102–184) and the α-helical domain III (residues 201–303), which is required for protein dimerization (10, 11). Importantly, the monomeric enzyme shows no catalytic activity, as was demonstrated for SARS–CoV 3CL M^{pro} (21–24). The catalytic site of 3CL M^{pro} employs a noncanonical Cys^{145}–His^{41} dyad thought to be assisted by a water molecule hydrogen-bonded to the catalytic histidine (18, 25). The cysteine thiol group functions as the nucleophile during the first step of the hydrolysis reaction by attacking the carbon atom of the scissile peptide bond. Substrate hydrolysis requires the catalytic dyad to be in the zwitterionic state with deprotonated Cys^{145} and protonated His^{41}, which either can be generated through a proton transfer from the Cys^{145} thiol to the His^{41} imidazole by a general acid-base mechanism (19) or may already be present before substrate binding (20, 26). However, the protonation states of the 3CL M^{pro} catalytic site have not been experimentally determined. The enzyme recognizes a general amino acid sequence of Leu-Gln↓Ser-Ala-Gly, where ↓ marks the cleavage site, but displays some substrate sequence promiscuity. The active-site cavity is located on the surface of the protease and can bind substrate residues in positions P1′ through P5 in the substrate-binding subsites S1′–S5, respectively (Fig. 2). Subsites S1, S2, and S4 are shaped into well-formed binding pockets, whereas S1′, S3, and S5 are located on the protein surface with no defined shape. The peptide bond cleavage occurs between the substrate residues at the C-terminal position P1′ and N-terminal position P1.

Current structure-assisted drug design efforts are mainly directed toward reversible and irreversible covalent inhibitors that mimic the protease substrate binding to subsites S1′–S5 in

Figure 1. Structure of SARS–CoV-2 3CL M[pro]. *A*, the catalytically active dimer is shown in cartoon representation, with the catalytic dyad residues Cys[145] and His[41] in ball-and-stick representation. *B*, the enzyme protomer shown in stick representation demonstrates that X-ray diffraction only provides the positions of heavy atoms, *i.e.* carbon, nitrogen, oxygen, and sulfur (2380 atoms in one protomer). Water molecules are shown as *red spheres*. *C*, the same protomer shown with deuterium atoms colored *yellow* and hydrogen atoms colored *gray* illustrates that neutron diffraction provides positions of all atoms in the enzyme (4681 atoms in one protomer). Notice how much busier the protein neutron structure is compared with its X-ray structure because there are twice as many atoms visible when using neutron diffraction data. Only oxygen atoms (*red spheres*) are visible for water molecules in the X-ray structure, whereas all three atoms are fully visible in the neutron structure.

Figure 2. SARS–CoV-2 3CL M[pro] active site architecture indicating the positions of substrate-binding subsites S1′–S5 and the oxyanion hole.

the active-site cavity (9–12, 14), whereas the dimer interface can also be explored for the design of dimerization inhibitors (27, 28). Knowledge of the SARS–CoV-2 3CL M[pro] active-site cavity structure at an atomic level of detail, including the actual locations of hydrogen atoms, can provide critical information to improve rational drug design. The presence or absence of hydrogen atoms at specific sites on amino acid residues determines their protonation states and, thus, their electrical charges, defining the electrostatics and hydrogen-bonding interactions. Of note, half of all atoms in protein and small-molecule drugs are hydrogen. X-ray crystallography is typically the standard experimental method for structure-assisted drug design but cannot reliably locate hydrogen atoms in biological macromolecules, leaving significant gaps in our understanding of biological function and drug binding (29). Electron clouds scatter X-rays; thus, scattering power is determined by the number of electrons present in an atom, *i.e.* by its atomic num-

ber. Hydrogen, with just a single electron that often participates in highly polarized chemical bonds, is the weakest possible X-ray scatterer and consequently is invisible in X-ray structures with a few exceptions beyond subatomic resolution (30–32). In contrast, atomic nuclei scatter neutrons, where the scattering power of neutrons is independent of the atomic number. Deuterium, a heavy isotope of hydrogen, scatters neutrons just as well as carbon, nitrogen, and oxygen. Neutron crystallography is capable of accurately determining positions of hydrogen and deuterium atoms and visualizing hydrogen-bonding interactions at moderate resolutions (33–36), where X-rays cannot locate functional hydrogen atoms (30). Moreover, unlike X-rays (37), neutrons cause no direct or indirect radiation damage to protein crystals, permitting diffraction data collection at near-physiological (room) temperature, avoiding possible artifacts induced by the use of cryoprotectant chemicals required for X-ray cryo-crystallographic measurements.

In neutron crystallographic experiments, protein crystals are usually hydrogen/deuterium–exchanged with the heavy water (D_2O) to increase the signal-to-noise ratio of the diffraction pattern because hydrogen has a large incoherent scattering cross-section that increases background. Also, the coherent neutron-scattering length of hydrogen is negative (-3.739 fm) and is therefore observed in the neutron-scattering length (or nuclear) density maps as troughs. At moderate resolutions, the negative neutron-scattering length of hydrogen leads to the density cancelation phenomenon observed for CH, CH_2, and CH_3 groups as hydrogen atoms attached to carbon atoms cannot exchange with deuterium. Conversely, deuterium has a coherent neutron-scattering length of $+6.671$ fm and, thus, is observed as peaks in nuclear density maps. Because deuterium atoms scatter neutrons just as well as other protein atoms, they can be directly detected in neutron structures at moderate resolutions as low as 2.5–2.6 Å (38, 39). Notably, sulfur has a coherent neutron-scattering length of $+2.847$ fm, less than half the magnitude of that for carbon, oxygen, nitrogen, and deuterium. Consequently, deprotonated thiol groups (S^-) in Cys and side-
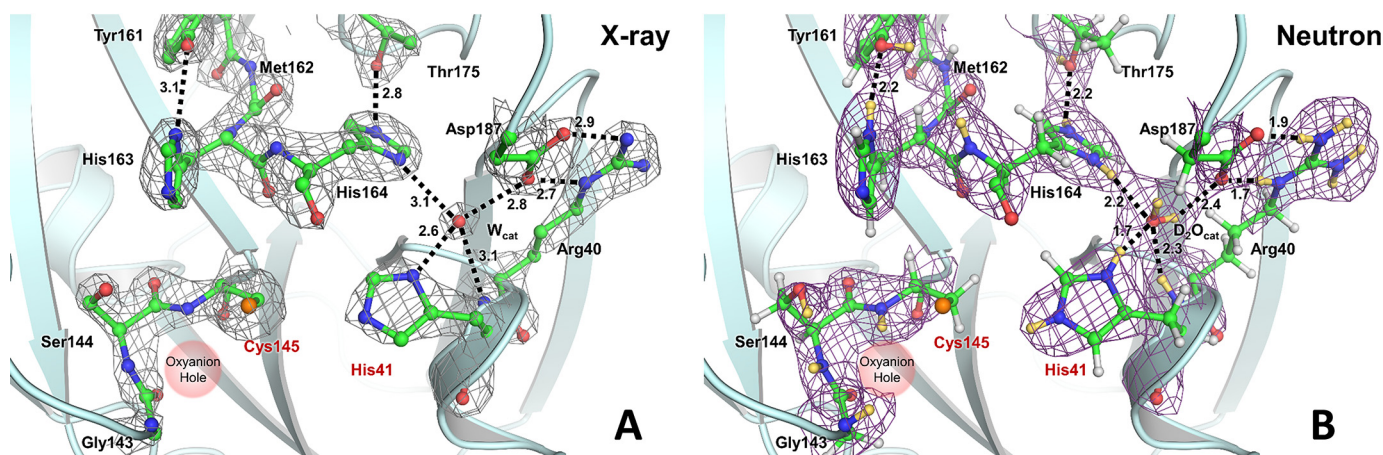

Figure 3. The catalytic site of SARS–CoV-2 3CL M^pro. X-ray diffraction data provide no information on the positions of hydrogen atoms as shown in *A*, whereas neutron diffraction data provide direct observation of deuterium atoms as shown in *B*. *A*, the $2F_o - F_c$ electron density map is contoured at 2.0 σ level (*gray mesh*). Distances between the heavy atoms in Ångstroms illustrate possible hydrogen bonds (*black dashed lines*). *B*, the $2F_o - F_c$ nuclear density map is contoured at 2.0 σ level (*violet mesh*), allowing visualization of the actual protonation states and hydrogen-bonding interactions shown as *black dashed lines* (deuterium–oxygen distances are shown in Ångstroms). chain sulfur atoms in Met residues are often not easily visible in nuclear density maps.

We grew neutron-quality crystals of the ligand-free SARS–CoV-2 3CL M^pro at pH 6.6, allowing us to obtain a room-temperature neutron structure of the enzyme refined jointly with a room-temperature X-ray data set collected from the same crystal (Fig. 1) (40). We accurately determined the locations of exchangeable hydrogen atoms that were observed as deuterium attached to electronegative atoms such as oxygen, nitrogen, or sulfur atoms. We discovered that the catalytic dyad comprising residues Cys^145 and His^41 is in the reactive zwitterionic state having deprotonated negatively charged Cys^145 and doubly protonated positively charged His^41. Our experimental observations identified the protonation states of all other ionizable amino acid residues, allowing us to accurately map the electric charges and hydrogen-bonding networks in the SARS–CoV-2 3CL M^pro active-site cavity and throughout the enzyme structure. Neutron diffraction data were collected from a hydrogen/deuterium–exchanged SARS–CoV-2 3CL M^pro crystal at pD 7.0 (pD = pH + 0.4) to 2.5 Å resolution (Fig. 3).

Results

Protonation states of the catalytic site and nearby residues

The electron density for the catalytic site and the nearby residues of SARS–CoV-2 3CL M^pro is shown in Fig. 3*A* Although hydrogen-bonding interactions can be inferred from the distances between the heavy atoms, the locations of hydrogen atoms and the protonation states of the amino acid residues can only be assumed. Instead, the nuclear density map shown in Fig. 3*B* displays the actual positions of exchanged deuterium atoms, accurately visualizing hydrogen-bond donors and acceptors. In the neutron structure, we observed that the catalytic Cys^145 thiol is in the deprotonated, negatively charged thiolate state.

In contrast, located 3.9 Å away from Cys^145, the catalytic residue His^41 is protonated on both Nδ1 and Nϵ2 nitrogen

atoms of the imidazole side chain and is therefore positively charged (Fig. S1). As a result, the catalytic site natively adopts the zwitterionic reactive state required for catalysis (19, 20, 41). His^41 is strongly hydrogen-bonded to a water molecule (D_2O_{cat}) that presumably plays the role of the third catalytic residue (18, 25) from a canonical catalytic triad, stabilizing the charge and position of the His^41 imidazolium ring. The Nδ1-D...O_{D_2O} distance is 1.7 Å. The position of the D_2O_{cat} molecule is stabilized by several more, but possibly weaker, hydrogen bonds with His^41 main chain, His^164, and Asp^187. His^164 is doubly protonated and positively charged; it donates a deuterium in a hydrogen bond with the Thr^175 hydroxyl within the interior of the protein. As expected, Asp^187 is not protonated, is negatively charged, and participates in a strong salt bridge with Arg^40. His^163 positioned near the catalytic Cys^145 is singly protonated and uncharged, making a hydrogen bond with the protonated phenolic side chain of Tyr^161, whose OD group is rotated away from the His^163 imidazole (Fig. S1). The main-chain deuterium atoms of Gly^143, Ser^144, and Cys^145 comprising the oxyanion hole are also readily visible in the nuclear density (Fig. 3*B*).

Substrate-binding subsite S1

The P1 group of a substrate, usually Gln, binds in a rather peculiar substrate-binding subsite S1 (Fig. 4*A*). From one side, it is flanked by residues 140–144, making a turn that creates the oxyanion hole and, on the opposite side, by Met^165, Glu^166, and His^172. The back wall of subsite S1 is created by the side chains of Phe^140 and His^163. Interestingly, the N terminus of Ser^1' of the second protomer within the active 3CL M^pro homodimer reaches in to cap the subsite S1 from the top. In our neutron structure, the N-terminal amine is the protonated, positively charged $-ND_3^+$ ammonium cation. It forms three hydrogen bonds, one each with the main chain carbonyl of Phe^140, the side chain carboxylate of Glu^166, and a D_2O molecule. Both histidine residues, His^163 and His^172, in this subsite are singly protonated and neutral (Fig. S1). The deprotonated Nδ1 of His^172 is hydrogen-bonded with the
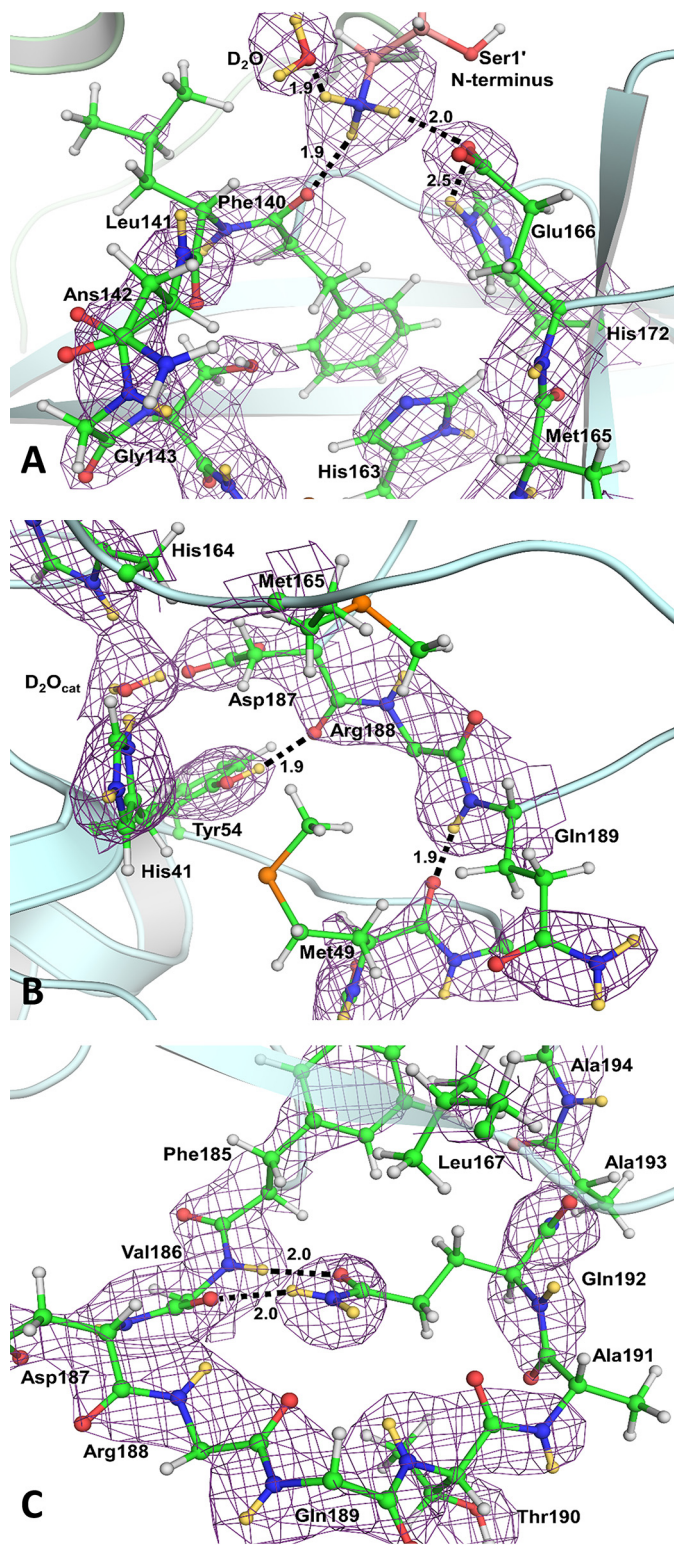

Figure 4. The architecture and hydrogen bonds in substrate-binding subsites S1 (*A*), S2 (*B*), and S4 (*C*). The $2F_o - F_c$ nuclear density map is contoured at 2.0 σ level (*violet mesh*). Hydrogen bonds are shown as *black dashed lines*. The deuterium–oxygen distances are in Ångstroms. For clarity, the side chains were omitted for Val[186], Arg[188], and Gln[189]. Deuterium atoms are colored *yellow*, whereas hydrogen atoms are colored *light gray*.

main-chain amide nitrogen of Gly[138] with a nitrogen–deuterium distance of 2.2 Å, whereas the protonated Nϵ2 makes a long, possibly weak, hydrogen-bond interaction with the

Glu[166] carboxylate with the deuterium–oxygen distance of 2.5 Å.

Substrate-binding subsite S2

Subsite S2 is more hydrophobic than subsite S1, because it binds the hydrophobic residues Leu or Phe in substrate position P2 (Fig. 4*B*). Subsite S2 is flanked by the π-systems of His[41] and the main chains connecting Asp[187], Arg[188], and Gln[189]. It is capped by Met[165], whereas Met[49], situated on the short P2 helix spanning residues Ser[46]–Leu[50], adopts a conformation impeding the entrance to this site. Met[49] appears to be conformationally flexible, vacating its position in the ligand-free enzyme to allow various P2 groups to occupy this subsite when inhibitors bind (9–11). Tyr[54] serves as the base of subsite S2, and its phenolic hydroxyl group donates its deuterium in a hydrogen bond with the main chain carbonyl of Asp[187].

Substrate-binding subsites S3–S5

Among the substrate-binding subsites S3, S4, and S5, only subsite S4 has a well-defined binding pocket architecture. Subsites S3 and S5 are on the protein surface, fully exposed to the bulk solvent, and have ill-defined borders. Subsite S3 is located between residues Glu[166] and Gln[189] that are >9 Å apart. Subsite S5 is between Pro[168] of the β-hairpin flap, spanning residues Met[165]–His[172], and the P5 loop consisting of residues Thr[190]–Ala[194] (Fig. 2). Subsite S4 is formed between a long loop spanning residues Phe[185]–Ala[194] that acts as its base and the β-hairpin flap on the top. The loop turns 180° at Gln[189], with its secondary structure being stabilized by hydrogen bonds between the Gln[192] side-chain amide and the main chain atoms of Val[186]. The side chains of Leu[167] and Phe[185] form the back wall of this site in the protein interior, creating a deep, mainly hydrophobic pocket (Fig. 4*C*).

Dimer interface

The two protomers in the SARS–CoV-2 3CL M[pro] homodimer interact through an extensive dimer interface. Protomer 1 (unprimed residue numbers) forms elaborate networks of hydrogen-bonding interactions with N-terminal residues 1′–16′, a β-strand with residues 118′–125′, and a loop containing residues 137′–142′ of protomer 2 (primed residue numbers; Fig. 5). There are also many hydrophobic interactions within the dimer interface. The N termini of the two protomers meet at the start of a short α-helix spanning residues Gly[11]–Cys[16] and Gly[11′]–Cys[16′] to form several hydrogen bonds involving the main-chain and side-chain atoms of Ser[10], Gly[11], Ser[10′], Gly[11′], and Glu[14′] (Fig. 5). The N-terminal loop then extends across the face of the opposite protomer to subsite S1. Here, Ala[7′], Phe[8′], Arg[4′], and Ser[1′] are observed making hydrogen bonds with Val[125], Glu[290], Lys[137], Phe[140], and Glu[166]. Ser[123′] and Asn[119′] of protomer 2 β-strand containing residues 118′–125′ have direct hydrogen bonds and water-mediated interactions with the C-terminal residues of protomer 1, in addition to the reciprocal hydrogen bonds between Val[125′] and Ala[7] formed because of the 2-fold symmetry of the enzyme dimer (Fig. 5). Similar reciprocity of hydrogen bonding is found for the loop consisting of residues 137′–144′ in protomer 2 that interacts
Figure 5. The dimer interface hydrogen bonding and water-mediated interactions visualized in the neutron structure of SARS–CoV-2 3CL M^pro. *Left panel*, cartoon representation in which protomer 1 (unprimed residues 1–306) is shown as a *green surface* and protomer 2 (primed residues 1'-306') is colored in *yellow*. The parts of protomer 2 interacting with protomer 1 are colored *blue*. *Right panels*, dimer interface hydrogen bonds made by the N-terminal residues 1'–16' shown in *panel 1*; interactions made by a β-strand 118'–125' shown in *panel 2*; and interactions made by a loop 137'–141– shown in *panel 3*. Deuterium atoms are colored *yellow*, whereas hydrogen atoms are omitted for clarity. Hydrogen bonds are shown as *black dashed lines*, and the distances are in Ångstroms.

with the N-terminal residues Ser[1] and Arg[4] of protomer 1. Also, the side-chain hydroxyl of Ser[139'] makes a hydrogen bond with the side-chain amide of Gln[299] (Fig. 5).

Protonation states of Cys residues

The SARS–CoV-2 3CL M^pro structure contains 12 Cys residues spread throughout the sequence. The reasons for such a large number of cysteines within the enzyme sequence and their functional roles are unknown, except for the catalytic Cys[145]. By examining the nuclear density, we established the protonation states of all Cys residues in the structure (Figs. S2 and S3). The side chains of residues Cys[16], Cys[85], Cys[117], Cys[156], Cys[160], Cys[265], and Cys[300] are protonated thiol groups. Conversely, the remaining Cys residues, Cys[22], Cys[38], Cys[44], Cys[128], and Cys[145], contain deprotonated thiolates. Sulfur is a soft chemical base, with a large van der Waals radius of 1.84 Å; thus, a deprotonated thiol group is stable in solution at the physiological pH (pK_a of free Cys is 8.35). Hence, it is not unexpected to observe deprotonated Cys residues in a protein structure at close-to-physiological pH. In addition, Cys[22] and Cys[128] are located close to the protein surface, with their negative charges further stabilized by the positive charges of nearby Lys[61] and Arg[4'] from the second protomer, respectively (Fig. S4). Cys[38] and Cys[44] are positioned within hydrophobic pockets, with their negative charges shielded from the bulk solvent. Deprotonation of Cys[145] is also consistent with it being reactive and oxidation prone, as reported previously (41). Accordingly,

because we can unambiguously differentiate between seven protonated and five deprotonated Cys side chains, this provides strong evidence that the catalytic Cys[145] is in the reactive negatively charged thiolate form.

Discussion

The COVID-19 pandemic has claimed over a million lives globally to date because of the lack of therapeutic intervention options and vaccines that specifically target the SARS–CoV-2 virus. Rational or structure-assisted and computational drug design efforts could greatly benefit from a detailed structural knowledge of the drug targets, such as the SARS–CoV-2 3CL M^pro enzyme. Considering that half of the protein atoms are hydrogens that play critical roles in various chemistries occurring in enzyme active sites and in inhibitor-binding events, it is of paramount importance to locate hydrogen atoms in a protein to understand enzyme function and to guide drug design. Neutron crystallography is the only technique capable of accurately determining the positions of hydrogen (and deuterium) atoms in biological macromolecules without causing radiation damage to the samples at near-physiological temperature (33). We have succeeded in determining a room-temperature neutron structure of the homodimeric SARS–CoV-2 3CL M^pro enzyme mapping the protonation states of amino acid residues in the active-site cavity and throughout the protein structure. Thus, for the first time, we determined protonation states of all

ionizable residues in a cysteine protease and any coronavirus protein. The neutron structure also reveals the elaborate hydrogen-bonding networks formed in the catalytic site, including those in the six substrate-binding subsites, and throughout the dimer interface. Protonation states are determined by the locations of hydrogen atoms, observed in the neutron structure as deuterium after the hydrogen/deuterium exchange was performed. Also, protonation states establish the electrical charges and therefore determine the electrostatic environment in the protein. The implications of knowing the actual protonation states in and around the active site are far-reaching because this information is essential for the structure-assisted and computational drug design. Structure-assisted drug design requires precise tailoring of inhibitor chemical groups to the electrostatic environment of an enzyme's binding site and has to take advantage of hydrogen-bonding opportunities because direct hydrogen bonds between a drug molecule and its protein target are the strongest noncovalent interactions that can dramatically improve the inhibitor-binding affinity. Moreover, if protonation states are not experimentally known and are assumed based on general chemical knowledge, computational methods will produce misleading results.

In the SARS–CoV-2 3CL M^{pro} neutron structure, we discovered that the catalytic dyad is observed in the reactive zwitterionic state in the crystal at pD 7.0, having a deprotonated negatively charged Cys^{145} and doubly protonated positively charged His^{41} (Fig. 3), instead of the catalytically resting (nonreactive) state (26) in which both catalytic residues are neutral (*i.e.* protonated Cys^{145} and singly protonated His^{41}). The negative charge on Cys^{145} thiolate is stabilized by the sulfur atom being a soft chemical base with a large van der Waals radius and by the positive charge on His^{41} side chain and the oxyanion hole main chain amides positioned in close proximity to the Cys^{145} side chain. His^{41} is hydrogen-bonded to the catalytic water molecule held in place by interactions with the doubly protonated His^{164} and negatively charged Asp^{87}. The substrate-binding subsite S1 contains the protonated positively charged N-terminal amine from protomer 2 and neutral His^{163}. The nonprotonated Nϵ2 of His^{163} is exposed and can be utilized as a hydrogen-bond acceptor by an inhibitor P1 substituent (Fig. 4). In the hydrophobic subsite S2, the Tyr^{54} hydroxyl can act as a hydrogen-bond acceptor for a P2 substituent with a hydrogen-bond donor functionality. Consequently, specific SARS–CoV-2 3CL M^{pro} protease inhibitor design needs to consider the observed charge distribution in the enzyme active-site cavity, taking a special note that the catalytic site contains a zwitterionic catalytic dyad but appears to be neutral because the opposite charges on Cys^{145} and His^{41} located close to each other cancel out.

We also accurately mapped the hydrogen-bonding networks within the dimer interface of SARS–CoV-2 3CL M^{pro}. Significantly, the N-terminal residues between Ser^1 and Cys^{16} (and Ser$^{1'}$ and Cys$^{16'}$) account for the most hydrogen bonds between the two protomers (Fig. 5). There are 13 direct hydrogen bonds formed by each N terminus interacting with the opposite protomer. Ser^1 is an essential residue for building the correct architecture of substrate-binding subsite S1. Truncation of the first four N-terminal residues in SARS–CoV 3CL M^{pro} has previ-

ously been shown to disrupt dimerization and dramatically diminish enzyme activity (22). We therefore suggest that the enzyme area that interacts with residues 1–16 from the other protomer may be the most promising part of the dimer interface for designing SARS–CoV-2 3CL M^{pro}-specific dimerization inhibitors, as was also proposed for the SARS–CoV enzyme (42, 43).

Conclusion

We have successfully determined the neutron structure of the ligand-free SARS–CoV-2 3CL M^{pro} at near-physiological (room) temperature and pH and mapped the locations of hydrogen atoms (observed as deuterium) in the enzyme. Thus, protonation states and electrical charges of the ionizable residues have been accurately resolved. Establishing the electrostatics in the enzyme active-site cavity and at the dimer interface is critical information to guide the structure-assisted and computational drug design of protease inhibitors, specifically targeting the enzyme from SARS–CoV-2.

Materials and methods

General information

Protein purification columns were purchased from Cytiva (Piscataway, NJ, USA). Crystallization reagents were purchased from Hampton Research (Aliso Viejo, CA, USA). Crystallographic supplies were purchased from MiTeGen (Ithaca, NY, USA) and Vitrocom (Mountain Lakes, NJ, USA).

Cloning, expression, and purification of SARS–CoV-2 3CL M^{pro}

The 3CL M^{pro} (Nsp5 M^{pro}) from SARS–CoV-2 was cloned into pD451-SR plasmid harboring kanamycin resistance (ATUM, Newark, CA, USA), expressed, and purified according to the procedure published elsewhere (25). To make the authentic N terminus of 3CL M^{pro}, the enzyme sequence is flanked by the maltose-binding protein followed by the protease autoprocessing site SAVLQ↓SGFRK (down arrow indicates the autocleavage site), which corresponds to the cleavage position between NSP4 and NSP5 in the viral polyprotein. To form the authentic C terminus, the enzyme construct codes for the human rhinovirus 3C protease cleavage site (SGVTFQ↓GP) connected to a His$_6$ tag. The N-terminal flanking sequence is autocleaved during the expression in *Escherichia coli* (BL21 DE3), whereas the C-terminal flanking sequence is removed by the treatment with human rhinovirus 3C protease (Millipore–Sigma). A detailed protocol for the enzyme expression, purification, and crystallization has been published elsewhere (44).

Crystallization

For crystallization, the authentic 3CL M^{pro} is concentrated to ∼4 mg/ml in 20 mM Tris, 150 mM NaCl, 1 mM tris(2-carboxyethyl)phosphine, pH 8.0. The methodology for growing large crystals of 3CL M^{pro} suitable for neutron diffraction is described as follows. Initial protein crystallization conditions were discovered by screening conducted at the Hauptman–Woodward Medical Research Institute (45). Crystal aggregates were reproduced using the sitting-drop vapor-diffusion method

using 25% PEG3350, 0.1 M Bis-Tris, pH 6.5, in 20-μl drops with 1:1 ratio of the protein:well solution. Microseeding using Hampton Research seed beads was performed to grow neutron-quality crystals in Hampton 9-well plates and sandwich box set-ups with 200-μl drops of protein mixed with 18% PEG3350, 0.1 M Bis-Tris, pH 6.0, 3% DMSO at a 1:1 ratio seeded with 1 μl of microseeds at a 1:500 dilution. This condition produced a final pH in the crystallization drop of 6.6 as measured by microelectrode. The crystal tray used to harvest a crystal for neutron diffraction was incubated initially at 18 °C and then gradually lowered to 10 °C over several weeks. The crystal grew to final dimensions of $\sim 2 \times 0.8 \times 0.2$ mm (~ 0.3 mm^3) in a triangular plate-like morphology. The crystal was mounted in a quartz capillary accompanied with 18% PEG3350 prepared with 100% D_2O and allowed to hydrogen/deuterium exchange for several days before starting the neutron data collection.

Neutron diffraction data collection

The large crystal was screened for diffraction quality using a broad-bandpass Laue configuration using neutrons from 2.8 to 10 Å at the IMAGINE instrument at the high flux isotope reactor at Oak Ridge National Laboratory (46–48). Neutron diffraction data were collected using the macromolecular neutron diffractometer instrument MaNDi at the Spallation Neutron Source (47, 49–51). The crystal was held still at room temperature, and diffraction data were collected for 24 h using all neutrons between 2 and 4.16 Å. Following this, the crystal was rotated by $\Delta\phi = 10°$, and a subsequent data frame was collected again for 24 h. A total of 23 data frames were collected in the final neutron data set. Diffraction data were reduced using the Mantid package, with integration carried out using three-dimensional TOF profile fitting (52). Wavelength normalization of the Laue data was performed using the Lauenorm program from the Lauegen suite (53, 54). The neutron data collection statics are shown in Table S1.

X-ray diffraction data collection

The room-temperature diffraction data set was collected from the same crystal used for the neutron data collection using a Rigaku HighFlux HomeLab instrument equipped with a MicroMax-007 HF X-ray generator and Osmic VariMax optics. The diffraction images were obtained using an Eiger R 4M hybrid photon counting detector. Diffraction data were integrated using the CrysAlis Pro software suite (Rigaku Inc., The Woodlands, TX). Diffraction data were then reduced and scaled using the Aimless (54) program from the CCP4 suite (55); molecular replacement using PDB code 6WQF (25) was then performed with Molrep (54) from the CCP4 program suite. The protein structure was first refined against the X-ray data using *Phenix.refine* from the Phenix (56) suite of programs and the *Coot* (57) molecular graphics program to obtain an accurate model for the subsequent X-ray/neutron joint refinement. The geometry of the final model was then carefully checked with MolProbity (58). The X-ray data collection statics are shown in Table S1.

Joint X-ray/neutron refinement

The joint X-ray/neutron refinement of ligand-free 3CL M^{pro} was performed using *nCNS* (40, 59), and the structure was manipulated in *Coot* (57). After initial rigid-body refinement, several cycles of positional, atomic displacement parameter, and occupancy refinement were performed. The structure was checked for the correctness of side-chain conformations, hydrogen bonding, and orientations of D_2O water molecules built based on the m$F_o - F_c$ difference neutron-scattering length density maps. The 2m$F_o - DF_c$ and m$F_o - DF_c$ neutron-scattering length density maps were then examined to determine the correct orientations of hydroxyl (Ser, Thr, and Tyr), thiol (Cys), and ammonium (Lys) groups and protonation states of the enzyme residues. The protonation states of some disordered side chains could not be obtained directly and remained ambiguous. All water molecules were refined as D_2O. Initially, water oxygen atoms were positioned according to their electron density peaks and then were shifted slightly in accordance with the neutron-scattering length density maps. All labile hydrogen positions in 3CL M^{pro} were modeled as deuterium atoms, and then the occupancies of those atoms were refined individually within the range of -0.56 (pure hydrogen) to 1.00 (pure deuterium). Before depositing the neutron structure to the PDB, a script was run that converts a record for the coordinates of a deuterium atom into two records corresponding to a hydrogen and a deuterium partially occupying the same site, both with positive partial occupancies that add up to unity. The percentage of deuterium at a specific site is calculated according to the following formula: % deuterium = {Occupancy(deuterium) + 0.56}/1.56.

Data availability

The coordinates and structure factors for ligand-free SARS–CoV-2 3CL M^{pro} have been deposited in the PDB with accession code 7JUN. Any other relevant data are available from the corresponding authors upon reasonable request.
