[a]National Institute for Health Research Bristol Biomedical Research Centre, University Hospitals Bristol NHS Foundation Trust and University of Bristol, Bristol, UK; [b]Musculoskeletal Research Unit, Translational Health Sciences, Bristol Medical School, University of Bristol, Learning & Research Building (Level 1), Southmead Hospital, Bristol, UK; [c]Institute of Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio, Finland; [d]Department of Medicine, Institute of Clinical Medicine, University of Eastern Finland, Kuopio, Finland; [e]Department of Medicine, Central Finland Health Care District Hospital District, Jyväskylä, Finland

ABSTRACT

Purpose: Emerging data suggest that coronavirus disease 2019 (COVID-19) has extrapulmonary manifestations but its renal manifestations are not clearly defined. We aimed to evaluate renal complications of COVID-19 and their incidence using a systematic meta-analysis.

Design: Observational studies reporting renal complications in COVID-19 patients were sought from MEDLINE, Embase and the Cochrane Library from 2019 to June 2020. The nine-star Newcastle-Ottawa Scale was used to evaluate methodological quality. Incidence with 95% confidence intervals (CIs) were pooled using random-effects models.

Results: We included 22 observational cohort studies comprising of 17,391 COVID-19 patients. Quality scores of studies ranged from 4 to 6. The pooled prevalence of pre-existing chronic kidney disease (CKD) and end-stage kidney disease was 5.2% (2.8–8.1) and 2.3% (1.8–2.8), respectively. The pooled incidence over follow-up of 2–28 days was 12.5% (10.1–15.0) for electrolyte disturbance (e.g. hyperkalaemia), 11.0% (7.4–15.1) for acute kidney injury (AKI) and 6.8% (1.0–17.0) for renal replacement therapy (RRT). In subgroup analyses, there was a higher incidence of AKI in US populations and groups with higher prevalence of pre-existing CKD.

Conclusions: Frequent renal complications reported among hospitalized COVID-19 patients are electrolyte disturbance, AKI and RRT. Aggressive monitoring and management of these renal complications may help in the prediction of favourable outcomes.

Systematic review registration: PROSPERO 2020: CRD42020186873

KEY MESSAGES

- COVID-19 affects multiple organs apart from the respiratory system; however, its renal manifestations are not clearly defined.
- In this systematic meta-analysis of 22 observational cohort studies, the prevalence of pre-existing chronic kidney disease (CKD) in COVID-19 patients was 5.2%.
- The most frequent renal complication was electrolyte disturbance (particularly hyperkalaemia) with an incidence of 12.5% followed by acute kidney injury (AKI) with an incidence of 11.0%; US populations and groups with higher prevalence of CKD had higher incidence of AKI.

Renal complications; acute kidney injury; COVID-19; meta-analysis

Introduction

Coronavirus disease 2019 (COVID-19), which is caused by severe acute respiratory syndrome coronavirus 2 (SARS CoV-2) was declared a global public health emergency on 30 January 2020. The COVID-19 pandemic has caused substantial morbidity and mortality worldwide [1] and poses the most significant modern-day public health challenge since the Spanish flu of 1918. Coronavirus disease 2019 predominantly affects the respiratory system, typically manifesting as acute respiratory distress syndrome (ARDS) and severe pneumonia in a few, whereas the majority of patients are asymptomatic or present with mild symptoms [2]. The most common symptoms of COVID-19 are fever, cough, myalgia or fatigue [3]. Older patients, males and those with pre-existing comorbidities such as cardiovascular disease (CVD), hypertension, chronic kidney disease (CKD), chronic liver disease and diabetes are reported to be more likely to be infected with

Supplemental data for this article can be accessed here.

SARS CoV-2 [4] and are at highest risk for severe illness or death [5,6]. Emerging data suggest that COVID-19 also affects multiple organs, leading to organ failure and eventually death [7]. Common cardiovascular complications reported to be associated with COVID-19 include myocardial injury and heart failure [8], which have been shown to correlate with the severity of or mortality from COVID-19 [9]. Furthermore, emerging data also suggest COVID-19 contributes to adverse renal manifestations such as acute kidney injury (AKI), which is also associated with severe COVID-19 or mortality [10]. Given the sparse data, the renal manifestations of COVID-19 are not clearly defined. Despite the rapidly growing knowledge base on the clinical course of the disease, no effective therapeutic agents have been identified. Further data on the clinical course of the disease could help in the development of effective treatment strategies. Understanding the interplay between COVID-19 and its renal manifestations could assist in the management of patients. In this context, we sought to address the following questions using a first systematic review and meta-analysis of published evidence: (i) what are the renal complications associated with COVID-19? (ii) what is the incidence of these complications? and (iii) are patients with pre-existing renal conditions more susceptible to these renal complications?

Materials and methods

Data sources and search strategy

The review was based on a predefined protocol which was registered in the PROSPERO International prospective register of systematic reviews (CRD42020186873) and it was conducted in accordance with PRISMA and MOOSE guidelines [11,12] (Supplementary materials 1–2). MEDLINE, Embase and The Cochrane library were searched from 2019 to 13 June 2020 for published studies reporting on renal complications in patients with COVID-19. We combined search terms and key words related to the population (e.g. "COVID-19", "SARS-CoV-2") and outcomes (e.g. "kidney", "renal", "acute kidney injury", "renal transplant therapy", "albuminuria") in humans, which was limited to only reports published in the English language given the potential for duplicate reporting using the same study participants [13]. The detailed search strategy can be found in Supplementary material 3. Titles and abstracts were screened for potential eligible studies following retrieval of citations. Following initial screening, full texts of potentially eligible studies were acquired for detailed evaluation. Manual scanning of key articles and review papers was conducted to identify additional articles missed by the search strategy.

Study selection and eligibility criteria

The protocol was pre-specified to include observational studies (prospective and retrospective, nested case-control and case-control designs), non-randomized clinical studies and randomized controlled trials (RCTs) which reported renal complications in patients with COVID-19. Our protocol was pre-specified to include all renal complications anticipated to be reported by studies such as AKI, proteinuria, haematuria, albuminuria, electrolyte disturbance, renal acidosis and alkalosis, need for renal replacement therapy (RRT) and kidney transplant among others. We also sought for studies reporting information on any pre-existing renal conditions (e.g. CKD, end-stage kidney disease); however, they were not included if they did not report on any renal complication. Patients must have had a period of follow-up prior to developing complications.

Data extraction and quality assessment

Using a pre-designed data extraction form, the following data were extracted from the eligible studies: author and year of publication; study characteristics (design, location and date of data collection); patient characteristics (average age, sex, percentage of males, total number of patients, pre-existing renal conditions and their counts and follow-up duration or hospital stay); and renal complications and their counts. Data were extracted and analyzed as reported. However, hyperkalaemia was reported by one study and was classified as an electrolyte disturbance to enhance consistency and enable pooling. To minimize over- and under-reporting and maintain consistency, extraction of prevalence and incidence data employed an intention-to-treat principle. Methodological quality of studies was assessed using the nine-star Newcastle-Ottawa Scale (NOS) [14], a tool which has been validated for assessing the quality of non-randomized studies.

Statistical analysis

Pooled prevalence of pre-existing renal conditions (e.g. CKD) with 95% confidence intervals (CIs) was calculated from the number of pre-existing renal

conditions/total number of patients with COVID-19 in the study. Incidence of renal complications with 95% CIs was estimated from the number of patients experiencing the specific renal complication within period of follow-up (hospital stay)/total number of patients with COVID-19. Given that the data were binary with some low counts, the Freeman–Tukey variance stabilizing double arcsine transformation [15] was used in calculating prevalence and incidence estimates as done in previous reports [16–18]. Heterogeneity was assessed and quantified using Cochrane χ^2 and I^2 statistics [19]. We also estimated 95% prediction intervals to determine the degree of heterogeneity, as they provide a region in which about 95% of the true effects of a new study are expected to be found [20,21]. Predefined study-level characteristics such as location, age and comorbidities which may explain heterogeneity were explored using stratified analysis and random effects meta-regression. STATA release MP 16 (StataCorp LP, College Station, TX, USA) was used for all statistical analyses.

Results

Study identification and selection

The process of study selection is presented in Figure 1. Overall, a total of 109 articles were identified from the search of major databases and manual scanning of reference lists of relevant articles. After initial screening based on titles and abstracts, full texts of 28 articles were retrieved for further evaluation. Six articles were excluded on the basis of (i) duplicates of the same study ($n = 4$); (ii) outcome not relevant

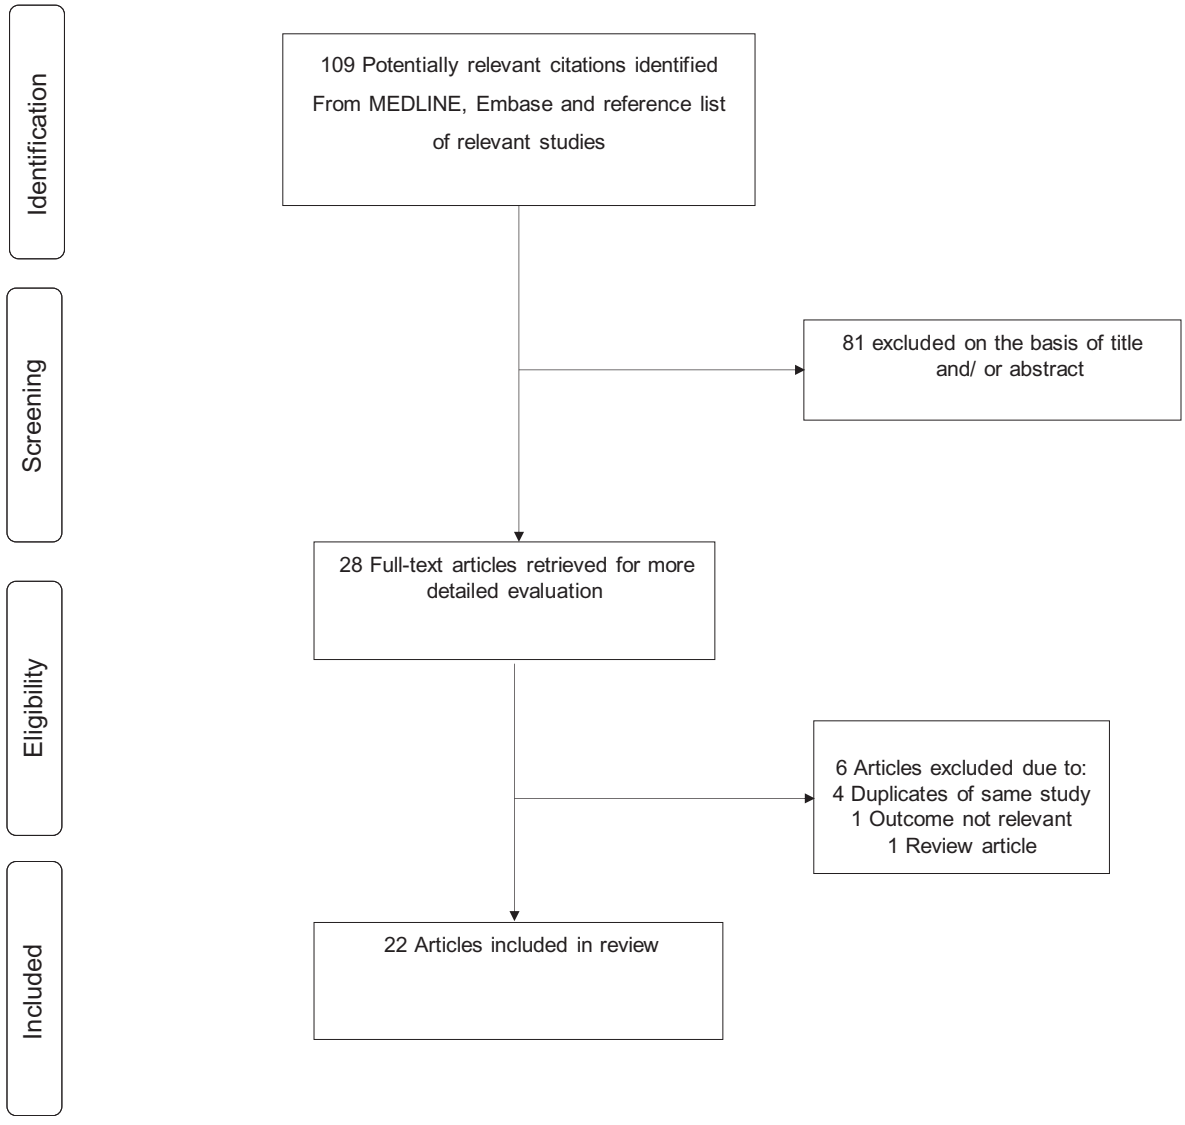

Figure 1. Selection of studies included in the meta-analysis.

($n = 1$) and (iii) review article ($n = 1$). This left a total of 22 articles for inclusion in the review [1,3,9,22–40].

Study characteristics and quality

All 22 studies were based on observational cohort designs (21 retrospective cohorts and 1 prospective cohort), altogether comprising of 17,391 patients with COVID-19 (Table 1). Sixteen studies were based in China and six based in the United States. The average age at baseline ranged from 46 to 71 years, with a weighted mean (standard deviation, SD) of 60 (5) years. All studies enrolled both male and female patients. Hospital stay or follow-up duration ranged from 2 to 28 days with a weighted mean (SD) of 7.0 (4.0) days. The overall NOS methodological quality scores of studies ranged from 4 to 6.

Prevalence of pre-existing renal conditions

Across 20 studies providing relevant data, the prevalence of pre-existing CKD in COVID-19 patients ranged from 0.7% to 47.6%, with a pooled random effects prevalence (95% CI) of 5.2% (2.8–8.1; $I^2 = 98\%$; 95% CI 97, 98%; p for heterogeneity $< .01$) (Figure 2). The 95% prediction interval for the summary prevalence was 0.0–23.1%, suggesting that the true prevalence of pre-existing CKD for any single new study will usually fall within this range. The prevalence of pre-existing end-stage kidney disease based on pooled analysis of two studies was 2.3% (1.8–2.8) (Figure 2).

Incidence of renal complications

Overhospital stays ranging from 2 to 28 days following admission, the pooled incidence for AKI ($n = 22$ studies) was 11.0% (7.4–15.1; $I^2 = 97\%$; 95% CI 97, 98%; p for heterogeneity $< .01$) (Figure 3). For 14 studies reporting data on the definition of AKI, 12 defined AKI according to Kidney Disease Improving Global Outcomes (KDIGO) criteria (Supplementary Appendix 4) [41]. The incidence of electrolyte disturbance ($n = 2$ studies), need for RRT ($n = 3$ studies) and acidosis ($n = 2$ studies) were 12.5% (10.1–15.0), 6.8% (1.0–17.0) and 5.0 (3.2–7.2), respectively (Figure 3). Based on the report by a single study, the incidence of alkalosis was 6.9 (4.5–10.6).

Given AKI was the outcome commonly reported by studies (22 studies) and with the substantial heterogeneity between contributing studies, we explored for potential sources of heterogeneity using stratified analysis and random effects meta-regression. There was

statistically significant evidence of effect modification on the incidence of AKI by location (p value for meta-regression $= 0.03$) and pre-existing CKD (p value for meta-regression $< .001$). There was no evidence of effect modification by age (Figure 4).

Discussion

In hospitalized patients with renal manifestations of COVID-19, the prevalence of pre-existing CKD was 5.2% and that for end-stage kidney disease was 2.3%. Over hospital stays ranging from 2 to 28 days, AKI was the common outcome reported by studies; howevere-lectrolyte disturbance (hyperkalaemia) was the most frequent renal complication with an incidence of 12.5% followed by AKI and RRT at 11.0% and 6.8%, respectively. Other reported complications included acidosis and alkalosis. Subgroup analyses suggested evidence of effect modification by location and pre-existing history of CKD on the incidence of AKI; the incidence of AKI was higher in the US population (than the Chinese population) and among groups with higher prevalence of pre-existing CKD (than those with lower prevalence). However, AKI incidence was comparable in younger (<60 years) and older (≥60 years) individuals.

Although COVID-19 predominantly affects the respiratory system, there is involvement of multiple organs, such as the gastrointestinal system, the cardiovascular system, the liver as well as the kidneys. These multiple organ disturbances may then interact with each other, which correlates with the severity of the disease. The virus SARS-CoV-2 is known to enter human lung cells by binding to angiotensin-converting enzyme 2 (ACE2) [42]. The multiorgan involvement of SARS-CoV-2 has been linked to the wide distribution of ACE2 in the body; the highest expression of ACE2 is found in the ileum and kidneys [43,44]. In the kidney, ACE2 is expressed on several cells including mesangial cells, podocytes, parietal epithelium of the Bowman's Capsule, and the collecting ducts [45]. Although the mechanisms for the renal manifestations of COVID-19 are still elusive, a complex multifactorial pathway has been proposed and it includes the

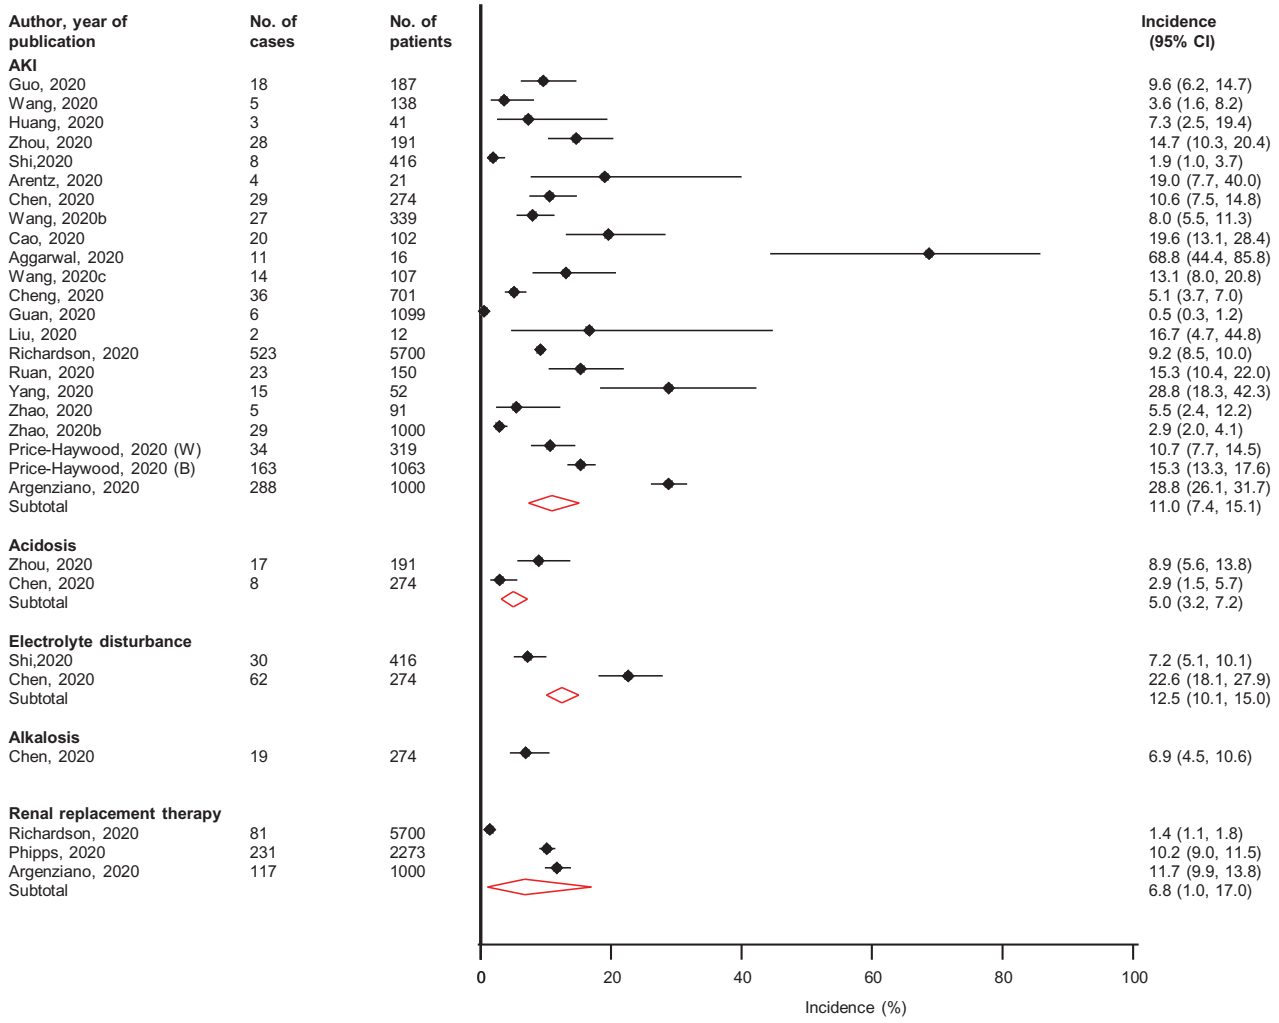

Figure 3. Incidence of renal complications in COVID-19 patients. AKI: acute kidney injury; CI: confidence interval (bars).

following: (i) direct viral involvement and replication in the kidneys leading to dysfunction [46]; (ii) local disruption in renin–angiotensin–aldosterone system (RAAS) homeostasis [44]; (iii) lung protective fluid management strategy during treatment of ARDS [40] and (iv) as a result of a systemic inflammatory response "cytokine storm" [44].

COVID-19 represents a great medical challenge and appears to have multisystem effects which include renal manifestations. The current data based on up-to-date evidence suggest that AKI is commonly reported as a complication among patients with COVID-19. In addition to pre-existing CKD being associated with severe illness or death in COVID-19 [5], it is also an independent risk factor for AKI [47]. Consistently, our study findings showed that groups with higher prevalence of pre-existing CKD might have higher incidence of AKI. Emerging evidence also suggests that renal manifestations of COVID-19 are also associated with increased risk of severe COVID-19 and fatal outcomes [10,30]. Monitoring of markers of kidney function during hospitalization for COVID-19 could help in the identification of patients who at high risk for worse outcomes, to enable early and more aggressive intervention. The current evidence provides better insight on the extent of kidney damage by COVID-19. However, more work is needed to help us better understand the pathophysiology underlying renal manifestations of COVID-19, to help in the identification of effective management strategies.

We have provided up-to-date data on the different renal manifestations of COVID-19 as well as their incidence rates. In addition, prevalence estimates of common renal comorbidities have also been presented. Other strengths of this study include ability to synthesize the data quantitatively as well as exploration for sources of heterogeneity. There were some limitations which were mostly inherent and included (i) inability to generalize the findings and the possibility of patient overlap, given that the majority of studies were based in China; (ii) the definition of CKD and classification into stages were not reported by included studies; (iii) a number of studies did not report on the definition for AKI; however, the majority defined AKI according to

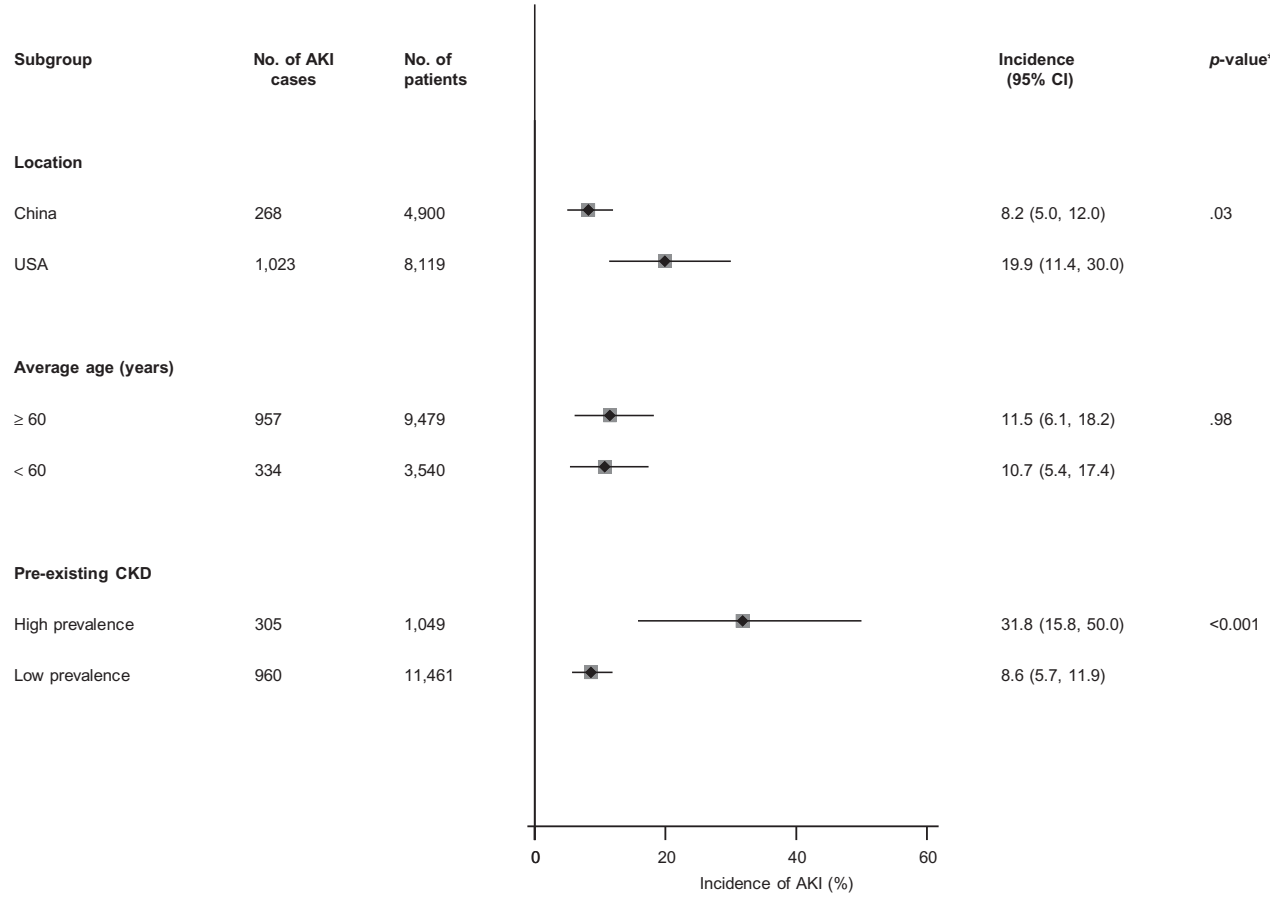

Figure 4. Incidence of acute kidney injury in COVID-19 patients, by clinically relevant characteristics. AKI: acute kidney injury; CI: confidence interval (bars); CKD: chronic kidney disease; *p value for meta-regression.

KDIGO criteria; (iv) studies reporting on the complications of acidosis and alkalosis did not distinguish whether these outcomes were of renal or lung origin; (v) one study reported an outcome of electrolyte disturbance, but did not provide a definition of this; (vi) the potential for differences in the timing during hospitalisation with regards to assessment of complications; and (vii) the low sample sizes of some of the studies.

Conclusion

Aggregate up-to-date synthesis of the existing literature suggests that the most frequent renal complications among patients hospitalized with COVID-19 are electrolyte disturbance (particularly hyperkalaemia), AKI and the need for RRT. Aggressive monitoring and management of these renal complications may help in the prediction of more favourable outcomes.
