ABSTRACT

Secretory pore-forming proteins (PFPs) have been identified in organisms from all kingdoms of life. Our studies with the toad species *Bombina maxima* found an interaction network among aerolysin family PFPs (af-PFPs) and trefoil factors (TFFs). As a toad af-PFP, BmALP1 can be reversibly regulated between active and inactive forms, with its paralog BmALP3 acting as a negative regulator. BmALP1 interacts with BmTFF3 to form a cellular active complex called $\beta\gamma$ -CAT. This PFP complex is characterized by acting on endocytic pathways and forming pores on endolysosomes, including stimulating cell macropinocytosis. In addition, cell exocytosis can be induced and/or modulated in the presence of $\beta\gamma$ -CAT. Depending on cell contexts and surroundings, these effects can facilitate the toad in material uptake and vesicular transport, while maintaining mucosal barrier function as well as immune defense. Based on experimental evidence, we hereby propose a secretory endolysosome channel (SELC) pathway conducted by a secreted PFP in cell endocytic and exocytic systems, with $\beta\gamma$ -CAT being the first example of a SELC protein. With essential roles in cell interactions and environmental adaptations, the proposed SELC protein pathway should be conserved in other living organisms.

INTRODUCTION

Endocytosis and exocytosis play fundamental roles in cell physiology

Endocytosis and exocytosis are fundamental in cell physiology for the exchange of information and material between cells and external environments as well as among cells. Macropinocytosis, phagocytosis, and receptor-mediated endocytosis are three major forms of endocytosis (Doherty & McMahon, 2009; Palm, 2019; Palm & Thompson, 2017; Scita & Di Fiore, 2010; Swanson & King, 2019; Wu et al., 2014). Different membrane organelles exist in distinctive endocytic pathways, including macropinosomes, phagosomes, and endosomes. Together with lysosomes, they are collectively referred to as endolysosomes. They are highly dynamic and play key roles in endocytosis and diverse cellular processes, including nutrient acquisition, membrane protein recycling, intracellular signaling, cell migration, metabolic adjustment, infection and immunity, development, and cell death (Antonescu et al., 2014; Cossart & Helenius, 2014; Cullen & Steinberg, 2018; Klumperman & Raposo, 2014; Moreno-Layseca et al., 2019; Palm & Thompson, 2017; Wang et al., 2018).

Cell exocytosis is a basic process in the homeostasis of cell physiology. The secretion of extracellular vesicles (EVs) comprised of exosomes and microvesicles, a heterogeneous

DOI: 10.24272/j.issn.2095-8137.2020.358

group of cell-derived membranous structures, is an important aspect of cell exocytosis. The secretion of EVs can be viewed as the means of selective elimination of material from cells, as well as a new mode of intercellular communication (Russell et al., 2019; Van Niel et al., 2018). EVs are attributed numerous roles in regulating both physiological and pathological functions (Lindenbergh & Stoorvogel, 2018; Oggero et al., 2019; Yáñez-Mó et al., 2015).

Pore-forming proteins

Pore-forming proteins (PFPs) exist in a water-soluble monomeric form, and many are secreted out of cells (Dal Peraro & Van Der Goot, 2016). After undergoing extensive conformational change under specific conditions, these non-classic membrane proteins can form transmembrane pores (channels) of various size (1 to 30 nm). Based on the second structure of pores formed on the membrane, PFPs can be divided into two groups: i.e., α -helix and β -barrel PFPs. Pore-forming toxins (PFTs) are PFPs from microbes and are virulence factors for infection (Dal Peraro & Van Der Goot, 2016; Omersa et al., 2019). Knowledge on PFPs derived from plants and animals primarily includes their roles in cell death, including Bcl-2 proteins, MACPF/perforin proteins, and gasdermins (Banjara et al., 2020; Broz et al., 2020; Lukoyanova et al., 2016).

Aerolysin is a β -PFT produced by the bacterium *Aeromonas hydrophila* (Fivaz et al., 2001). The aerolysin domain is defined according to its structural similarity to the transmembrane domain of aerolysin (Szczeny et al., 2011). Proteins with an aerolysin fold can be found in all organisms. Particularly, a diverse array of aerolysin family PFPs (af-PFPs, previously referred to as aerolysin-like proteins, ALPs) harboring an aerolysin domain fused with other domains have been identified in various plant and animal species (Dang et al., 2017; Szczeny et al., 2011; Zhang, 2015).

Amphibian research model

Amphibians exhibit physiological traits in common with all vertebrates, including mammals. Our knowledge on many aspects of animal physiology has been gained from the study of amphibians. Historically, at least eight Nobel prizes have involved the use of amphibian models. Currently, amphibians are also used to answer fundamental questions on developmental biology, regeneration, genetics, and toxicology (Burggren & Warburton, 2007; Liu et al., 2016; Tandon et al., 2017; Yokoyama et al., 2018).

Here, we review the discovery of the af-PFP and trefoil factor (TFF) complex (named $\beta\gamma$ -CAT) from the Chinese red belly toad (*Bombina maxima*) as well as its cellular actions and biological functions. We then propose that this secreted PFP complex represents a hitherto unknown secretory endolysosome channel (SELC) pathway, with $\beta\gamma$ -CAT as the first example of a SELC protein. Its regulatory assembly mode, cell action mode, and endocytosis and exocytosis regulation reflect interaction between cells and the environment, as well as new regulatory strategies and

effectors in adapting to the environment. The putative conservation of the $\beta\gamma$ -CAT-like SELC pathway in other living organisms is also discussed. Future directions and challenges in this newly emerging field are also addressed below.

SECRETORY PFP COMPLEX $\beta\gamma$ -CAT AND ITS CELLULAR ACTIONS

Discovery of af-PFP and TFF complex $\beta\gamma$ -CAT

Af-PFPs and TFFs are major components in *B. maxima* skin secretions: The toad species *B. maxima* was selected as our research model. In addition to the rich existence of well-known hormone-like and antimicrobial peptides, af-PFPs, TFFs, oxidoreductases, immunoglobulin G (IgG) fragment crystallizable (Fc)-binding protein, and albumin have also been identified in its skin secretions (Zhang, 2015; Zhao et al., 2014). We previously isolated a protein complex composed of an af-PFP ($\beta\gamma$ -crystallin domain fused with an aerolysin domain, termed BmALP1 α -subunit) and a TFF (BmTFF3 β -subunit), which was subsequently named $\beta\gamma$ -CAT to reflect its domain composition (Liu et al., 2008). This protein complex formed membrane pores with a functional diameter of about 1.5–2.0 nm (Gao et al., 2011b; Liu et al., 2008).

Regulated assembly of $\beta\gamma$ -CAT complex relies on environmental cues: BmALP1 and BmTFF3 are products of two genes with distinct secretory pathways (Liu et al., 2008; Wang et al., 2020). For the assembly and dissociation of complexes in toads, positive and negative control methods are required. Indeed, as a novel af-PFP, BmALP3 is characterized by a lack of membrane pore formation capacity (Wang et al., 2020). BmALP3 senses environmental oxygen tension and acts as a negative regulator of the $\beta\gamma$ -CAT complex. These two af-PFPs (i.e., BmALP1 and BmALP3) contain a conserved cysteine in their C-terminal regions. BmALP3 binds to a homodimer to oxidize BmALP1 through disulfide bond exchange, thereby forming a BmALP1 homodimer and polymer. This effect causes the $\beta\gamma$ -CAT complex to dissociate and lose its biological activity (Wang et al., 2020).

Double receptor binding pattern for $\beta\gamma$ -CAT endocytosis: $\beta\gamma$ -CAT exerts biological actions intracellularly via its secretory components. Cell surface molecules mediate the binding and endocytosis of $\beta\gamma$ -CAT. An interaction between $\beta\gamma$ -CAT and acidic glycosphingolipids (AGSLs) was uncovered. Further detailed study revealed that the aerolysin-like domain of $\beta\gamma$ -CAT, but not the $\beta\gamma$ -crystallin domain, specifically binds to gangliosides, while the BmTFF3 subunit of the complex binds to sulfatides, thus revealing a double receptor binding pattern (Guo et al., 2019). Most AGSLs exist in membrane lipid raft microdomains (McGonigal et al., 2019). Accordingly, disruption of lipid rafts can impair the actions of $\beta\gamma$ -CAT (Guo et al., 2019).

As $\beta\gamma$ -CAT is an exogenous factor to mammals, who therefore lack relevant control or regulatory systems, $\beta\gamma$ -CAT shows potent biological activities, including *in vivo* and *in vitro* toxicity to mammals and mammalian-derived cell lines (Gao et al., 2011a; He et al., 2008a, 2008b; Qian et al., 2008a,

2008b). However, growing experimental evidence suggests that this PFP complex is not a typical biological “toxin” or “weapon” for preventing potential attack by other living organisms, but is an important endogenous physiological element in *B. maxima*, in which it plays a fundamental physiological function (Li et al., 2017; Xiang et al., 2014).

Cellular actions of $\beta\gamma$ -CAT and biological outcomes

Amphibian skin exhibits important physiological functions, like water economy, respiration, metabolite exchange, and immunity. Skin is constantly confronted by a complex mixture of potentially injurious factors and environmental interactions to ensure sufficient uptake of water, electrolytes, and oxygen (Haslam et al., 2014; Jørgensen, 2000; Varga et al., 2018). Obviously, mucosal barrier maintenance and immune defense are essential in the amphibian life cycle. Accordingly, we investigated and determined that the PFP complex $\beta\gamma$ -CAT indeed plays an active role in these biological requirements.

Stimulating macropinocytosis: In nucleated cells, $\beta\gamma$ -CAT α -subunit BmALP1 is rapidly endocytosed with large intracellular vacuole (>200 nm) formation, in which neutral red uptake of the cells increases in a $\beta\gamma$ -CAT dose-dependent manner, indicating its capacity to stimulate cell macropinocytosis. Protein endocytosis is important for cellular functions, such as inducing cell detachment and migration (Liu et al., 2008). In addition, $\beta\gamma$ -CAT stimulates macropinocytosis in dendritic cells (DCs) (Deng et al., 2020). The capacity of $\beta\gamma$ -CAT to induce and participate in cell macropinocytosis has been also determined in cells from *B. maxima*, including peritoneal cells (Li et al., 2017) and epithelial cells from the toad (Zhao et al., unpublished observation). These results reveal the capacity of the protein in stimulating cell endocytosis in the form of macropinocytosis.

Enhancing antigen presentation via endolysosome modulation: $\beta\gamma$ -CAT enhances the macropinocytosis of DCs, thereby increasing the internalization of ovalbumin (antigen) (Deng et al., 2020). At the same time, $\beta\gamma$ -CAT and ovalbumin are rapidly endocytosed along the DC endocytic pathway. The acidification of the antigen-containing vesicles in DCs is neutralized, and the pores formed by the $\beta\gamma$ -CAT α -subunit (BmALP1) serve as channels to deliver endocytic antigen peptides to the cytoplasm. Specifically, $\beta\gamma$ -CAT stimulates robust EV release from DCs, which rapidly activates T lymphocytes. Finally, the action of $\beta\gamma$ -CAT leads to both cellular and humoral immune responses *in vitro* and *in vivo* (Deng et al., 2020). Interestingly, the release of EVs promoted by $\beta\gamma$ -CAT has also been observed in *B. maxima* peritoneal cells (Li et al., 2017).

Neutralizing endocytic organelle acidification to counteract intracellular pathogens: Upon intracellular infection with *Listeria monocytogenes* in *B. maxima* peritoneal cells and fibroblasts, the $\beta\gamma$ -CAT α -subunit (BmALP1) co-localizes with the bacteria in endocytic vesicles. The presence of BmALP1 and its pore formation result in the acidification and neutralization of intracellular pathogen-containing vesicles. Furthermore, $\beta\gamma$ -CAT stimulates cell exocytosis, and

protein treatment leads to augmentation of non-lytic expulsion of pathogen-containing vesicles. Thus, *in vivo*, $\beta\gamma$ -CAT effectively protects the toad against *L. monocytogenes* infection (Li et al., 2017).

Causing lysosome destabilization to activate inflammasomes: In the face of extracellular bacterial infection, the $\beta\gamma$ -CAT α -subunit (BmALP1) is rapidly endocytosed in *B. maxima* peritoneal cells. It is oligomerized and forms pores along the endocytic pathway. Lysosomal destabilization and cathepsin B release occur. This action results in the activation of inflammasomes and subsequent interleukin-1 β (IL-1 β) maturation and release. Accordingly, in toad and mouse peritoneal infection models, $\beta\gamma$ -CAT greatly accelerates bacterial clearance and increases animal survival (Xiang et al., 2014).

Promoting tissue repair: $\beta\gamma$ -CAT exhibits a strong ability to promote tissue repair. For example, consistent with the above studies, inflammasomes are activated and IL-1 β is rapidly released upon protein treatment in murine cutaneous injury models (Gao et al., 2019). The healing process is characterized by accelerated re-epithelialization, ameliorated dermal edema, and scar-less healing. Thus, $\beta\gamma$ -CAT may fulfill the physiological requirement of rapid tissue repair and skin permeability for amphibian survival at the same time (Gao et al., 2019).

Taken together, the secreted PFP complex $\beta\gamma$ -CAT assembles according to changes in environmental cues and acts on AGSLs in lipid rafts to induce endocytosis, especially macropinocytosis, in sensitive cells. Oligomerization and pore formation of the $\beta\gamma$ -CAT α -subunit (BmALP1) along the endocytic pathway result in the formation of channels on the endolysosome membranes, which facilitate the exchange of substances between endocytic vesicles and cytoplasm. The content and biochemical properties of these intracellular vesicles can be modulated. Depending on various cellular and environmental conditions, $\beta\gamma$ -CAT activity can lead to diverse cellular responses and biological outcomes (Li et al., 2017; Wang et al., 2020; Xiang et al., 2014).

$\beta\gamma$ -CAT REPRESENTS A NOVEL STRATEGY AND EFFECTOR IN CELL PHYSIOLOGY

Secretory endolysosome channel (SELC) pathway in cell endocytic and exocytic systems

The experimental evidence associated with $\beta\gamma$ -CAT combined with the necessity of cell physiology led us to propose the hypothesis of secretory endolysosome channels (SELCs) and related cellular pathways (SELC pathways), which function in cell physiology and homeostasis as well as in cell adaptations to environmental variations. $\beta\gamma$ -CAT is the first example of a SELC protein.

Major components in SELC pathway: The central element of the SELC pathway is a secretory SELC PFP that can form an endolysosome channel, and which belongs to af-PFPs, other PFP families, or unidentified proteins with pore forming capacity (Figure 1). In the extracellular environment, the SELC

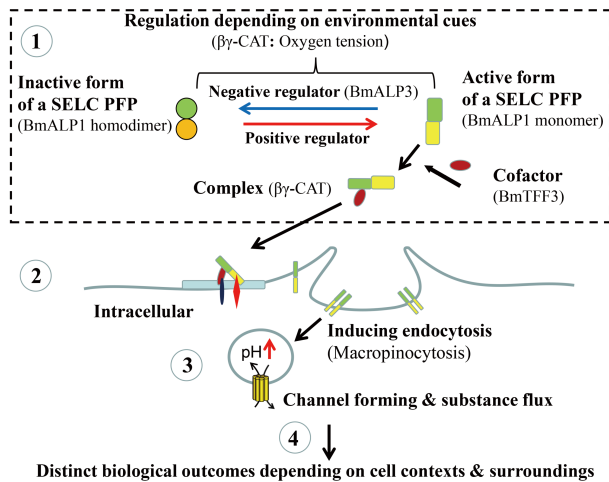

Figure 1 Proposed SELC pathway based on $\beta\gamma$ -CAT evidence

There are four main steps in the proposed SELC pathway. Related elements of $\beta\gamma$ -CAT pathway are bracketed. (1) In extracellular surroundings, a SELC PFP can be reversibly converted between inactive or active forms by specific negative or positive regulators in response to variations in environmental conditions (like oxygen tension, water balance, pH, nutrients, metabolites, pathogens). Active form of SELC PFP may or may not be necessary to interact with a cofactor to form a cellular active complex. $\beta\gamma$ -CAT is the former case. (2) Active PFP or the complex binds membrane receptor(s) and stimulates endocytosis, especially macropinocytosis. (3) PFP then oligomerizes and forms channels on endolysosomes to facilitate material exchange. (4) Actions result in distinct biological outcomes depending on cell contexts and environment, see text.

PFP can be reversibly converted between inactive and active forms. There should be specific sensors and regulators that can sense and integrate environmental conditions (like oxygen tension, water balance, pH, nutrients, metabolites, or pathogens) to regulate the conversion of the SELC PFP negatively or positively. In the case of $\beta\gamma$ -CAT, BmALP3 senses environmental oxygen tension. Furthermore, active SELC PFPs may or may not need to interact with a cofactor chaperon to form an active PFP complex, with $\beta\gamma$ -CAT being the former case (Figure 1).

Manipulation of endocytic and exocytic systems by endolysosome channels: An active SELC protein or its complex (like $\beta\gamma$ -CAT) stimulates and participates in endocytosis, especially in the form of macropinocytosis, which, in turn, facilitates the uptake of extracellular substances. SELC proteins then oligomerize and form pores on endolysosomes, which can be used as channels for material exchange between endocytic organelles and cytoplasm (Figures 1, 2).

Depending on the various temporal and spatial parameters of distinct cell contexts as well as the conditions of cell surroundings, several cellular action modes can be proposed after SELC protein endocytosis (Figure 2). First, macropinocytosis induced by the SELC protein could result in

Figure 2 SELC proteins manipulate endocytosis and exocytosis

Depending on distinct cell contexts and environments, cellular action of SELC proteins is well adapted for material uptake and exchange as well as vesicular transport either within a cell or across cells. (1) Macropinocytosis induced by SELC protein results in uptake of external material, including water and solutes (nutrients or antigens). Solute may be processed and/or hydrolyzed in endolysosomes, and channels formed by SELC protein can mediate the release of resulting products from vesicles to cytoplasm. (2) Channels formed by SELC protein on endolysosomes can mediate material exchange, which results in biochemical property modulation of vesicles (e.g., pH and/or content), leading to specific cellular responses. (3) Furthermore, exocytosis can be induced and modulated in the presence of a SELC protein, which plays a role in transcytosis of cell surrounding materials (like lipids with a carrier), secretion of intracellular materials, and waste expulsion. (4) SELC proteins may participate in the recycling and redistribution of membrane components, like functional proteins and lipid components.

the uptake of external materials (like antigens, water, and solutes). The channels formed in endolysosomes by the SELC protein could mediate the release of acquired solutes, which may have been hydrolyzed and processed into unfolded small molecular mass components in the organelles to cytoplasm. Second, SELC proteins could lead to the modification of the biochemical properties of SELC-containing vesicles (like pH and/or content) due to their channel formation on endolysosomes, resulting in specific cellular reactions. Third, exocytosis could be induced and modulated in the presence of SELC proteins, which function in the transcytosis of materials surrounding cells, such as lipids bound in a carrier (like albumin), as well as the secretion of intracellular materials. Fourth, SELC proteins may participate in the recycling and redistribution of membrane-integrated components, like functional proteins and lipid components (Figure 2).

Necessity of SELC pathway in cell physiology

Characteristics of SELC pathway: SELC proteins have their own intrinsic advantages and characteristics in the communication between cells and their surroundings. (1) A SELC protein could be constitutively expressed *in situ* or could circulate in biological fluids, extending their actions remotely.

(2) Depending on environmental cues, the related sensors and regulators of a SELC protein (Figure 1) could immediately manipulate the state of the protein to fulfill specific cell requirements with high efficiency, especially in emergency conditions. (3) An activated SELC protein could act in specific and distinct cell regions in a temporal and spatial manner to trigger proper cellular responses. (4) SELC proteins may undertake direct vesicular transportation of cargo, which can be released within cells or transported across cells in their native forms and/or processed products within endolysosomes (Figure 2).

Roles in cell physiology and homeostasis: The SELC pathway may play active and essential roles in cell interactions with and adaptations to the environment surrounding the cell. As exemplified by $\beta\gamma$ -CAT and depending on cell contexts and environmental cues, the action of SELC proteins could lead to diverse cellular responses and biological outcomes. It can be reasonably predicted that the SELC pathway is necessary and functions in external material uptake (like oxygen, water, nutrients, antigen, and other necessary substances) and vesicular transport, immune surveillance and responses, metabolic adjustment, and exocytosis modulation (including expulsion of metabolites, poisons, and waste as well as unconventional secretion).

Collaboration with classic membrane-integrated proteins: Classic membrane proteins, like receptors, ion channels, and transporters, are responsible for communication between intracellular and extracellular environments. The SELC pathway conducted by a SELC protein and accessory components in the extracellular environment may function as the humoral regulatory network of cell endocytosis and exocytosis. Secreted PFPs like the SELC protein $\beta\gamma$ -CAT may also be viewed as secretory vesicular transporters. Obviously, this humoral system could collaborate with classic membrane-integrated proteins in cell physiology and homeostasis. It is possible that the endocytosis stimulated by a SELC protein plays a role in the sorting of specific plasma membrane elements, such as functional integrated proteins or lipid components, which help to regulate cell responses to environmental variations (Figure 2).

It can be speculated that in undifferentiated cells, like oocytes, stem cells, progenitor cells, and end differentiated cells like keratinocytes in the epidermis, classic membrane-integrated proteins may be in short states, and the humoral system may be more significant and effective. For instance, the SELC pathway may play an essential role in the process of nutrient acquisition from egg white and yolk in proliferating embryonic cells of oviparous animals.

SELC protein candidates

In various living organisms, SELC protein candidates may come from secretory PFPs. These secretory PFPs may belong to different PFP families. In addition, new proteins with potential membrane pore-forming capacities are awaiting identification.

$\beta\gamma$ -CAT is the pioneer SELC protein member. Interestingly,

$\beta\gamma$ -CAT-like PFPs, which are members of af-PFPs, are highly conserved within various species of the same class of plants and animals (Szczyzny et al., 2011; Zhang, 2015). However, these proteins are characterized by low sequence similarity, especially in the aerolysin domain (<20% similarity), raising difficulties in resolution of their conservation by traditional methods (Szczyzny et al., 2011; Zhang, 2015). Alternatively, many proteins are grouped into af-PFPs based on their 3D structures, though they are elusive at the sequence level (Cirauqui et al., 2017; De Colibus et al., 2012).

Plant af-PFPs: In a single plant species, there are multiple gene copies encoding af-PFPs, which are composed of two N-terminal agglutinin domains and a C-terminal aerolysin-like domain and are well conserved in various species along plant evolutionary lineages. Sixteen genes encoding af-PFPs have been retrieved from the cucumber genome (Dang et al., 2017). Overexpression of a flower-specific af-PFP in *Rumex acetosa* alters flower development and induces male sterility in transgenic tobacco (Manzano et al., 2017). A gene encoding an af-PFP protein confers resistance to fusarium head blight, a devastating disease of wheat and barley (Rawat et al., 2016).

Animal af-PFPs: Lysenin and biomphalysin are af-PFPs found in the earthworm *Eisenia fetida* and snail *Biomphalaria glabrata*, respectively (Galinier et al., 2013; Sekizawa et al., 1997). Mutation of Lin-24, an af-PFP derived from *Caenorhabditis elegans*, causes abnormal vulva development, leading to a failure to lay eggs (Galvin et al., 2008). Ep37 proteins from the newt *Cynops pyrrhogaster* are homologous to BmALP1, which is proposed to be involved in epidermal development (Ogawa et al., 1997, 1998). Fish af-PFPs, including *Danio rerio* Din1 (Jia et al., 2016), *Thalassophryne nattereri* natterins (Magalhães et al., 2005), and those from lampreys (Pang et al., 2017; Wu et al., 2017), are proposed as defense molecules in fish immune systems.

The regulatory C-terminal cysteine residue in the $\beta\gamma$ -CAT α -subunit (BmALP1), which links protein machinery with *B. maxima* skin respiration, is highly conserved from fish to reptiles, suggesting that the SELC pathway may play a role in hypoxia adaptation (Wang et al., 2020). Interestingly, the conserved cysteine site is mutated to a serine residue in birds. Fish and amphibians live in water and sensing environmental oxygen tension and initiating proper cellular responses are essential in their life cycle. Accordingly, the regulatory site is a cysteine residue in these animals. Birds live on land with rich oxygen and a well-evolved lung respiration system, and actively sensing oxygen tension change may not be fatal. Serine substitution can convert the regulatory model into a new adaptation (Wang et al., 2020).

It should be noted that SELC proteins may not necessarily be af-PFP family members. In contrast, not all af-PFP members from eukaryotic organisms may function as a SELC protein. Obviously, in the evolutionary process, af-PFPs in different organisms have evolved to play distinct biological functions. Besides bacterial virulence factors, some af-PFPs have been recruited to animal venom glands as toxins (Zhang,

2015).

Do $\beta\gamma$ -CAT-like af-PFPs exist in mammals?: Though af-PFPs are well conserved and easily identified from fish to birds, their existence in mammals remains elusive. Until now, no homologue to the aerolysin domain has been found in mammalian species following sequence-based search methods. In contrast, the domains that are often fused with the aerolysin domain to form af-PFPs in vertebrates, such as the $\beta\gamma$ -crystallin, lectin, and Ig-like domains, are well conserved in mammals. Specifically, the β -subunit of $\beta\gamma$ -CAT is a TFF, which are well conserved in mammals (Zhang et al., 2011). There are several possibilities to explain this phenomenon.

First, as mentioned above, af-PFPs are characterized by low sequence similarity with each other, which may lead to missing homologous sequences during searching (Cirauqui et al., 2017; Szczesny et al., 2011). Accordingly, the discovery of potential structural similarities shared by mammalian proteins with $\beta\gamma$ -CAT-like PFPs depends on comparison of their 3D structures.

Second, for unknown reasons, other protein family members may have evolved to be SELC proteins in mammals along the evolutionary process. As mentioned above, SELC proteins may not necessarily be af-PFP family members. These alternative proteins may be responsible for cellular actions similar to those of $\beta\gamma$ -CAT-like SELC proteins. It is worth noting that human RegIII α (also known as HIP/PAP) possesses a previously unappreciated pore forming capacity for the C-type lectin family (Mukherjee et al., 2014). α -Synuclein, a presynaptic enriched protein, has been found to form pores in lipid membranes (Schmidt et al., 2012). Of course, other secretory proteins with pore forming capacities are awaiting future identification.

Third, the strategies and effectors involved in cellular interactions with and adaptations to the environment via modulation of cell endocytic and exocytic pathways by secretory elements, like SELC proteins, may not have been suitable and have been lost in mammals. As discussed above, the SELC pathway proposed here should represent one of the primary strategies and protein working networks in cell physiology because they interact with the surrounding environment as well as among cells themselves. Accordingly, the sudden and total disappearance of SELC proteins seems improbable. In our opinion, the first two possibilities are more likely the case in mammals.

Differences between physiological SELC protein $\beta\gamma$ -CAT and bacterial aerolysin toxin

$\beta\gamma$ -CAT is the first example of a SELC protein. Though the $\beta\gamma$ -CAT α -subunit (BmALP1) is a bacterial PFP aerolysin family member, its nomenclature only reflects that the protein contains a membrane insertion domain similar to that of the aerolysin toxin. These two proteins are different in their molecular compositions, regulatory and activation patterns, cell targets, cellular acting pathways, and pathophysiological relevance.

Activation mechanism: Aerolysin is a bacterial single gene

product that is activated via proteolytic cleavage of a C-terminal fragment by host proteases (Van Der Goot et al., 1994). Comparatively, the regulatory manner of $\beta\gamma$ -CAT appears to be more meticulous. The initial action of the $\beta\gamma$ -CAT α -subunit (BmALP1) needs a cofactor, i.e., BmTFF3, which is a distinct gene product secreted by a different pathway. Consistent with its physiological requirements, BmALP1 is reversibly regulated by its paralog BmALP3 depending on environmental redox states, like oxygen tension (Wang et al., 2020).

Cellular targets and actions: Glycosylphosphatidylinositol (GPI)-anchored proteins act as membrane receptors to mediate aerolysin action, whereas the SELC protein $\beta\gamma$ -CAT interacts with membrane AGSLs in a double binding pattern (Guo et al., 2019). Unlike aerolysin, which forms pores on the host cell plasma membrane (Gurcel et al., 2006), $\beta\gamma$ -CAT α -subunit (BmALP1) acts on cell endolysosomes. $\beta\gamma$ -CAT is the first example of an endogenous PFP that stimulates the production and release of functional exosome-like EVs via the endosomal system, which differs from the plasma membrane-derived microvesicles stimulated by bacterial PFTs (Gurcel et al., 2006; Romero et al., 2017).

Biological functions and significance: The biological outcomes of these two PFPs are different. For example, aerolysin perturbs cell tight junction integrity and induces barrier defects in intestinal epithelial cells for the purpose of invasion (Bücker et al., 2011). In contrast, the SELC protein $\beta\gamma$ -CAT maintains mucosal barrier integrity by accelerating re-epithelialization during tissue repair (Gao et al., 2019). The divergence of these two proteins is consistent with the fact that aerolysin is a virulence factor for bacterial invasion (Chang et al., 1997), whereas $\beta\gamma$ -CAT is a physiological component of *B. maxima* (Gao et al., 2019; Li et al., 2017; Wang et al., 2020; Xiang et al., 2014).

FUTURE DIRECTION AND CHALLENGES

Evolutionary conservation of and variation in $\beta\gamma$ -CAT-like SELC pathways

Investigations on evolutionary conservation of $\beta\gamma$ -CAT-like SELC pathways in other vertebrates is an important future challenge. Predictably, variations with specific physiological relevance may have occurred in the SELC pathway in different vertebrates, which deserves further study. Many possibilities could be postulated for the physiological functions of the SELC pathway in vertebrates. Key points should focus on the fundamental processes related to animal interactions with and adaptations to distinct environments. These include, but are not limited to, external material uptake (e.g., water, oxygen, nutrients, antigens) and vesicular transport, as well as regulation of immune responses and maintenance of mucosal barrier function, metabolic flexibility, and exocytosis modulation.

Future study should help illustrate how the SELC pathway in vertebrates is linked to basic cellular processes (endocytosis and exocytosis) and to fundamental issues in animal

interactions with and adaptations to various environments, especially the water-oxygen-metabolism axis in the vertebrate life cycle and conservation and variation within different animal classes along evolutionary processes.

SELC protein $\beta\gamma$ -CAT in *B. maxima* skin water-oxygen balance

Water and oxygen are essential for life. Given that toads, such as *B. maxima*, live on land and in water, their skin is an important organ in water uptake and loss as well as respiration (gas exchange). While oxygen is abundant on land, dehydration is a real challenge. In contrast, low oxygen tension (potential hypoxia) can be problematic in water environments. Accordingly, water-oxygen balance is an essential issue for toads. As major protein components in skin secretions, af-PFPs and TFFs likely play direct and indirect roles in essential physiological processes, including the following.

Function in water uptake and maintenance: The SELC protein $\beta\gamma$ -CAT in toads can induce cell macropinocytosis. Reasonably, this property of the protein machinery may function for water uptake to counteract dehydration under hypertonic irritation. Furthermore, internalization and recycling of aquaporins between the plasma membrane and endosomal compartments play roles in controlling water uptake and maintenance (Shibata et al., 2014; Suzuki et al., 2015). Potential endocytosis and re-distribution of aquaporins induced by $\beta\gamma$ -CAT may also modulate water uptake and loss in toads. Thus, the potential actions of other PFP homologues of $\beta\gamma$ -CAT should be considered in future study.

In many species of amphibian, the skin surface is covered with a lipid layer, which prevents evaporative water loss (EWL) on land (Barbeau & Lillywhite, 2005; Centeno et al., 2015; Haslam et al., 2014; Sadowski-Fugitt et al., 2012). The SELC protein $\beta\gamma$ -CAT and/or its PFP homologues may modulate the lipid barrier in a temporal and spatial manner via endocytosis and vesicular trafficking to facilitate water balance. In *B. maxima*, albumin is expressed in the skin and is widely distributed around the membranes of epithelial layer cells and within the stratum spongiosum of the dermis (Zhang et al., 2005). Albumin may participate in the modulation of skin lipids by acting as a lipid carrier and could be transported via $\beta\gamma$ -CAT- and/or PFP homologue-induced macropinocytosis.

Function in respiration: The oxygen tension-dependent control of the SELC protein $\beta\gamma$ -CAT by its paralog BmALP3 links protein machinery with skin respiration (Wang et al., 2020). Albumin expressed in *B. maxima* skin is distinct from that in serum by binding to a haem b cofactor (Zhang et al., 2005). One of possible functions of the haem b cofactor in toad skin albumin may be in cutaneous gas exchange. Whether albumin transport mediated by $\beta\gamma$ -CAT and/or PFP homologues from external environments to intercellular spaces can facilitate gas exchange in toad skin is an important question.

Hypoxia and inflammation are intertwined at the molecular, cellular, and clinical levels (Eltzschig & Carmeliet, 2011;

Medzhitov, 2008). In some cell contexts under specific environmental conditions, $\beta\gamma$ -CAT can activate inflammasomes to induce inflammatory responses (Xiang et al., 2014), which should dilate blood vessels and increase blood flow to facilitate gas exchange, especially under acute hypoxic conditions. The possible link between $\beta\gamma$ -CAT and the activation and translocation of hypoxia-inducible factor 1 (HIF-1) deserves further investigation.

Membrane trafficking and recycling of endosomes play active roles in epithelial remodeling, during which cells change shape and position while maintaining cell to cell contact (Jouette et al., 2019; Le Droguen et al., 2015). It is speculated that the endocytosis and re-distribution of cell adhesion proteins and cytoskeleton elements induced by $\beta\gamma$ -CAT and/or its PFP homologues may lead to cell shape changes and remodeling of epidermal cell layers to modulate water-oxygen balance in toad skin.

Roles in material acquisition and vesicular transport

In cell metabolism: Endocytosis in the form of macropinocytosis can uptake extracellular material (solutes in fluid phase) (Lim & Gleeson, 2011; Palm, 2019). As mentioned, the SELC protein $\beta\gamma$ -CAT may be viewed as a novel type of secretory vesicular transporter. It is highly possible that this af-PFP and its homologues participate in the uptake and vesicular transport of external material and/or membrane components (Figure 2). Furthermore, $\beta\gamma$ -CAT and its PFP homologues may facilitate cells to acquire macromolecules as nutrients as well as other necessary solutes in the cell life cycle, and the related significance in cell metabolism and biomass building deserves further study. On the other hand, due to the molecular pathway shown in Figure 2, these PFPs may play a role in vesicular transport and output of cell metabolites, which also requires further investigation.

In cell migration: Macropinocytosis is involved in cell motility (Donaldson et al., 2009; Gu et al., 2011; Llanses Martinez & Rainero, 2019). $\beta\gamma$ -CAT promotes cell migration rapidly in wound healing (Gao et al., 2019). The potential regulation of cell adhesion and cytoskeleton components via endocytic and exocytic recycling triggered by $\beta\gamma$ -CAT could modulate cell shape and cytoskeleton network to facilitate cell migration.

In transcytosis: Transcytosis is a strategy used by multicellular organisms to move material between two environments while maintaining cellular barrier functions (Conner & Schmid, 2003; Tuma & Hubbard, 2003). The neutralization of the acidification of endolysosomes along the endocytic pathway by $\beta\gamma$ -CAT could prevent lysosome degradation of material in the $\beta\gamma$ -CAT-containing vesicles, which may result in material transcytosis via EV release (Figure 2).

SELC protein $\beta\gamma$ -CAT directly acts on EVs

EVs circulate in all biological fluids and can trigger biological responses at a distance. To deliver their cargo into recipient cells, the cells engulf EVs via receptor-mediated endocytosis,

macropinocytosis, or membrane fusion (Meldolesi, 2018; Record et al., 2018; Van Niel et al., 2018). However, many molecules in EVs, such as cytokines, growth factors, and metabolites, act on their targets on the cell surface or exhibit biological effects in the extracellular environments. Conceivably, there may be alternative ways *in vivo* for the release of specific EV cargo into extracellular fluids, which could be mediated by secretory PFPs under specific regulation.

Accordingly, it would be interesting to study the direct action of the SELC protein $\beta\gamma$ -CAT and its PFP homologues on EVs and their physiological relevance. Under proper conditions, the oligomerization and channel formation of PFPs in EVs may lead to the spatiotemporal release of EV cargo molecules to fit specific biological requirements *in situ* (Figure 3). Alternatively, the channels formed by PFPs may also serve to uptake specific material in cell surroundings, and the cell may acquire the materials taken up by fusion with the vesicles containing PFP channels, serving as an alternative way for cells to acquire extracellular materials (Figure 3). Thus, SELC proteins could extend their functions as secretory EV channels.

Mechanism of SELC protein $\beta\gamma$ -CAT endocytosis

The SELC protein $\beta\gamma$ -CAT exerts cellular effects after endocytosis in the form of macropinocytosis. Macropinocytosis is believed to be a signal- and actin-dependent process that normally occurs in response to growth factor stimulation (Lim & Gleeson, 2011; Palm, 2019; Swanson & King, 2019). Interestingly, $\beta\gamma$ -CAT targets AGSLs in lipid rafts to initiate stimulation and participation in macropinocytosis. The signals

Figure 3 Proposed direct action of SELC PFP on EVs

EVs comprised of exosomes and microvesicles circulate in biological fluids. They bear cargo molecules, like proteins and metabolites. Membrane active secretory PFPs, like SELC protein $\beta\gamma$ -CAT, can be tightly regulated by specific regulators relying on distinct micro-environmental conditions (Figure 1). Subsequent oligomerization and channel formation of PFPs in EVs may lead to release of EV cargo molecules in a temporal and spatial manner to fit specific cellular and biological requirements *in situ*. Alternatively, channels formed by PFP can also be used to take up specific substances in the surrounding environment, and cells can obtain these substances by fusing with vesicles containing PFP channels, functioning as an alternative way for cells to acquire extracellular material.

downstream of the lipid components and their relationship with cytoskeleton rearrangement are important open questions. Thus, the putative variation between classic macropinocytosis and that induced by $\beta\gamma$ -CAT could be expected and should be emphasized.

Membrane pore/channel properties of SELC protein $\beta\gamma$ -CAT

A question that needs to be addressed is the selectivity of channels formed by the SELC protein $\beta\gamma$ -CAT for specific substance(s) in living cells. The pore size formed by an af-PFP is around 1.5 nm (Jia et al., 2016; Liu et al., 2008; Podobnik et al., 2016), similar to that formed by aerolysin. Aerolysin pores have been applied as nano-sensors in biomolecular detection and identification (Ouldali et al., 2020; Wang et al., 2018). Peptides, unfolded proteins, nucleic acids, and polysaccharide chains can be transported through aerolysin pores (Ouldali et al., 2020; Wang et al., 2018). This raises the possibility that these substances could potentially be transported through the pore formed by the endogenous SELC protein $\beta\gamma$ -CAT.

After endocytosis with $\beta\gamma$ -CAT, the solutes in extracellular fluids could be transported to the cytosol or intercellular spaces (Figure 2). The transport of antigen peptides to the cytosol via the $\beta\gamma$ -CAT pore has been observed previously (Deng et al., 2020). Alternatively, substances in cytosol, like unfolded proteins, nucleic acids, or lipids, could be transported to $\beta\gamma$ -CAT-vesicles for subsequent vesicular transport within or out of the cell (Figure 2).

Regulation of SELC protein $\beta\gamma$ -CAT in various stages

The SELC protein $\beta\gamma$ -CAT is likely to be tightly regulated, however, this requires further investigation. In the extracellular milieu, positive and negative regulatory elements exist for the assembly and disassociation of the $\beta\gamma$ -CAT complex; for example, its paralog BmALP3 (Wang et al., 2020). In addition, putative positive regulator(s) for the promotion of $\beta\gamma$ -CAT assembly is the focus of ongoing studies.

In the process of $\beta\gamma$ -CAT oligomerization, micro-environmental parameters, like membrane lipid compositions or pH, may influence PFP oligomerization and channel formation. Weak acidic environments (pH 5.5–6.5) facilitate $\beta\gamma$ -CAT α -subunit (BmALP1) oligomerization (Ye, 2020), in accordance with a fact that $\beta\gamma$ -CAT α -subunit (BmALP1) prefers to oligomerize and form channels on endolysosomes (Li et al., 2017; Xiang et al., 2014).

Growing evidence suggests that some unknown elements may regulate the opening or closing of channels formed by the SELC protein $\beta\gamma$ -CAT. The $\beta\gamma$ -CAT α -subunit (BmALP1) is an af-PFP with two $\beta\gamma$ -crystallin domains fused at its N-terminal part, which can bind to nucleotides (He et al., 2008b). Adenosine triphosphate (ATP) and guanosine triphosphate (GTP) block fluorescent dye efflux out of the BmALP1 channels, implying that nucleotide binding may lead to channel closure (Ye, 2020).

The C-terminal cysteine residue in the $\beta\gamma$ -CAT α -subunit

(BmALP1), which is conserved in vertebrate af-PFPs, is the site involved in the regulation of $\beta\gamma$ -CAT assembly in the extracellular milieu (Wang et al., 2020). However, after BmALP1 oligomerization and channel formation on endolysosomes, it is also possible that the cysteine residue acts as a key site in sensing intracellular conditions (like redox states) and in regulating the properties of the channels formed.

Potential application of SELC protein $\beta\gamma$ -CAT

Molecular probe in cell biology: As the first example of a SELC protein, the SELC pathway of $\beta\gamma$ -CAT suggests that the protein may be an extremely valuable molecular probe, especially in cell biology. Following the cellular path of $\beta\gamma$ -CAT could result in exciting discoveries concerning endocytosis and exocytosis.

The $\beta\gamma$ -CAT α -subunit (BmALP1) can exist in multiple forms, including monomers, homodimers, and BmTFF3 complexes (Liu et al., 2008; Wang et al., 2020). Consequently, how to detect active $\beta\gamma$ -CAT with physiological functions is an important question. Quantitative hemolysis assay could help detect active $\beta\gamma$ -CAT. Alternatively, monoclonal antibodies against $\beta\gamma$ -CAT could be developed to detect the biologically active complex. In addition, as $\beta\gamma$ -CAT works in the form of oligomers in the membrane, it would be necessary to determine the number of monomers that form oligomers, which is a subject of ongoing study.

Therapeutic agent: $\beta\gamma$ -CAT is highly effective at stimulating immune responses to counteract pathogen infections (Deng et al., 2020; Li et al., 2017; Xiang et al., 2014) and to promote wound healing (Gao et al., 2019). $\beta\gamma$ -CAT may reduce excessive epithelial hyperplasia and prevent scar formation by the activation of cell death signals (Gao et al., 2019). These properties make the protein an ideal candidate as a therapeutic agent in clinical settings. However, $\beta\gamma$ -CAT drug development is currently hindered by the relatively low quantity obtained by purification from skin secretions.

Adjuvant in vaccine preparation: A big challenge for a vaccine adjuvant is its ability to induce cellular immunity against extracellular pathogens or malignant cells. DC cross-presentation plays a vital role in vaccine development (Coffman et al., 2010; Ho et al., 2018). The SELC protein $\beta\gamma$ -CAT may strongly stimulate MHC-I-mediated cross presentation. Particularly, $\beta\gamma$ -CAT stimulates robust EV release from DCs, which rapidly activates T lymphocytes (Deng et al., 2020). These properties render $\beta\gamma$ -CAT a potent adjuvant candidate.

CONCLUDING REMARKS

Secretory PFPs have been identified in organisms from all kingdoms of life. Most studies on PFPs have focused on their role in cell death, including virulence factors of pathogens or effectors of host immune systems (Dal Peraro & Van Der Goot, 2016; Delbridge et al., 2016; Kovacs & Miao, 2017; Liu & Lieberman, 2020; Merle et al., 2015; Zhang, 2015). To benefit from amphibian research models, sufficient amounts of

af-PFP and TFFs can be identified and purified from the skin secretions of *B. maxima*, especially in their natural form. Studies have illustrated an unexpected interaction network among extracellular af-PFPs (paralog regulation of BmALP1 by BmALP3) and TFFs (formation of SELC protein complex $\beta\gamma$ -CAT) depending on environmental conditions.

Importantly, one of the formation modes of regulated SELC protein $\beta\gamma$ -CAT is oxygen tension dependent. The PFP complex acts in the endocytic pathway by channel formation on endolysosomes, including stimulating cell macropinocytosis, which can facilitate substance uptake and exchange as well as vesicular transport. On the other hand, cell exocytosis would be induced and/or modulated in the presence of SELC proteins depending on cell contexts and surroundings. These cellular effects are in accordance with the biological requirements of the toad in material acquisition and exchange, vesicular transport, water-oxygen balance, and metabolic adjustment, whilst maintaining mucosal barrier homeostasis and fulfilling immune defense.

Our research identified an unexpected SELC pathway conducted by a secretory PFP in cell endocytic and exocytic systems with relevant physiological effects. With this newly obtained evidence, future studies should illustrate the possible conservation and variation of these novel cellular strategies and SELC pathways in interactions with and adaptations to the environment in other living organisms (especially vertebrates) and clarify their physiological relevance. Such studies will eventually lead to novel strategies and methods to combat human diseases, like cancer, atherosclerosis, neurodegeneration, and immune abnormalities.
