Abstract

In this study, integrated experimental tests and computational modeling are proposed to investigate the failure mechanisms of open-hole cross-ply carbon fiber reinforced polymer (CFRP) laminated composites. In particular, we propose two effective methods, which include width-tapered double cantilever beam (WTDCB) and fixed-ratio mixed-mode end load split (FRMMELS) tests, to obtain the experimental data more reliably. We then calibrate the traction-separation laws of cohesive zone model (CZM) used among laminas of the composites by leveraging these two methods. The experimental results of fracture energy, i.e. G_{Ic} and G_{Tc}, obtained from WTDCB and FRMMELS tests are generally insensitive to the crack length thus requiring no effort to accurately measure the crack tip. Moreover, FRMMELS sample contains a fixed mixed-mode ratio of G_{IIc}/G_{Tc} depending on the width taper ratio. Examining comparisons between experimental results of FRMMELS tests and failure surface of B-K failure criterion predicted from a curve fitting, good agreement between the predictions and experimental data has been found, indicating that FRMMELS tests are an effective method to determine mixed-mode fracture criterion. In addition, a coupled experimental-computational modeling of WTDCB, edge notched flexure, and FRMMELS tests are adopted to calibrate and validate the interfacial strengths. Finally, failure mechanisms of open-hole cross-ply CFRP laminates under flexural loading have been studied systematically using experimental and multi-scale computational analyses based on the developed CZM model. The initiation and propagation of delamination, the failure of laminated layers as

well as load-displacement curves predicted from computational analyses are in good agreement with what we have observed experimentally.

1. Introduction

Carbon fiber reinforced polymer (CFRP) laminated composites are widely used in structural design of automotive components because of their high specific strength, high specific stiffness, and other desirable characteristics. Although their physical and mechanical properties have made them a superior candidate in many applications, their failure/damage properties and behaviors dictate, to a large extent, their limitations in these applications. One of the most important damage mechanisms, commonly referred to as delamination, is caused by debonding of two adjacent plies of the laminate [1, 2]. Furthermore, composite structures usually experience mixed-mode delamination in the real engineering applications, for instance, a mixed normal stress- and shear stress-led delamination. Thus, good understanding of the onset and propagation of the mixed-mode delamination as well as the underlying mechanisms is critical to guide and promote the applications of CFRP laminated composites.

Most numerical and theoretical analyses on the delamination growth are based on fracture mechanics approach, which basically evaluates the energy release rate. For instance, virtual crack closure technique (VCCT), first formulated by Rybicki and Kanninen [3], is computationally simple for calculation of energy release rate in flat laminates with an embedded delamination. However, it is not an efficient method for the simulation of delamination growth because it requires complex moving mesh techniques to advance the crack front when the energy release rate reaches its critical value. Compared to VCCT, cohesive zone model (CZM) incorporates both damage and fracture mechanics theories and thus allows investigation of both the onset and propagation of delamination in the same analysis. The CZM method presents fracture as a gradual phenomenon in which separation takes place across a cohesive zone modeled interface represented by a local traction-separation relationship[4–13]. Williams et al. [14] introduced various simplified forms of traction-separation laws, and bilinear CZM has been the most often used one due to its simplicity and good accuracy in the prediction of delamination growth in laminated composites [15]. Furthermore, CZM method offers significant flexibility to consider the mixed-mode failure, especially in the delamination case [16].

The penalty stiffness, interfacial strength and fracture toughness are three parameters of mixed-mode CZM that often determine the accuracy of the computational analysis by using cohesive elements. Among these parameters, the fracture toughness of different failure modes can be obtained experimentally through standardized tests, such as the double cantilever beam (DCB, mode-I) [17], end-notched flexure (ENF, mode-II) [18], and mixed-mode bending (MMB, mixed-mode) [19]. Recently, researchers have also designed and

employed innovative specimens to conduct fracture toughness tests, such as reinforced double cantilever beam [20], adhesive strip modified double cantilever beam [21], tapered double cantilever beam [22], crack lap shear [23, 24], asymmetric double cantilever beam [25], single leg bend [26, 27], and four-point bending tests [28]. However, some of the abovementioned test specimens have intrinsic shortcomings. For example, some of them produce only limited mixed-mode conditions and some need complex fixtures for loading [29]. Generally speaking, a suitable fracture toughness test specimen should have some advantages, such as simple configuration, inexpensive preparation method, ease of loading set-up, and ability of providing accurate experimental results. Compared to the fracture toughness, it is much less straightforward to determine the interfacial strengths and the penalty stiffness for accurate computational modeling, and no standard tests are available for the direct measurement of interfacial strengths and the penalty stiffness is usually a non-physical numerical parameter [30]. Meanwhile, in order to determine relative displacements at the crack tip, those above standardized fracture toughness tests require the use of external equipment such as digital image correlation (DIC) or linear voltage differential transformer (LVDT) [31–33] for monitoring the crack position throughout the test, which inevitably introduces certain degree of operator dependency and measurement errors. Experimental difficulties associated with the existing measurement methods have been reported, most often related to inaccurate results in the measurement of very small crack tip separations [33]. In summary, despite recent progress, simple and accurate methods for determining the traction-separation law of mixed-mode CZM are extremely important and urgently needed for effective design and analysis of different composite materials and structures.

Additionally, the presence of irregularities in the geometry of a composite structure, such as holes, notches, and changes in cross-section area causes stress concentrations. During the manufacturing of a laminated composite structure, open holes are usually employed, for example, for joining several elements or for access (doors, windows, vents, etc.) [34]. Due to the prominent stress concentration phenomena around the fastener hole, open hole is usually the weakest section in the laminate structure. Statistics show that approximately 70% of the failure of structures is initiated from open hole [35]. This issue is more serious to composite joints, and the stress concentration induced by holes usually results in delamination and a dramatic reduction in mechanical performance. There are two main reasons: (1) composites are generally brittle materials, showing nearly linear characteristics before failure, which means little local yielding and stress redistribution around fastener holes; (2) composites are anisotropic materials, which are susceptible to delamination and sensitive to environmental conditions. The anisotropy will lead to a high-stress concentration and low transverse strength of joints [35]. In recent years, studies have focused on the mechanical behavior of open-hole composite laminates by carrying out experimental tests [36–39]. In addition, recent studies have presented innovative ways to predict delamination damage in open-hole tension (OHT) [40–42], open-hole compression (OHC) [43, 44], and impact-damaged open-hole composite laminates [12, 45, 46]. In engineering practice of laminated composite parts, the major internal stresses are induced by bending loads [3], which may cause delamination in the laminates. Consequently, it is necessary to conduct experimental and computational research on the flexural behavior of open-hole cross-ply laminates for the acquisition of valid data to provide support for composite joints.

In the current work, with the aim to determine the accurate traction-separation law of mixed-mode CZM, an integrated method of both experimental tests and computational modeling are proposed. Specifically, first, width-tapered double cantilever beam (WTDCB) and fixed-ratio mixed-mode end load split (FRMMELS) tests are carefully designed and utilized to characterize the mode-I fracture toughness, mixed-mode fracture toughness, and Benzeggagh-Kenane (B-K) fracture criterion [47]. Second, computational modeling of WTDCB, edge notched flexure (ENF), and FRMMELS tests are carried out to calibrate the inter-laminar interfacial strengths and get validated by the experimental results. Finally, to obtain a more comprehensive understanding of the failure mechanisms in the open-hole cross-ply laminates under four-point bending load, an integrated experimental and multi-scale computational framework based on mixed-mode CZM is established. In the multi-scale computational model, open-hole cross-ply laminates are modeled by means of an elastic-plastic-damage model by combining the Liu-Huang-Stout (or LHS) yield criterion [48] and RVE-based failure criteria [13, 49]. ABAQUS VUMAT subroutine is adopted to calculate the composite properties degradation. The interface between the adjacent layers is modeled by means of mixed-mode CZM. Additionally, the corresponding damage initiation and propagation as well as load-carrying capacity of the open-hole cross-ply laminates under four-point bending load are compared and analyzed through both computational and experimental results.

2.   Description of mixed-mode CZM

The initial response of the CZM is considered to be fully linear until the condition defined by the damage criterion is met. Damage initiation is based on a quadratic stress criterion applied on the interface, as described by Ye [24] and Brewer [25]. This criterion determines damage onset at the interface, and the degradation starts at a specific point. Moreover, it contains strong correlation with stress values when delamination failure starts. Such criterion states damage onset when the criterion is set to 1.

$$\left(\frac{\langle\sigma_n\rangle}{N_n}\right)^2 + \left(\frac{\langle\tau_s\rangle}{S_s}\right)^2 + \left(\frac{\langle\tau_t\rangle}{S_t}\right)^2 = 1 \tag{1}$$

where the terms σ_n, τ_s, and τ_t are the normal and shear stresses transferred by the interface, respectively. The terms N_n, S_s, and S_t stand for interface strength in tension and shear, respectively. Symbol $< >$ represents Macaulay brackets, indicating that a compressive normal stress does not contribute to the damage initiation.

Once the damage initiates, the stress transferred through the crack is reduced depending on an interface damage parameter d. The corresponding traction-separation law is expressed by:

$$\sigma_n = (1 - d)K\bar{\sigma}_n, if \ \bar{\sigma}_n > 0$$

$$\tau_s = (1 - d)K\bar{\tau}_s \tag{2}$$

$$\tau_t = (1 - d)K\bar{\tau}_t$$

where K is the interface stiffness, which should be large enough to keep a stiff connection between two neighboring sublaminates; $\bar{\sigma}_n, \bar{\tau}_s,$ and $\bar{\tau}_t$ are the stress components from the traction-separation law if failure has yet happened. The damage variable d is a function of the displacement jump and accounts for the reduction in the load-carrying ability of the material as a result of the damage [50].

Camanho and Davila [21] also recommended using effective displacement in order to capture the damage evolution at the interface under a combination of normal and shear strains.

$$\delta_m = \sqrt{\delta_n^2 + \delta_s^2 + \delta_t^2} \tag{3}$$

In this case, a damage evolution variable d is introduced, and Eqn. (4) shows its value for a linear softening law, as the one showed in Fig. 1. d is defined as a relationship between the displacement jumps.

$$d = 0; if\ \delta_m^{max} < \delta_m^0$$

$$d = \frac{\delta_m^f\left(\delta_m^{max} - \delta_m^0\right)}{\delta_m^{max}\left(\delta_m^f - \delta_m^0\right)}; if\ \delta_m^0 < \delta_m^{max} < \delta_m^f \tag{4}$$

$$d = 1; if\ \delta_m^f < \delta_m^{max}$$

where δ_m^0 and δ_m^f denote the damage onset and final displacement jumps at mixed-mode loading. δ_m^{max} is the maximum mixed-mode displacement jump in loading history, the threshold value of the necessary displacement jump to accumulate damage under unloading or reloading conditions. d is monotonically increase to show the damage status of material: d = 0 for elastic phase; $0 < d < 1$ for softening phase; and $d = 1$ for the completely debonded condition.

Damage evolution in the present model is governed by the energy released throughout the whole damage process, i.e., fracture energy. This energy is represented in the area below the traction-separation curve. The relationships of such energy to the mixed mode are governed by the fracture criterion proposed by Benzeggagh and Kenane [47]

$$G_{Tc} = G_{Ic} + (G_{IIc} - G_{Ic})\left(\frac{G_{IIc}}{G_{Tc}}\right)^m, G_{Tc} = G_{Ic} + G_{IIc} \tag{5}$$

where G_{Tc} is the total specimen (mixed mode) strain energy release rate; G_{Ic} and G_{IIc} are the critical fracture toughness values for pure mode I and mode II fracture, which are to be determined by experimental tests; m is the BK material parameter.

3. Determination of material parameters of CZM by experiments and computational modeling

3.1. Material

In current work, laminated samples for mode-I, mode-II and mixed-mode fracture toughness testing are molded with A42 carbon fiber and thermoset epoxy resin with a fiber volume fraction of 51.4%. Both carbon fiber and epoxy resin are supplied by Dow Chemical Company. The samples are cut from plaques, and the requisite mid-plane notch is formed by a razor-blade tapping method. Initial pre-crack formed by insertion of razor blade into mid-plane of sample, which is treated as the initial delamination. Mechanical properties of the laminated samples are listed in Table 1.

3.2. Inter-laminar fracture toughness measurement

3.2.1. Mode-I fracture toughness tests

3.2.1.1. Width-tapered double cantilever beam (WTDCB) tests: For mode-I fracture toughness testing, a novel WTDCB specimen geometry, as shown in Fig. 2(a), is proposed. The width taper of this specimen can be designed in such way that the change of compliance with change of crack length, dC/da, is a constant [51]. The WTDCB specimen compliance is found to be [52]:

$$C = \frac{\delta}{P} = \frac{12}{E_{11}h^3}\left[\left(a^2 - S^2\right)k + \frac{2S}{3B}\right] + \frac{12}{5hG_{13}}\left[\ln\left(\frac{a}{S}\right) + \frac{S}{B}\right] \tag{6}$$

Various symbols in Eqn. (6) correspond to WTDCB specimen geometry and loading as shown in Fig. 2(a). Specifically, δ is the end deflection of the specimen under applied load P, E_{11} is the longitudinal elastic modulus of the composite material; G_{13} is the shear modulus of the composite material in plane of bending; a is the crack length; S is the tab length; B is the tab width; k is the width taper ratio expressed as $k = a/b = 1/2\tan(\theta/2)$, i.e., ratio of crack length (a) to specimen width (b) of the DCB specimen at the crack tip; θ is the angle of taper and $2h$ is the specimen thickness.

Mode I strain energy release rate (G_{Ic}) from Eqn.(6) at any given instant can be expressed as [52, 53]:

$$G_{Ic} = \frac{1}{2}\frac{P^2}{b}\frac{dC}{da} = \frac{12P^2k^2}{E_{11}ha^2}\left[k\left(\frac{a}{h}\right)^2 + \frac{1}{10}\left(\frac{E_{11}}{G_{13}}\right)\right] \approx \frac{12P^2k^2}{E_{11}h^3} \tag{7}$$

It is worth noting that the approximate expression for G_{Ic} in Eqn. (7) above is independent of crack length a, thus making it easier to obtain G_{Ic} value without the extra effort in

requiring continuous measurement of crack length. This is further discussed in sub-section 3.2.1.3.

WTDCB specimen test setup is shown in Fig. 2(b). The tests are conducted in a servo-hydraulic tensile testing machine with continuous recording of the load-displacement response of the test specimen. Two piano hinges are mounted on the surfaces at the notched end of the specimen. The other ends of the piano hinges are clamped by a pair of loading fixtures mounted on the test machine. WTDCB specimen dimensions used in the present work have L=114 mm, B=21.6 mm, S=19.1 mm, S_1=6.4 mm, initial crack length a_0=20 mm, thickness $2h$=2.3 mm, and width taper ratio $k = 2.26$.

The specimen is tested at a constant displacement rate of 0.5 mm/min. Load-displacement curves exhibit a constant load 'plateau' during crack extension, indicating that the crack growth occurs in a stable manner under displacement rate controlled loading, as shown in Fig. 3(a). Instantaneous G_I versus displacement traces can be readily obtained from the load-displacement curves using Eqn. (7), as shown in Fig. 3(b). Because of the small-scale variation in the G_I-displacement curves, it is more reliable to take a mean value from such curves (see the dashed line in Fig. 3(b)).

However, some tests exhibit higher initial peak load (unstable crack growth) because of razor blade pre-crack length being insufficient and not extended past the fillet region of the coupon, as shown by the black trace in Fig. 3(a). Therefore, we neglect the initial unstable portion of the test to obtain reasonable and consistent values of G_{Ic}. From four WTDCB tests, the average G_{Ic} of WTDCB tests is 534 J/m^2 and coefficient of variation (CoV) is 12.3%.

3.2.1.2.   Fixed-width double cantilever beam (FWDCB) tests: In order to confidently claim that the WTDCB tests can be taken as an accurate method for characterizing mode-I fracture toughness G_{Ic}, a typical FWDCB test specimen made from the same CFRP composites are tested. The crack length is monitored using ARAMIS DIC technique. Note that FWDCB specimen geometry is often employed in mode I fracture toughness testing of composites due to its general simplicity of fabrication [54, 55]. In the case of the FWDCB specimen shown in Fig. 4(a), the specimen compliance C is expressed as [56]:

$$C = \frac{\delta}{P} = \frac{24}{E_{11}b}\left[\frac{1}{3}\left(\frac{a}{h}\right)^3 + \frac{1}{10}\left(\frac{E_{11}}{G_{13}}\right)\left(\frac{a}{h}\right)\right] \approx \frac{8a^3}{E_{11}bh^3} \tag{8}$$

G_{Ic} can be expressed in terms of the specimen compliance C as:

$$G_{Ic} = \frac{1}{2}\frac{P^2}{b}\frac{dC}{da} = \frac{12P^2}{E_{11}hb^2}\left[\left(\frac{a}{h}\right)^2 + \frac{1}{10}\left(\frac{E_{11}}{G_{13}}\right)\right] \approx \frac{12P^2a^2}{E_{11}b^2h^3} \tag{9}$$

where δ, P, E_{11}, G_{13}, a, b and h have the same nomenclature as noted earlier for the WTDCB test specimen geometry (see Fig. 4(a)).

The FWDCB specimens are prepared in accordance with ASTM D5528–94A standard [17]. The edge of the specimens is painted with a random black speckle pattern on a white background in order to monitor the crack tip displacement field by means of a DIC system. Two cameras from a DIC stereo system are used to monitor the strain field in the crack tip region as shown in Fig. 4(b). FWDCB specimen dimensions used are L=120 mm, with initial crack length a_0=20 mm, b=25 mm, and $2h$=2.3 mm. The specimen is loaded with a constant displacement rate of 0.5 mm/min. The corresponding applied load and displacement are measured according to the above ASTM standard.

A representative load-displacement curve obtained from the test machine is presented in Fig. 5. The load-displacement curve shows a linear loading path until pre-crack initiation occurs followed by a nonlinear softening as the crack extends. We can observe that the load-displacement is not ideally smooth after the peak load. The fluctuation in the load-displacement curve is accompanied by unstable crack growth, which introduces uncertainty in the measurement of crack length.

The crack tip location for FWDCB specimen is monitored using DIC technique and detailed crack growth information is presented in Fig. 6(a)–(d). In addition, instantaneous crack length is utilized to plot G_I versus crack length (or R-curve), as shown in Fig. 6(e). Results of the critical strain energy release rate G_{Ic} are obtained by taking an average value (i.e., dashed line in Fig. 6(e)) from the R-curve. The instantaneous G_I as a function of displacement of the material, per Eqn. (9), is shown in Fig. 6(f). From four FWDCB tests, the average experimental result of G_{Ic} for FWDCB tests is 522 J/m^2 with CoV=19.7%.

3.2.1.3.   Assessment of WTDCB tests: As discussed in Section 3.2.1.1 and 3.2.1.2, the average experimental values of G_{IC} are similar from the two tests (534 J/m^2 for WTDCB versus 522 J/m^2 for FWDCB) with a much larger CoV in FWDCB tests compared to WTDCB tests (12.3% for WTDCB versus 19.7 % for FWDCB). Compared to traditional FWDCB specimen, WTDCB specimen is generally insensitive to the crack length. As a result, the calculation of G_{Ic} can be simplified by continuously recording the applied load and end displacement only. This avoids the tedious measurement of crack length at the crack tip. In general, measurement of the crack length in the traditional FWDCB tests is not always accurate. Numerous factors impede accurate measurement of the crack length, such as the difficulty in observing the crack and confirming the crack tip location, which leads to large scatters in experimental data as noted earlier. Thus, WTDCB specimen proposed in this study offers an easier and more accurate means to determine the mode I inter-laminar fracture toughness of CFRP composites.

3.2.2.   Mode-II fracture toughness tests—For the mode-II tests, the commonly employed ENF specimen is utilized as there are no better candidates in terms of easy setup and accuracy. The ENF specimen geometry and test setup is shown in Fig. 7(a). The specimens are prepared in accordance with ASTM D7905/D7905M [18]. The length (2L) is 50.8 mm, width (b) is 20 mm and the thickness (2h) is 2.3 mm. An initial crack length of a =0.5L=12.7 mm is chosen to avoid the effects of stress concentrations at the rollers and to minimize the measurement errors.

The specimen compliance is expressed as [56]:

$$C = \frac{\delta}{P} = \frac{1}{8bh}\left[\frac{2L^3 + 3a^2}{E_{11}h^2} + \frac{12L + 9a}{5G_{13}}\right] \quad (10)$$

The compliance method is again invoked to obtain an expression for G_{IIc}:

$$G_{IIc} = \frac{1}{2}\frac{P^2}{b}\frac{dC}{da} = \frac{9P^2}{16E_{11}bh}\left[\left(\frac{a}{h}\right)^2 + \frac{1}{5}\left(\frac{E_{11}}{G_{13}}\right)\right] \approx \frac{9P^2a^2}{16E_{11}b^2h^3} \quad (11)$$

Tests are conducted in a servo-hydraulic load frame under conditions of displacement rate control with a constant speed of 0.025 mm/min. Unlike the Mode-I DCB tests, the Mode-II ENF tests generally lack a character of stable crack growth. The load-displacement curve is one shows a steep drop in load at first release, followed by a monotonically declining load as the crack is extended further, as shown in Fig.7(b). Tests generally exhibit only peak-load behavior before sudden release. Hence, only the peak load at the instant of crack propagation is used to calculate the G_{IIc}. In addition, the ENF tests are coupled with DIC allowing measurement of the crack tip shear displacement during test, as shown in Fig. 7(c)–(d). For ENF tests, a total of six sets of tests are performed, and the average experimental result of G_{IIc} is 913 J/m^2 with CoV=17.6%.

3.2.3. Mixed-mode fracture toughness tests

3.2.3.1.   Fixed-ratio mixed-mode end load split (FRMMELS) tests: Popular mixed-mode tests are crack lap shear [23, 24], asymmetric double cantilever beam [25], single leg bend [26, 27], and four-point bending tests [28], but the most universally accepted is the mixed-mode bend test [57, 58]. Due to disadvantages associated with these existing tests, none of them is considered to be an optimal mixed-mode test solution for the evaluation of flexural behavior of CFRP composites. In this study, a new FRMMELS specimen geometry is employed to measure the mixed-mode fracture toughness. This geometry is a modified version of the end load split (ELS) test [59] where the inter-laminar crack in a beam type specimen is forced to propagate under variation of mixed mode depending on the crack length. The geometry of FRMMELS specimen used here is the same as WTDCB tests in terms of tapered width, as shown in Fig. 8(a). FRMMELS specimen dimensions used here are $L = 114$ mm, $B = 21.6$ mm, $S = 19.1$ mm, $2h = 2.3$ mm, initial crack length $a_0 = 20$ mm, and width taper ratio $k = 2.26$. The FRMMELS tests are conducted under the displacement rate controlled condition with a constant speed of 0.25 mm/min. A representative load-displacement curve obtained from the test is shown in Fig. 8(b).

The compliance of the FRMMELS specimen is expressed as:

$$C = \frac{\delta}{P} = \frac{k}{2\kappa h G_{13}}\left[1 + \ln\left(\frac{L^2}{s(L-a)}\right)\right] + \frac{k}{4E_{11}h^3}\left(3L^2 + 42La - 21a^2 - 3s^2\right)$$
$$+ \frac{2s^3}{4E_{11}Bh^3} + \frac{s}{2\kappa BhG_{13}}$$

(12)

where the usual nomenclature δ, *P, L, a, B, s* and *2h* stand for end deflection, applied load, span between the fixed and simple loading points, crack length, loading tab width, loading tab length, and total specimen thickness, respectively, and *k* is the Timoshenko shear coefficient (κ=5/6 for rectangular cross section). The elastic parameters are shear modulus G_{13} and longitudinal elastic modulus E_{11}.

Applying the compliance method, one obtains the total strain energy release rate as:

$$G_{Tc} = \frac{P^2 k^2}{4h}\left[\frac{6}{5G_{13}}\left(\frac{1}{L-a}\right)^2 + \frac{21}{E_{11}h^2}\right] \approx \frac{21P^2 k^2}{4E_{11}h^3}$$

(13)

The peak load is used to calculate G_{Tc}, and the average G_{Tc} of four FRMMELS tests is 788 J/m^2 with CoV=3.0%. The FRMMELS specimen not only resembles pure mode-I WTDCB specimen, but also, with a few modifications, a mixture of mode-I and mode-II load cases. The method of imposing multiple modes is most readily understood by decomposing the end loading conditions into two more obvious cases of pure mode-I and pure mode-II behavior, as shown in Fig. 9. Based on the Timoshenko beam theory, G_{Ic} can be calculated as:

$$G_{Ic} = \frac{3P^2 k^2}{E_{11}h^3}$$

(14)

Eqns. (13) and (14) thus yield,

$$G_{IIc} = G_{Tc} - G_{Ic} = \frac{9P^2 k^2}{4E_{11}h^3}$$

(15)

From this analysis, the ratio of G_{IIc}/G_{Tc} is

$$\frac{G_{IIc}}{G_{Tc}} = \frac{3}{7}$$

(16)

B-K fracture criterion [47] can be expressed as:

$$G_{Tc} = G_{Ic} + (G_{IIc} - G_{Ic})\left(\frac{3}{7}\right)^m$$

(17)

Hence, the mode mixity parameter *m* is obtained as:

$$m = \frac{\log\left(\frac{G_{Tc} - G_{Ic}}{G_{IIc} - G_{Ic}}\right)}{\log\left(\frac{3}{7}\right)} \qquad (18)$$

On substituting the mean value of G_{Ic} from WTDCB tests (534 J/m²), mean value of G_{IIc} from ENF tests (913 J/m²), and mean value of G_{Tc} from FRMMELS tests (788 J/m²) into Eqn. (18), the B-K interaction parameters m is obtained as 0.475.

It is to be noted that the present method uses only fracture toughness values obtained from DCB, ENF, and FRMMELS tests with a constant mixed-mode ratio (of $\frac{G_{IIc}}{G_{Tc}} = 3/7$) to completely define the B-K delamination failure criterion as:

$$G_{Tc} = 536 + 377\left(\frac{G_{IIc}}{G_{Tc}}\right)^{0.475} \qquad (19)$$

3.2.3.2.   Typical mixed-mode bending tests: To create the mixed mode I/II delamination in laminated composites, the typical mixed-mode bending (MMB) apparatus, as shown in Fig. 10(a), is designed in accordance with ASTM D6671/D6671M standard [19] for verifying the accuracy and testing confidence of FRMMELS tests. Specimen dimensions used here are $2L = 50.8$ mm, initial crack length $a_0 = 20$ mm, width $W=25$ mm and thickness $2h=2.3$ mm. In order to fully characterize the mixed-mode fracture toughness of the CFRP composites, four mixed-mode ratios of G_{IIc}/G_{Tc} are used, namely 0.25, 0.5, 0.75 and 0.8. The moment arm length c to produce the desired mode-mixity G_{IIc}/G_{Tc} is obtained in terms of the following expression [19]:

$$c = \frac{12\beta^2 + 3\alpha + 8\beta\sqrt{\alpha}}{36\beta^2 - 3\alpha} L \qquad (20)$$

where α is the mode mixture transformation parameter for setting the moment arm length, β is the non-dimensional crack length correction parameter for mode-mixture and L is the half-span length of the typical MMB test apparatus (see Fig. 10(a)). The parameters α and β are derived as:

$$\alpha = \frac{1 - G_{IIc}/G_{Tc}}{G_{IIc}/G_{Tc}}, \beta = \frac{\alpha + \chi h}{a + 0.42\chi h} \qquad (21)$$

where χ is a correction factor defined in ASTM standard D6671/D6671M [19]. The corresponding c for mode-mixity 0.25, 0.5, 0.75, and 0.8 are 42.3 mm, 22.2 mm, 15.2 mm, and 14.2 mm, respectively.

The tests are conducted under a displacement rate of 0.25 mm/min using a 20 kN load-cell to record the load. The crack opening displacement is determined by measuring the relative displacement between the upper and the lower substrates at the initial crack tip using the DIC technique. The typical MMB apparatus is a combination of a FWDCB (mode-I)

specimen and an ENF (mode-II) specimen, which introduces mode-I loading at the end of lever and mode-II loading at the fulcrum, as shown in Fig. 10(b).

The mode-I and mode-II portions of loads in a typical MMB test are determined from Eq. (22).

$$P_I = \left(\frac{3c - L}{4L}\right)P, \qquad P_{II} = \left(\frac{c + L}{L}\right)P \tag{22}$$

where P is the applied load. The G_{Ic} and G_{IIc} are calculated based on the modified beam theory as follows [60]:

$$G_{Ic} = \frac{12P^2(3c - L)^2}{16W^2h^3L^2E_{11}}(a + \chi h)^2 \tag{23}$$

$$G_{IIc} = \frac{9P^2(c + L)^2}{16W^2h^3L^2E_{11}}(a + 0.42\chi h)^2 \tag{24}$$

$$G_{TC} = G_{IC} + G_{IIC} \tag{25}$$

where E_{11} is the longitudinal elastic modulus of the composite material which controls the bending response, and symbols a, W and $2h$ have their usual meaning.

The load value at the first deviation from the linear part in the load-displacement curve (see Fig. 10(c)) is chosen to measure the critical strain energy release rate at the delamination initiation. The experimental results for four mixed-mode ratios are listed Table 2 and shown in Fig. 10(d).

3.2.3.3.   Assessment of FRMMELS tests: There are other sample geometries which may accomplish a similar effect of imposing multiple modes [59, 61–63]. FRMMELS specimen geometry is selected because of multiple advantages. In essence, the sample mimics the geometry of pure Mode-I WTDCB as a means of obviating the need to directly measure the crack length. Moreover, FRMMELS sample contains an inherent constant ratio of fracture energies of different modes, which depends on the width taper ratio k. This is very useful when conducting a test to keep control of the interaction of modes.

Fig. 11 shows a comparison between experimental data obtained from FRMMELS tests and mixed-mode failure envelope of B-K criterion obtained from a least-square-fitting to all the experimental results of mode-I WTDCB, FWDCB tests, mode-II ENF tests as well as the traditional MMB tests. The detailed experimental values and statistical analysis of the obtained results for mode-I WTDCB, FWDCB tests, mode-II ENF tests, mixed-mode FRMMELS tests as well as typical MMB tests are listed in Table 2–3. Good agreement between the predictions and experimental data is generally observed. The m value of 0.484 obtained from the curve fit procedure is very close to 0.475 obtained from FRMMELS tests.

In summary, the new mixed-mode test, FRMMELS, developed in the present work appears to be a simple yet effective method to determine mixed-mode inter-laminar fracture toughness and the B-K criterion.

3.3. Computational modeling and determining the inter-laminar interfacial strengths

Inter-laminar interfacial strengths have been traditionally difficult to be measured through experiments owing to the challenges in accurately determining the onset of delamination traction [64], which is usually chosen artificially. In this section, computational models of mode-I WTDCB and mode-II ENF are developed to carry out parametric studies to obtain realistic interfacial strengths. With appropriate initial interface stiffness ($K = 4 \times 10^5$ N/mm^3), viscosity coefficient (10^{-5}), the number of cohesive elements (N_e=5) in the cohesive zone and the fracture toughness values obtained from experimental tests, a suitable interfacial strength in the tensile direction (N_n) is firstly obtained through computational modeling of WTDCB by matching the load-displacement curves obtained from experimental tests. Similarly, interfacial strength in the shearing direction (S_s) is then determined by conducting computational modeling of ENF test. To further validate the calibrated interfacial strengths, computational modeling of FRMMELS is carried out to verify the accuracy. Three-dimensional (3D) computational models of WTDCB, ENF and FRMMELS are shown in Fig. 12(a)–(c), respectively.

The loading position and initial crack length are consistent with the experimental tests. In the delamination area, hard contact is applied to prevent the two sub-laminates from penetrating each other. C3D8R element is used in ABAQUS-Explicit FE code to discretize the laminated plate, and COH3D8 element is used to discretize the cohesive area. The outer 0° plies are modeled as homogenized and with a linear-elastic transversely isotropic material law. The relevant material properties are E_{11}=125.9 GPa, E_{22}=E_{33}=8.6 GPa, G_{12}=G_{13}=4.584 GPa, G_{23}=2.735 GPa, v_{12}= v_{13}=0.33 and v_{23}=0.606.

3.3.1. Calibration of interfacial strengths from parametric studies

3.3.1.1. Parametric analysis scheme for interfacial tensile strength N_n: The chosen trial values of interfacial tensile strength N_n are set as 10, 15, 17, and 20 MPa and fracture toughness G_{Ic} values are 500, 550, 600, and 650 J/m^2, respectively in the parametric study. First, G_{Ic} is set as 600 J/m^2 and then we study the influence of N_n on the peak and stable load from computational simulations of WTDCB test. The predicted load-displacement curves and G_I-displacement curves by using these N_n values are shown in Fig. 13(a) and (b), respectively. The results show that N_n has negligible effect on the predictions of stable load and G_{Ic}, while the peak load increases with increasing N_n. The best agreement between the experimental and predicted load-displacement traces is observed for N_n value of 17 MPa.

Next, the value of N_n is set to 17 MPa while G_{Ic} values are varied. The predicted load-displacement curves and G_I-displacement curves by using various G_{Ic} are shown in Fig. 13 (c) and (d), respectively. The results show that G_{Ic} has negligible effect on the predictions of peak load, while predicted stable load and G_{Ic} increase with increasing values of G_{Ic}. The best agreement between the experimental and predicted load-displacement traces is found for G_{Ic} value of 550 J/m^2.

In sum, the peak force is largely governed by N_n while the plateau in force that occurs after delamination propagation is highly influenced by the value of G_{Ic}. The N_n and G_{Ic} values are calibrated as 17 MPa and 550 J/m^2 respectively through the parametric study.

An example of delamination initiation and propagation observed by computational modeling of WTDCB (N_n=17 MPa, G_{Ic}=550 J/m^2) is shown in Fig.14. The delamination front shapes are somewhat jagged, suggesting that growth happens in one location then stops and continues at another location across the width. On average, however, the delamination appears to grow uniformly across the length direction.

3.3.1.2. Parametric analysis scheme for interfacial shear strength S_s: In the computational model of ENF test, the chosen initial values of S_s are 45, 50, 55, and 60 MPa while G_{IIc} is set to 913 J/m^2, consistent with the experimental result in section 3.2.2. As shown in Fig. 15(a), two stages can be observed in force-displacement curves involving (I) elastic deformation and (II) delamination initiation and propagation. In stage I, as the load increases linearly with displacement, no observable interfacial cracks are observed during the elastic deformation, as shown in Fig. 15(b). In stage II, all curves reach their peak load and the samples are damaged instantaneously. Simultaneously, as indicated in Fig. 15(c), an occurrence of delamination is observed.

Examining the load-displacement relationships from experimental results and computational predictions, it is evident that the peak load is highly influenced by S_s, and increasing S_s causes an increase in the maximum force. Compared with the experimental results, the load-displacement curve observed from S_s=60 MPa gives a reasonable replication of the experimentally observed load-displacement curve with an initial linear region followed by a drop in the load as the delamination propagation begins, as shown in Fig. 15(a). Thus, S_s is calibrated to be 60 MPa.

3.3.2. Validating the interface strength—The load-displacement curves predicted from computational modeling (N_n=17 MPa, G_{Ic}=550 J/m^2, S_s=60 MPa and G_{IIc}=913 J/m^2) and FRMMELS mixed-mode test are compared in Fig. 16(a). Good agreement is observed in the linear elastic region and a slight difference can be seen in the nonlinear stage. The deviation from linearity appears to be a consequence of delamination initiation as shown in Fig. 16(b). With further increment in load, a gradual reduction in stiffness occurs as a result of delamination propagation, as shown in Fig. 16(c)–(d). Good agreement between the computational and experimental result is found, indicating that the interface strengths calibrated from computational modeling of WTDCB and ENF are indeed reliable.

4. Failure prediction of open-hole cross-ply laminates subjected to four point bending load

4.1. Experimental methodology

In real applications, CFRP laminated components are often fastened to the main body-in-white using bolts or rivet joints and thus usually contain holes. It is therefore very important to understand the failure mechanisms of open-hole CFRP laminated composites. Hart-Smith

[65] proposed a good illustration of the relative joint strength efficiency of fibrous composites, as shown in Fig. 17. The results shown that strength efficiency of composite joint reaches the peak point when ratio of hole diameter to specimen width (d/W) is about 0.22. Thus, in this study, the hole diameter d and the specimen width W are chosen to be 10 mm and 45 mm, respectively, which gives $d/W \approx 0.22$.

In this study, open-hole cross-ply laminates with a stacking sequence of $[0/90/90/0/0/0]_s$ and a total thickness of 2.5 mm are used in this study. The sample is molded with A42 carbon fiber and thermoset epoxy resin with a fiber volume fraction of 51.4%. The laminate is built-up with 12 layers of unidirectional prepregs and prepared by hot compression with holding time of 3 minutes for curing. Both carbon fiber and epoxy resin are supplied by Dow Chemical Company. The high-pressure water-jet machining can cause delamination or separation around the hole in a test specimen. Therefore, to improve the quality of the hole, the cross-ply laminates are pre-drilled with circular holes on a drill press prior to water-jet cutting of the outer boundaries of the specimen. In the process of producing pre-drilled holes, we find that macroscopic cracks appear around the hole when the diameter of hole is 5 mm. While, no initial cracks and delamination can be found if the diameter less than 2 mm, as shown in Fig. 18(a). Therefore, a pre-drilled hole with a diameter of 2 mm is selected in this study. Subsequently, the diameter of the hole is expanded to 10 mm and the required sample size is cut by using water-jet. We have confirmed that in this way, we can get rid of the delamination/separation around the hole during the described sample preparation process.

The detailed open-hole specimen geometry and test setup are shown in Fig. 18(b). Tests are conducted at a crosshead displacement rate of 5 mm/min. Three specimens are tested to characterize the failure mechanism of open-hole cross-ply laminates by AMTS 810 servo-hydraulic test machine with four-point bending fixture in order to provide verification data for computational predictions.

Experimental load-displacement curves of open-hole cross-ply laminates under four-point bending load are shown in Fig. 19(a). From these tests, an average peak load of 1.2 kN is obtained. The load-displacement curves for all test specimens could be divided into three stages: Stage I is the elastic stage, in which the load-displacement curves have a linear relation; In stage II, delamination initiates at the interface between the 0° and 90° plies at the vicinity of the hole and sample edge, as shown in Fig. 19(b)–(c). Then, delamination propagates along the ply interface with a non-linear increase in the bending load with displacement; In stage III, 0° layer breakage occurs when the compressive stress at the compressive bending side reaches the longitudinal compression strength of CFRP composites, which results in an instantaneous drop in peak load to 1/2 of its value (see Fig. 19(d)). Subsequently, the load remains nearly constant (0.6 kN) with severe delamination around the hole and edge area. Finally, failure initiation and propagation of the 0° layers and 90° layers on the tensile bending side lead to catastrophic failure of the open-hole cross-ply laminates, as shown in Fig. 19(e)–(f).

The experimental results show that delamination plays a critical role during the bending deformation of open-hole cross-ply laminates. In order to accurately characterize the

delamination behavior of open-hole cross-ply laminates subjected to four-point bending load, the material parameters of CZM for computational modeling are extremely important. In the next section, we will use the parameters determined by combined experimental characterization and computational modeling in Section 3 and carry out multiscale computational modeling to get a thorough understanding of the failure mechanisms of cross-ply laminates subjected to four-point bending.

4.2. Multi-scale computational modeling

4.2.1. Description of multi-scale computational model—A multi-scale computational model of the open-hole cross-ply laminates with a stacking sequence of $[0/90/90/0/0/0]_s$ is developed to simulate the failure process under flexural loading. The model consists of rectangular planar specimen with dimensions of $294 \times 45 \times 2.5$ mm^3 with a central symmetric open hole between the two supports and two indenters, as shown in Fig. 20. The span between two supports and two indenters are 200 mm and 100 mm respectively, which are consistent with the experimental setup. Both the cylindrical pin supports and indenters are defined as discrete rigid, all with a radius of 10 mm same as in the experiments.

The open-hole cross-ply laminates are meshed using 8-node linear brick element (C3D8R) with the reduced integration and hourglass control. Both the global and local coordinates are defined to interpret the ply orientation and to accurately capture the mechanical behaviors of laminated layers. The interfaces between two adjacent plies are meshed using the first-order cohesive elements (COH3D8).

The contact condition between the indenter and the open-hole cross-ply laminates is surface-to-surface with small displacement, and the friction coefficient is chosen as 0.2 [66]. In order to mimic the boundary conditions of the experiments, the right and left supports are coupled with the open-hole cross-ply laminates and the contact conditions between them are rigid. The boundary conditions are defined by constraining all degrees of freedom of the supports. In order to facilitate solution convergence, the loading conditions of the model are divided into two steps. In the first step, a very small displacement of 0.001 mm is applied to the reference point of the indenters to ensure contact between the test specimen and the indenters. In the second step, a downward displacement of 40 mm is applied which leads to the failure of the open-hole cross-ply laminates due to flexural bending.

4.2.2. Material constitutive laws

4.2.2.1. CFRP laminated layers: The CFRP laminated layers are modeled using an elastic-plastic-damage model combining the Liu-Huang-Stout (LHS) yield criterion [48] and the RVE-based failure criteria [49].

LHS yield criterion is used to describe the elasto-plastic behaviors of the CFRP laminated layers. The yield criterion is defined as：

$$\emptyset = \sqrt{F(\sigma_{22} - \sigma_{33})^2 + G(\sigma_{33} - \sigma_{11})^2 + H(\sigma_{11} - \sigma_{22})^2 + 2L\tau_{23}^2 + 2M\tau_{13}^2 + 2N\tau_{12}^2} \quad (26)$$
$$+ I\sigma_{11} + J\sigma_{22} + K\sigma_{33} - 1$$

where F, G, H, L, M, N I, J and K are parameters characterizing the current state of anisotropy. These parameters can be simplified and defined as follows:

$$F = \frac{1}{2}\left[\sum\nolimits_2^2 + \sum\nolimits_3^2 - \sum\nolimits_1^2\right], G = \frac{1}{2}\left[\sum\nolimits_3^2 + \sum\nolimits_1^2 - \sum\nolimits_2^2\right], H = \frac{1}{2}\left[\sum\nolimits_1^2 + \sum\nolimits_2^2 - \sum\nolimits_3^2\right]$$

$$\sum\nolimits_1 = \frac{\sigma_{1c} + \sigma_{1t}}{2\sigma_{1c}\sigma_{1t}}, \sum\nolimits_2 = \frac{\sigma_{2c} + \sigma_{2t}}{2\sigma_{2c}\sigma_{2t}}, \sum\nolimits_3 = \frac{\sigma_{3c} + \sigma_{3t}}{2\sigma_{3c}\sigma_{3t}}$$

$$L = \frac{1}{2\left(\tau_{23}^y\right)^2}, M = \frac{1}{2\left(\tau_{31}^y\right)^2}, N = \frac{1}{2\left(\tau_{12}^y\right)^2} \quad (27)$$

$$I = \frac{\sigma_{1c} - \sigma_{1t}}{2\sigma_{1c}\sigma_{1t}}, J = \frac{\sigma_{2c} - \sigma_{2t}}{2\sigma_{2c}\sigma_{2t}}, K = \frac{\sigma_{3c} - \sigma_{3t}}{2\sigma_{3c}\sigma_{3t}}$$

where σ_{1t} and σ_{1c} are the longitudinal tensile and compressive yield stresses; σ_{2t} (σ_{3t}) and σ_{2c} (σ_{3c}) are the transverse tensile and compressive yield stresses; τ_{12}^y(τ_{31}^y) and τ_{23}^y are the in-plane and out-of-plane shear stresses.

An associative flow rule is adopted to describe the yield surface evolution:

$$\dot{\varepsilon} = \dot{\gamma}\frac{\partial \emptyset}{\partial \sigma} \quad (28)$$

where $\dot{\gamma}$ represents the plastic multiplier and is determined by the Newton-Raphson method.

In order to characterize the damage evolution, the above elastic-plastic constitutive model is implemented into the continuum damage mechanics (CDM) framework. RVE-based failure criteria incorporating various damage mechanisms is adopted to describe the damage initiation, as described in our previous work [49]. Both the tension and compression failures in the longitudinal and transverse directions are identified as characteristic failure modes, which are described as follows:

Tension dominated failure $(\sigma_{22} > 0)$	$\dfrac{\sigma_{22}}{Y^T} + \left(\dfrac{\tau_{12}}{S^L}\right)^2 = 1$	(29)

Shear dominated failure $(\sigma_{22}^{Tran} < \sigma_{22} \le 0)$	$\left(\dfrac{\tau_{12}}{S^L}\right)^2 + \alpha\dfrac{\sigma_{22}}{Y^T} = 1$ $\alpha = \dfrac{Y^T}{\left|\sigma_{22}^{Tran}\right|}\left[\left(\dfrac{\left|\tau_{12}^{Tran}\right|}{S^L}\right)^2 - 1\right]$	(30)
Compression dominated failure $(-Y^c \le \sigma_{22} \le \sigma_{22}^{Tran})$	$\left(\dfrac{\sigma_{22}}{Y^C}\right)^2 + \beta^2\left(\dfrac{\tau_{12}}{Y^C}\right)^2 = 1$ $\beta = \dfrac{Y^C - \left|\sigma_{22}^{Tran}\right|}{S^L}$	(31)
Fiber-compression dominated failure $(\sigma_{11}\quad 0)$	$-\dfrac{\sigma_{11}}{X^C} + \left(\dfrac{\tau_{12}}{S^L}\right)^2 = 1$	(32)
Fiber-tension dominated failure $(\sigma_{11} > 0)$	$\dfrac{\sigma_{11}}{X^T} = 1$	(33)

where X^T, X^C, Y^T, Y^C, and S^L are the failure strengths for fiber tension, fiber compression, transverse tension, transverse compression, and in-plane shear, respectively. The symbols σ_{22}^{Tran} and τ_{12}^{Tran} represent transverse normal and in-plane shear stress of the transition point.

The damage evolution of the CFRP laminated layers is defined through a reduction in the stiffness matrix $C(D)$:

$$C(D)=\begin{bmatrix} d_1^2 C_{11} & d_1 d_2 C_{12} & d_1 d_3 C_{13} & & & \\ & d_2^2 C_{22} & d_2 d_3 C_{23} & & & \\ & & d_3^2 C_{33} & & & \\ & & & d_4 C_{44} & & \\ & sym & & & d_5 C_{55} & \\ & & & & & d_6 C_{66} \end{bmatrix} \tag{34}$$

where C_{ij} (i=1–6, j=1–6) are the components of undamaged stiffness matrix, and the parameters d_i are defined as follows:

$$d_1 = 1 - d_L, d_2 = 1 - d_T, d_3 = d_2$$
$$d_4 = \left(\frac{2d_1 d_2}{d_1 + d_2}\right)^2, d_5 = d_4, d_6 = d_2^2 \tag{35}$$

where d_L and d_T are denoted as:

$$d_L = \frac{\varepsilon_{Lf}(\varepsilon - \varepsilon_{L0})}{\varepsilon(\varepsilon_{Lf} - \varepsilon_{L0})}, \quad d_T = \frac{\varepsilon_{Tf}(\varepsilon - \varepsilon_{T0})}{\varepsilon(\varepsilon_{Tf} - \varepsilon_{T0})} \tag{36}$$

In Eqn. (36), ε_{Lf} is the tensile or compressive failure strain along fiber direction; ε_{L0} is the tensile or compressive initial damage strain along fiber direction; ε_{Tf} is the tensile or

compressive failure strain along transverse direction; ε_{T0} is the tensile or compressive initial damage strain along transverse direction.

To avoid the element size effect, the strain at the end of failure is determined by the fracture toughness based on smeared formulation:

$$\varepsilon_{Lf} = \frac{2G_L}{X^{T,C} * L_c}, \varepsilon_{Tf} = \frac{2G_T}{Y^{T,C} * L_c} \tag{37}$$

where G_L and G_T are the fracture toughness, which are adopted from the results of unidirectional reinforced carbon/epoxy laminate in Ref.[67]. In Eqn. (37), L_c is the characteristic element size.

The above damage model is implemented at the integral point in every element of laminated layers by the user subroutine VUMAT in ABAQUS [68]. Mechanical properties of the laminated layers are listed in Table 1.

4.2.2.2.   Inter-laminar 0°/0°, 90°/90° and 0°/90° interface: The interface between the adjacent plies is modeled by means of a general mixed-mode CZM. Although a number of experimental studies indicate that the most conservative fracture toughness values can be obtained by propagating the interlaminar crack in the fiber direction in UD composites [69], there is growing experimental evidence that the interface lay-up for 0°/θ° [70–72], anti-symmetric $+ \theta^{\circ}/ - \theta^{\circ}$ interfaces [73–75], and the direction of the interlaminar crack propagation with respect to the reinforcement directions of the adjacent plies have significant influences on the fracture toughness [76]. Polaha et al. [77] tested C12K/R6376 with lay-up of [$\theta^{\circ}/\theta^{\circ}$] ($\theta$=0, 15, 30), and the experimental data indicated fracture toughness G_{Ic} increase with increasing fiber angle θ. Laksimi et al. [78] tested considerably tougher T300/VICOTEX M10 for 0°/0° and 90°/90° layers, and the fracture toughness G_{Ic} increased by 26% when propagation direction was changed from along the fibers (0°/0° interface) to transverse to the fibers (90°/90° interface). Meanwhile, experimental work showed that the apparent values of the fracture toughness G_{Ic} of 0°/90° were two times higher than those of 0°/0° layers under steady state propagation conditions [71]. In addition, Hwang et al. [79] tested mode II fracture toughness of C12K/R6376 with lay-up of [$\theta^{\circ}/\theta^{\circ}$] ($\theta$=0, 15, 30, 45), and the fracture toughness G_{IIc} was found to decrease as the fiber angle θ increased. Rubbrecht and Verpoest [80] also studied cross-ply interface for HTA/6376 and AS4/3501–6, and found that fracture toughness G_{IIc} decreases monotonically with increasing θ. Qualitatively similar results were obtained by Laksimi et al. [81] for E-glass/M10 using ELS tests for fiber orientation θ=0, 15, 30, 45, and 60. Furthermore, experimental results shown that the fracture toughness G$_{IIc}$ for delamination direction normal to reinforcement (90°/90° interface) was lower by 40% than that along the fibers (0°/0° interface) [82]. Trakas and Kortschot [82] compared fracture toughness G$_{IIc}$ for cross-ply interface (0°/45°) of AS4/3501–6 to that of UD composite (0°/0°), and found somewhat smaller (by about 20%) average fracture toughness G$_{IIc}$ for cross-ply interface by ENF test. Similar results were obtained by Russell et al. [83] for AS1/3501–6. Therefore, application of appropriate fracture toughness values for different ply interfaces is necessary for accurate prediction of delamination development.

Based on above experimental observations, in this study, the mode I and mode II interfacial properties of 90°/90° are set to be 1.26 and 0.6 times of 0°/0° interface, respectively. For the 0°/90° interface, the mode I and mode II interfacial properties are set to be 2 and 0.8 times of 0°/0° interface respectively. The corresponding interfacial properties of 0°/0°, 90°/90°, and 0°/90° for different modes are listed in Table 4, where the interfacial properties of 0°/0° have been obtained from experimental and computational results in Section 3.

4.3. Computational results and discussions

Fig. 21(a) shows a comparison between the experimental and simulation results on the load-displacement curves. In general, the computational curve agrees well with the experimental curve in terms of the shape as well as the magnitudes of loads and displacement values. The numerical peak and stable loads are 1.19 kN and 0.57 kN respectively with a relative difference of less than 1% compared to the experimental values. Such a tiny difference in experimental and numerically predicted values gives enough confidence that the computational model can predict the load-carrying capacity of the CFRP laminated composite under four-point bending load quite accurately.

In addition, the multi-scale computational model is able to capture the sequence of damage initiation and propagation at different stages of load-displacement curve in the open-hole cross-ply laminates subjected to four-point bending load, as shown in Fig. 21(b)–(e). The initiation and propagation of delamination of interface between the adjacent layers as well as the final failure of CFRP laminated-layers is consistent with the experimental observations. Summarizing the multi-scale computational modeling results, we have the following key results:

1. Under the four-point bending load, delamination at the interface between the 0° and 90° plies first occurs at the vicinity of the hole where the stress concentration is the highest, which is made clear through an enlarged view of the hole area in the inset in Fig. 21(b).

2. With continued bending, the cracks in 0° layers at compressive bending side initiate around the poles of the hole when the compressive stress reaches the longitudinal compression strength of CFRP composites. This results in a dramatic load drop to half of the maximum load, as shown in Fig. 21(c).

3. Interfacial cracks between the 0° and 90° plies and the cracks of 0° layers at compressive bending side propagate through width direction, as shown in Fig. 21(d). During this period, the load bearing capacity of the open-hole cross-ply laminates remains stable.

4. Finally, severe delamination followed by a macroscopic crack initiation and propagation along the width direction in 0° layers on tensile side of the bending leads to ultimate failure of the open-hole cross-ply laminates, as shown in Fig. 21(e).

In summary, the whole failure process as predicted by the multi-scale model is in good agreement with what has been observed experimentally (Fig. 19). Furthermore, the multi-

scale modeling framework enables a more comprehensive understanding of the damage mechanisms in the open-hole cross-ply laminates subjected to four-point bending load.

5.   Conclusions

In this paper, an integrated experimental and computational effort has been demonstrated to enable a better understanding of the deformation and failure behavior of open-hole cross-ply CFRP composites under flexural loading conditions. First, two novel WTDCB and FRMMELS specimen geometries are proposed to characterize the mode-I fracture toughness and mixed-mode fracture toughness behavior of CFRP composite using the B-K fracture criterion. Since the proposed WTDCB specimen is generally insensitive to the crack length, the calculation of G_{Ic} has been greatly simplified. By comparing G_{Ic} obtained from WTDCB tests and the typical FWDCB tests, it is found that WTDCB specimen offers a more accurate and reliable means to determine G_{Ic}, as its geometry obviates the need to directly measure the crack tip location during tests. The FRMMELS specimen resembles not only pure mode-I WTDCB specimen, but also enables the calculation of G_{Tc} with a few modifications to introduce a mixture of mode-I and mode-II loading cases, which has also been shown to be independent of crack length. Moreover, FRMMELS sample contains a fixed mixed-mode G_{IIc}/G_{Tc} ratio that depends on the width taper ratio k. A comparison between curve-fitted mixed-mode failure envelope of B-K criterion based on a set of test results from mode-I WTDCB, FWDCB, mode-II ENF, and MMB tests with experimental data obtained from FRMMELS tests also shows excellent agreement. This indicates that FRMMELS test offers a simple yet effective method to determine mixed-mode G_{Tc} and thereby B-K criterion mode mixity parameter.

In addition, the interfacial strength parameters N_n and S_s are calibrated based on computational modeling of WTDCB and ENF tests by matching the experimental results. Subsequently, the accuracy of calibrated interface strength parameters are validated by comparing the computational and experimental results of FRMMELS tests. Building upon the series of efforts, failure mechanisms prevalent in the open-hole cross-ply CFRP laminates subjected to four-point bending have been studied systematically using experimental and multi-scale computational analyses with the developed CZM model. The initiation and propagation of delamination, the failure of laminated layers, and the load-displacement curves predicted from computational analyses are all in good agreement with what have been observed experimentally.

In conclusion, we have presented a detailed analysis of deformation and failure characteristics of open-hole cross-ply laminates by combining experimental and computational investigations. The analyses and methods presented in this study would enable a new level of understanding of the damage mechanisms in the open-hole cross-ply laminates and would further offer certain effective solutions to the great challenge of delamination prediction for CFRP laminated composites used in structural applications.
