HER2-positive (HER2<sup>+</sup>) breast cancers (BrCs) contain approximately equal numbers of ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> and ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> cases. An enduring obstacle is the unclear cell lineage-related characteristics of these BrCs. Although ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> BrCs could lose ER $\alpha$  to become ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> BrCs, direct evidence is missing. To investigate ER $\alpha$  dependencies and their implications during BrC growth and metastasis, we generated ER $\alpha$ <sup>Cre</sup>RFP-T mice that produce an RFP-marked ER $\alpha$ <sup>+</sup> mammary gland epithelial cell (MGEC) lineage. RCAS virus-mediated expression of Erbb2, a rodent Her2 homolog, first produced comparable numbers of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>Erbb2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> MGECs. Early hyperplasia developed mostly from ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>Erbb2<sup>+</sup> cells and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells in these lesions were rare. The subsequently developed ductal carcinomas in situ had 64% slow-proliferating ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>Erbb2<sup>+</sup> cells, 15% fast-proliferating ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells derived from ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>Erbb2<sup>+</sup> cells, and 20% fast-proliferating ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells. The advanced tumors had mostly ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells and only a very small population of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>Erbb2<sup>+</sup> cells. In ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells, GATA3 and FoxA1 decreased expression and ER $\alpha$  promoter regions became methylated, consistent with the loss of ER $\alpha$  expression. Lung metastases consisted of mostly ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells, a few ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells, and no ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>Erbb2<sup>+</sup> cells. The high metastatic capacity of ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells was associated with ERK1/2 activation. These results show that the slow-proliferating, nonmetastatic ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>Erbb2<sup>+</sup> cells progressively lose ER $\alpha$  during tumorigenesis to become fast-proliferating, highly metastatic ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>Erbb2<sup>+</sup> cells. The ER $\alpha$ <sup>-</sup>Erbb2<sup>+</sup> BrCs with an ER $\alpha$ <sup>+</sup> origin are more aggressive than those ER $\alpha$ <sup>-</sup>Erbb2<sup>+</sup> BrCs with an ER $\alpha$ <sup>-</sup> origin, and thus, they should be distinguished and treated differently in the future.

cell lineage tracing | estrogen receptor | HER2<sup>+</sup> breast cancer | cancer cell origin | metastasis

The mammary gland (MG) epithelium contains both ER $\alpha$ <sup>+</sup> and ER $\alpha$ <sup>-</sup> luminal epithelial cells (1). Breast cancers (BrCs) may arise from either ER $\alpha$ <sup>+</sup> or ER $\alpha$ <sup>-</sup> MG epithelial cells (MGECs). BrCs are heterogeneous and can be roughly grouped into ER $\alpha$ <sup>+</sup>, HER2<sup>+</sup>, and triple negative BrCs. About 70% of BrCs belong to the ER $\alpha$ <sup>+</sup> group, which is associated with a relatively good prognosis, and about 20% fall into the HER2<sup>+</sup> group with a much worse prognosis. About 50% of HER2<sup>+</sup> BrCs express ER $\alpha$  (2), so HER2<sup>+</sup> BrCs are accordingly designated as ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> and ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> BrCs. In ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> cancers, the cross-talk between ER $\alpha$  and HER2 signaling pathways and loss of ER $\alpha$  partially account for resistance to endocrine therapy (3, 4). ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> cancers exhibit a wide range of disease relapse time, metastatic potential, and responsiveness to anti-HER2 treatment, while ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> cancers generally are more malignant with earlier relapse, stronger metastatic potential, and much worse prognosis (5–13). ER $\alpha$  and HER2 expression vary during tumor progression, and patients can have both ER $\alpha$ <sup>+</sup> primary tumors as well as ER $\alpha$ <sup>-</sup> metastases (3, 14, 15). In some patients with recurrent BrCs, the ratios of ER $\alpha$ <sup>+</sup> to ER $\alpha$ <sup>-</sup> cancer cells may be reduced (16). These observations suggest

that some ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> BrCs may progress to ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> BrCs; yet, direct evidence is missing since cell lineage tracing in people is unethical.

To elucidate the relationships among the HER2<sup>+</sup> BrC subtypes, we set out to answer three unresolved biomedical questions: First, do ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> cancers lose ER $\alpha$  to become the more aggressive ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> cancers? Second, do ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> BrCs originate directly from ER $\alpha$ <sup>-</sup> MGECs or indirectly from ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> cancer cells? Third, are ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> cancers derived from preexisting ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> cancers and do ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> cancers that stem from ER $\alpha$ <sup>-</sup> MGECs have different cell proliferation rates and metastatic capabilities? To answer these important questions, we developed a trigenic mouse model that allows for in vivo tracing of the ER $\alpha$ <sup>+</sup> and ER $\alpha$ <sup>-</sup> MGEC lineages during tumorigenesis and metastasis. In this model, breast carcinogenesis was induced by Erbb2 (the rodent homolog of HER2) expression in both ER $\alpha$ <sup>+</sup> and ER $\alpha$ <sup>-</sup> MGECs in adulthood, and all tumor cells arising from the ER $\alpha$ <sup>+</sup> MGEC lineage were traced with red fluorescent protein (RFP) expression during the entire process of cancer initiation, progression, and metastasis. ER $\alpha$  expression history, cell proliferation rate, and metastatic capability were compared and characterized among different subtypes of BrC cells.

## Significance

HER2<sup>+</sup> breast cancers (BrCs) are heterogeneous, but they are treated as a single type. Using a mouse model with Erbb2 (the rodent homolog of HER2)-induced BrC and cell lineage-tracing capacity, we found that ER $\alpha$ <sup>+</sup>Erbb2<sup>+</sup> cancer cells proliferate slowly and are nonmetastatic but then progressively lose ER $\alpha$  expression to become fast proliferating and highly metastatic ER $\alpha$ <sup>-</sup>Erbb2<sup>+</sup> cancer cells. ER $\alpha$ <sup>-</sup>Erbb2<sup>+</sup> cancer cells with an ER $\alpha$ <sup>-</sup> origin proliferate fast, but they metastasize weakly. These findings suggest: 1) ER $\alpha$  expression should be preserved in ER $\alpha$ <sup>+</sup>HER2<sup>+</sup> BrCs to restrict growth and metastasis; 2) ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> BrCs contain a highly metastatic subtype with an ER $\alpha$ <sup>+</sup> origin and a weakly metastatic subtype with an ER $\alpha$ <sup>-</sup> origin, indicating a future need to identify and differentially treat these two subtypes.

**Fig. 1.** ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells progressively cease ER $\alpha$  expression while they transform into ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells during MG tumor progression. (A) Analysis of ErbB2<sup>+</sup> cells by double IF at week 1 after viral infection. Data collected from 12 analyzed sections prepared from six MGs with two sections/MG showed  $17 \pm 3$  ErbB2<sup>+</sup>ER $\alpha$ <sup>+</sup>,  $15 \pm 5$  ErbB2<sup>+</sup>RFP<sup>+</sup>,  $20 \pm 7$  ErbB2<sup>+</sup>ER $\alpha$ <sup>-</sup>, and  $15 \pm 6$  ErbB2<sup>+</sup>RFP<sup>-</sup> cells per MG. The ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cell number represents both ER $\alpha$ <sup>+</sup>ErbB2<sup>+</sup> and RFP<sup>+</sup>ErbB2<sup>+</sup> cells since these cells overlap as confirmed by double IF for ER $\alpha$  and RFP at this stage. ER $\alpha$ <sup>-</sup>ErbB2<sup>+</sup> and RFP<sup>-</sup>ErbB2<sup>+</sup> cells also overlap. The percentages of each cell type numbers compared to total ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cell number are presented. ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells were not observed. (B) At week 4, IF staining for ErbB2 and double IF staining for ER $\alpha$  and RFP were performed on adjacent sections. Six sections from each MG and a total of six MGs were examined. For each section, the ErbB2<sup>+</sup> hyperplasia regions were identified, and the numbers of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup> cells in these regions were counted. The data are presented as average percentages of the indicated cell type numbers compared to total ErbB2<sup>+</sup> cell number. ER $\alpha$ <sup>-</sup>RFP<sup>+</sup> cells were not observed in ErbB2<sup>+</sup> hyperplasia regions. (C) At week 13, adjacent sections were prepared, IF staining was performed, and data were collected and presented as described in B. (D) At week 27, five pieces of tissues (1 cm  $\times$  1 cm  $\times$  0.3 cm) were sampled from different regions of each large tumor ( $n = 8$ ), and sections were prepared from each tissue piece. IHC was performed to detect ErbB2, ER $\alpha$ , and RFP on each set of three serial sections. All stained sections were imaged for analysis. ImageJ software was used to quantify ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>, ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>, and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells in the tumor sections. Shown are average numbers relative to the respective areas each cell type occupied in the tumor sections. The red-dotted line demarcates the regions with ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells. The boxed areas in the Upper panels with ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells are amplified in the Lower panels. "+" and "-" indicate regions with positive and negative immunoreactivities of the indicated proteins. n.s. in A, not significant ( $P > 0.05$ ), and \*\* in B and C,  $P < 0.01$ , by Student's  $t$  test (A and B) or one-way ANOVA test (C).

## Results and Discussion

### In Vivo Cell Lineage Tracing Revealed a Progressive Loss of ER $\alpha$ Expression in ErbB2<sup>+</sup> Tumor Cells during MG Tumor Growth and Progression. Heterozygous trigenic ER<sup>Cre</sup>RFP-T mice were generated by

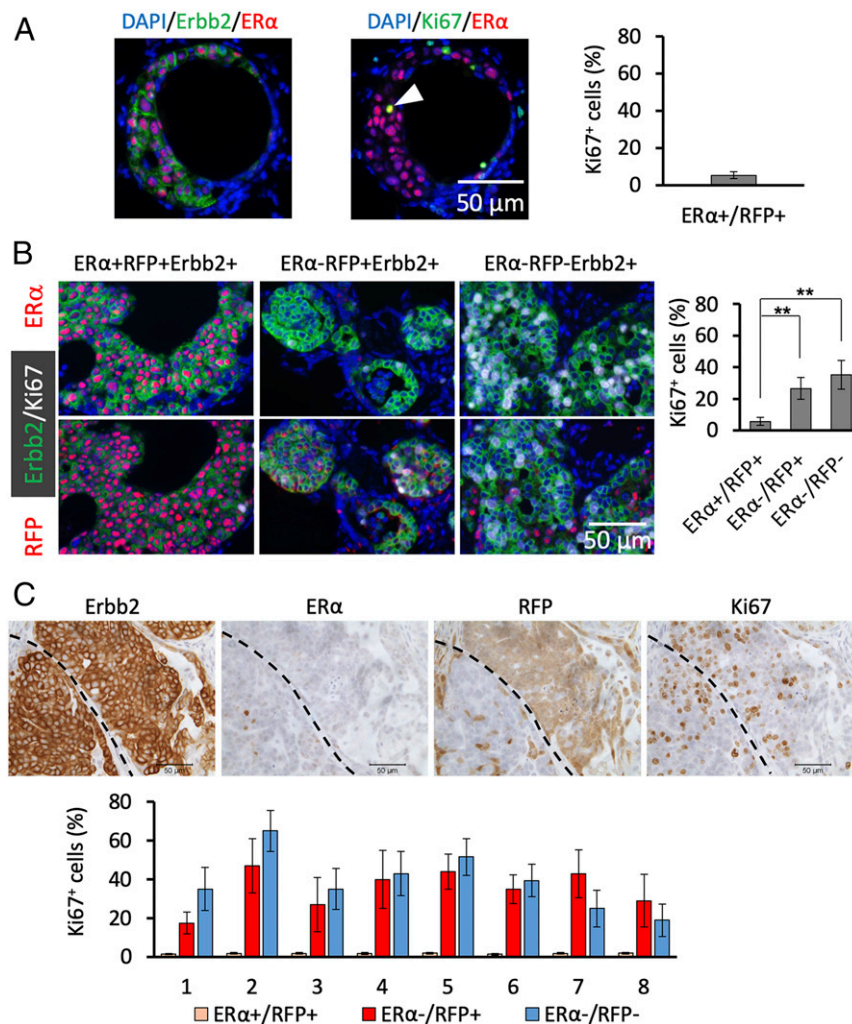

cross-breeding ER $\alpha$ -F2A-Cre mice with Cre expression in ER $\alpha$ -positive cells, Rosa26-LoxP-STOP-LoxP-tdRFP mice with a Cre-activated RFP expression cassette, and mouse mammary tumor virus long terminal repeat-tumor virus A (MMTV-TVA) mice (17–19) (SI Appendix, Fig. S1A). Replication-competent avian leukosis virus long terminal repeat with splice acceptor-ErbB2HA (RCAS-ErbB2HA) virus was introduced into the MG ductal lumens of 9-wk-old ER<sup>Cre</sup>RFP-T mice as described previously (19, 20). In ER<sup>Cre</sup>RFP-T mice, Cre expressed in ER $\alpha$ <sup>+</sup> MGECs activates RFP expression driven by the Rosa26 locus and is used as a lineage-tracing marker. No ER $\alpha$ <sup>-</sup>RFP<sup>+</sup> MGECs were detected, indicating that normal ER $\alpha$ <sup>+</sup> MGECs always maintain ER $\alpha$  expression (SI Appendix, Fig. S1B). TVA, a receptor for RCAS avian virus, was expressed in both ER $\alpha$ <sup>+</sup>RFP<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup> MGECs, allowing the RCAS-ErbB2HA virus to infect both types of MGECs. The RCAS-ErbB2HA virus mediates stable expression of the hemagglutinin antibody epitope (HA)-tagged rodent ErbB2 active protein (21). Palpable MG tumors were detected 14 wk after RCAS-ErbB2HA virus injection into the MG lumens of ER<sup>Cre</sup>RFP-T mice, and these tumors grew rapidly (SI Appendix, Fig. S2A). Immunohistochemistry (IHC) staining for HA-tagged ErbB2 protein identified ErbB2<sup>+</sup> tumor cells in ductal carcinoma in situ (DCIS) lesions at week 13, and ErbB2<sup>+</sup> poorly differentiated tumor cells in advanced large MG tumors at week 27. Luminal epithelial markers such as K8 and E-cadherin were expressed in these ErbB2<sup>+</sup> tumor cells at both stages. Progesterone receptor (PR), which usually is coexpressed with ER $\alpha$  in MGECs, was detected in DCIS cells at week 13, but not in most of the ErbB2<sup>+</sup> tumor cells at week 27. K14, a myoepithelial marker, was observed only in ErbB2<sup>-</sup> myoepithelial cells. Vimentin, a mesenchymal cell marker, was not detected in any of the ErbB2<sup>+</sup> tumor cells (SI Appendix, Fig. S2B). These results suggest that these MG tumors emerged as highly differentiated DCIS lesions and then progressed into poorly differentiated luminal-type BrCs.

One week after viral infection, the HA-tagged ErbB2 protein was detected in comparable numbers of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup> MGECs, indicating that RCAS-ErbB2HA virus infected both types of MGECs with similar efficiency. There were no detectable ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells at this stage (Fig. 1A). Four weeks after infection, we observed atypical hyperplastic lesions that consisted of 93% ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells and only 7% ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells. ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells still were not found at this stage (Fig. 1B). These observations indicate that ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells detected at week 1 survived better or proliferated faster than ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells, and that ER $\alpha$  expression is well maintained at this stage. At 13 wk, we detected DCIS lesions that contained 64.2% ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and 20.4% ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells, as well as 15.4% ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells that often were colocalized with ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells (Fig. 1C and SI Appendix, Fig. S3). These results indicate that a subset of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells detected at weeks 1 and 4 have lost ER $\alpha$  expression to form a new ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cell population. At 27 wk, most tumor volumes reached 13,500 mm<sup>3</sup> at an experimental endpoint (SI Appendix, Fig. S2A). In these advanced large tumors, the number of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells became quite few, averaging only 1.8% of the total ErbB2<sup>+</sup> tumor cells, and clusters of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> or ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells were frequently observed (Fig. 1D). However, the ratio of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> to ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells varied significantly in the eight examined tumors: Tumor Nos. 1 through 3 and Nos. 6 through 8 consisted of mostly ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells, respectively; No. 4 had 62% ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> and 38% ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells; and No. 5 had similar numbers of ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells (Fig. 1D). Although ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells originated from different luminal cell lineages, they exhibited indistinguishable morphologies. These results demonstrate that the predominant

ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cell population at week 13 has become a minor cell population at week 27, while ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> or ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells have become dominant cell populations at week 27. These cell lineage-tracing data prove that ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells originated from ER $\alpha$ <sup>+</sup> and ER $\alpha$ <sup>-</sup> MGECs, respectively, and that a significant proportion of the ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells progressively abrogated ER $\alpha$  expression to become ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells that proliferate and become a substantial cell population in many advanced tumors. Although the initial ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells do not multiply well at an early stage, their numbers also progressively increased at later stages to become one of the two major tumor cell populations.

FoxA1 and GATA3 are required for normal ER $\alpha$  expression (22, 23). FoxA1 and GATA3 protein levels were high in ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells, but much lower in ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells (SI Appendix, Fig. S4). DNA methylation

has been implicated as a mechanism to silence ER $\alpha$  expression in ER $\alpha$ <sup>-</sup> BrC (24). Three CpG islands are predicted in the ER $\alpha$  promoter regions (SI Appendix, Fig. S5A). Our DNA methylation assays revealed moderately methylated CpG sites in island 1 in normal ER $\alpha$ <sup>-</sup> MGECs and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells, and no methylation in this island in normal ER $\alpha$ <sup>+</sup> MGECs and ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells (SI Appendix, Fig. S5B). In island 2, no methylation was detected in normal ER $\alpha$ <sup>+</sup> MGECs, but normal ER $\alpha$ <sup>-</sup> MGECs showed moderate levels of CpG methylation. Moderate to high levels of methylation were observed in ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells, with relatively high levels at CpG sites -113 and -108 (SI Appendix, Fig. S5B). No CpG methylation was detected in island 3 in all examined cells. In agreement with the methylated CpG islands 1 and/or 2, ER $\alpha$  mRNA levels were high in normal ER $\alpha$ <sup>+</sup> MGECs, but extremely low in normal ER $\alpha$ <sup>-</sup> MGECs, ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells, and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells (SI Appendix, Fig. S5C). Together,

**Fig. 2.** Loss of ER $\alpha$  expression is associated with a robust increase in cell proliferation. (A) At week 4 after viral infection, adjacent sections were prepared from six MGs and double IF was performed for ErbB2/ER $\alpha$  and for Ki67/ER $\alpha$ . At this stage, all ER $\alpha$ <sup>+</sup>ErbB2<sup>+</sup> cells were RFP positive (Fig. 1B). The numbers of ErbB2<sup>+</sup>ER $\alpha$ <sup>+</sup> cells and Ki67<sup>+</sup>ER $\alpha$ <sup>+</sup> cells in hyperplastic regions were identified and counted, and  $972 \pm 162$  ER $\alpha$ <sup>+</sup>ErbB2<sup>+</sup> and  $51 \pm 9$  Ki67<sup>+</sup>ER $\alpha$ <sup>+</sup> cells per section were identified. ER $\alpha$ <sup>-</sup>ErbB2<sup>+</sup> and Ki67<sup>+</sup>ER $\alpha$ <sup>-</sup> cells were rare and their proliferation rate could not be determined at this stage. The arrowhead indicates a Ki67<sup>+</sup>ER $\alpha$ <sup>+</sup> cell. (B) At week 13, adjacent sections were prepared from six MGs for ErbB2/ER $\alpha$ /Ki67 and ErbB2/RFP/Ki67 triple IF staining. The numbers of Ki67<sup>+</sup> cells were counted in ER $\alpha$ <sup>+</sup>RFP<sup>+</sup> ( $n = 4,469$ ), ER $\alpha$ <sup>-</sup>/RFP<sup>+</sup> ( $n = 7,290$ ), and ER $\alpha$ <sup>-</sup>/RFP<sup>-</sup> ( $n = 6,960$ ) cell populations.  $**P < 0.01$  by one-way ANOVA test. (C) At week 27, five pieces of tumor tissues with a volume of  $1 \times 1 \times 0.3$  (cm) per piece were sampled from different regions of each tumor. Serial tumor sections were prepared from eight tumors as described in Fig. 1D. IHC was performed with sets of four serial sections for ErbB2, ER $\alpha$ , RFP, and Ki67. Images were obtained by scanning the stained sections. Quantitative image analysis was performed by identifying the tumor regions containing ErbB2<sup>+</sup>ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>, ErbB2<sup>+</sup>ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>, and ErbB2<sup>+</sup>ER $\alpha$ <sup>-</sup>RFP<sup>-</sup> cells and then determining the relative number of Ki67<sup>+</sup> cells in each region.

these results suggest that decreased FoxA1 and GATA3 expression and ER $\alpha$  promoter methylation indicatively contribute to the loss of ER $\alpha$  expression during the progression of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells to ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells.

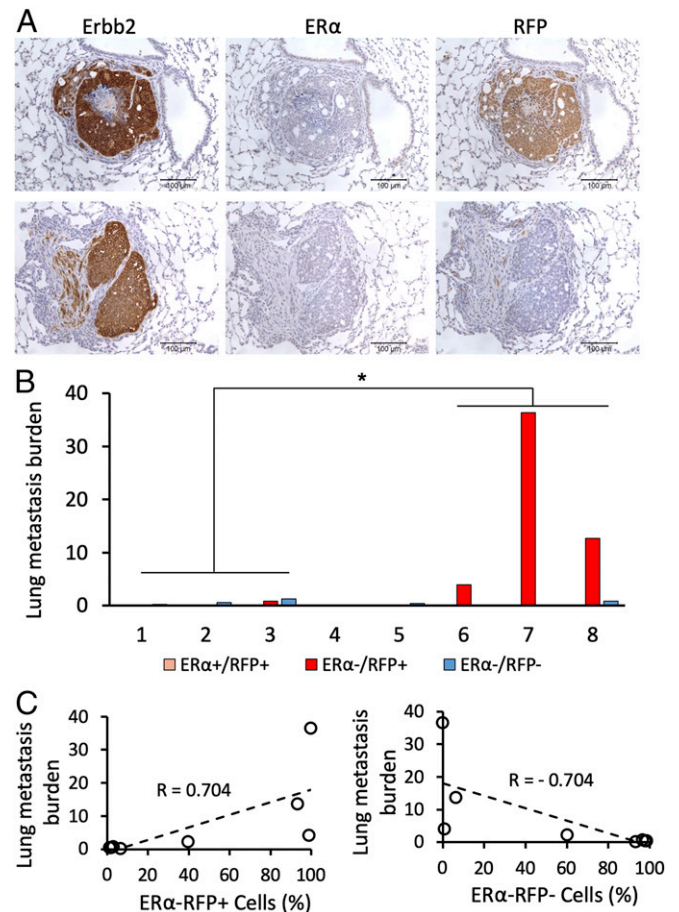

**The Loss of ER $\alpha$  Expression in ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> Tumor Cells Is Associated with Robustly Increased Cell Proliferation.** One week after viral infection, both ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> MGECs were not proliferating and appeared as individual cells among normal MGECs (Fig. 1A). At week 4, Ki67 IHC revealed proliferating cells in about 5% of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells in atypical hyperplastic lesions (Fig. 2A). The very low number of ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells at this stage foiled reliable quantification of their proliferating cells. In DCIS lesions analyzed at week 13, Ki67 was expressed in 5% of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells and in 25% of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells, indicating that loss of ER $\alpha$  expression is associated with dramatically increased cell proliferation. The proliferation rate of ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells was higher than the rates of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells (Fig. 2B). This high proliferation rate of ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells explained the increase in this cell population at week 13 compared to what we found at week 4. In advanced tumors at week 27, Ki67 immunostaining and BrdU incorporation assays revealed that very few ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells were proliferating, while ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells were highly proliferative (Fig. 2C and *SI Appendix, Fig. S6*). These results indicate that the initial ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells originating from ER $\alpha$ <sup>+</sup> MGECs multiply slowly, but while they progressively lose ER $\alpha$  expression they become fast-proliferating ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells and, consequently, largely replace the population of slow-proliferating ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells of early hyperplastic lesions. On the other hand, ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells that originated from ER $\alpha$ <sup>-</sup> MGECs are fast-proliferating tumor cells throughout the cancer progression process.

In normal MGs of adult mice, ER $\alpha$ <sup>+</sup> MGECs barely proliferate, while ER $\alpha$ <sup>-</sup> MGECs are highly proliferative in response to hormonal stimulation (25). The slow- and fast-proliferating features of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells may be inherited from their parental ER $\alpha$ <sup>+</sup> and ER $\alpha$ <sup>-</sup> MGECs. Together, these findings suggest that ER $\alpha$  plays an important role in restricting the proliferation of both normal ER $\alpha$ <sup>+</sup> MGEC and ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells.

**The Loss of ER $\alpha$  Expression in ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> Cells Is Associated with Distant BrC Metastasis.** To determine the metastatic potentials of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>, ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>, and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells, we sectioned through the lungs of eight ER<sup>Cre</sup>RFP-T mice with large MG tumors at week 27 after viral infection. We examined ErbB2, ER $\alpha$ , and RFP expressions in tumor cells on adjacent sections by IHC and calculated the percentage of areas occupied by ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells relative to total lung areas examined. We found that most lung metastases were made of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells, and only a few metastatic nodules contained ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells. Three mice (Nos. 6 through 8) bearing MG tumors with mostly ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells developed extensive lung metastases containing the same type of tumor cells, while other mice (Nos. 1 through 5) carrying similar size MG tumors with predominantly ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells only developed low grade lung metastases (Figs. 3A and B and 1D and *SI Appendix, Fig. S2A*). We did not find any ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells in all examined lungs, suggesting that these tumor cells do not metastasize (Fig. 3A and B). Interestingly, the ratios of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> to ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells showed a positive correlation, while ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> to ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cell ratios showed a negative correlation with lung metastasis burdens (Fig. 3C).

To confirm the significantly different metastatic competence of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells, we then

grew cell line-specific tumors in mouse xenograft models. Since the advanced MG tumors at week 27 mainly consisted of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells with only a few ER $\alpha$ <sup>+</sup>RFP<sup>+</sup> tumor cells (Fig. 1D), we used flow cytometry to isolate RFP<sup>+</sup> and RFP<sup>-</sup> tumor cells from these large tumors. We orthotopically inoculated a half million cells of each RFP type as well as a 1:1 mixture of both into the MG fat pads of severe combined immunodeficiency (SCID) mice (Fig. 4A). The growth rates of xenograft tumors developed from these three groups were similar (*SI Appendix, Fig. S7A*). As expected, we did not find any ER $\alpha$ <sup>+</sup>ErbB2<sup>+</sup> tumor cells in these tumors, and the tumors derived from RFP<sup>+</sup> and RFP<sup>-</sup> cell groups mainly had ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells, respectively. The tumors derived from the cell mixture averaged about 40% ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>

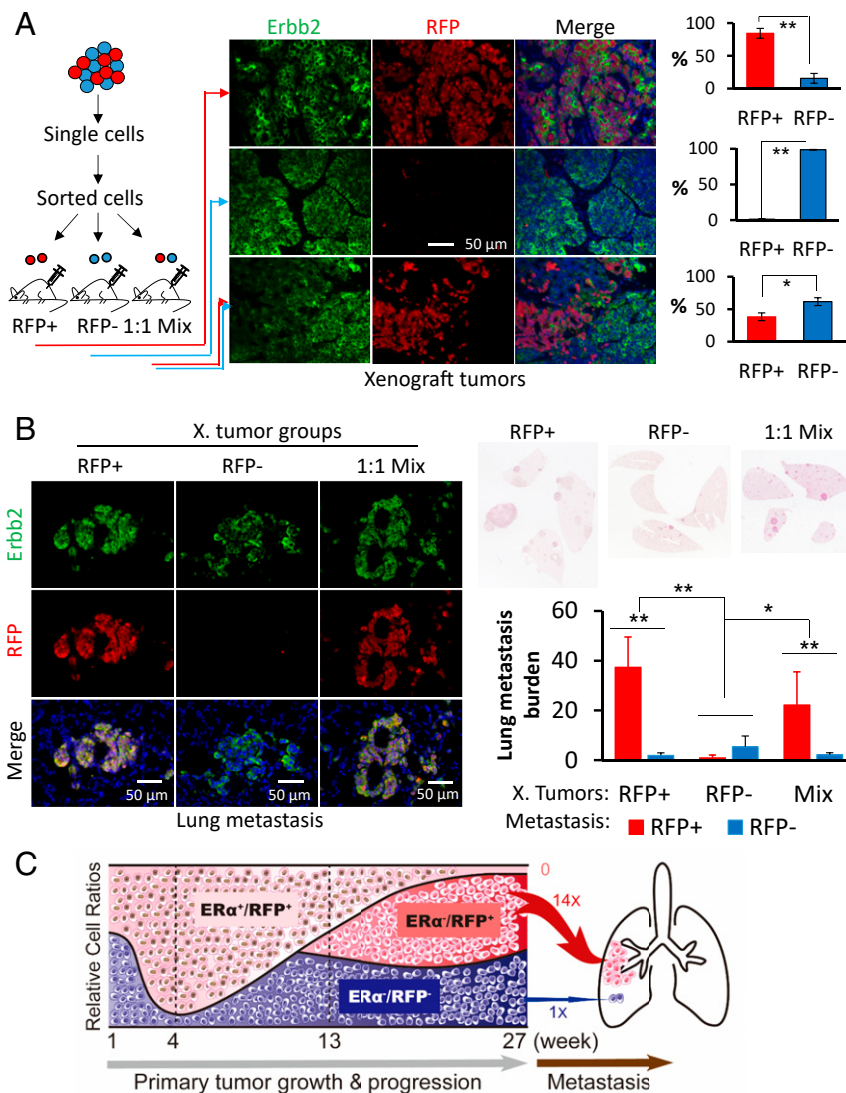

**Fig. 3.** The number of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells in the primary MG tumors was positively associated with lung metastasis. (A) IHC analysis of ErbB2, ER $\alpha$ , and RFP expression in adjacent sections of lung metastases at week 27 after viral infection. (B) Quantitative analysis of lung metastasis developed from the indicated types of tumor cells in eight ER<sup>Cre</sup>RFP-T mice at week 27 after viral infection. Each whole lung was sectioned, and sets of three serial sections with a 50- $\mu$ m interval between each set were used for IHC to assay ErbB2, ER $\alpha$ , and RFP expression. Digital images were taken from each stained section for quantifying areas with ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>, ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>, and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> metastatic tumor cells using ImageJ software. The sum of metastatic areas of each indicated tumor cell type on all examined sections was used to represent the metastasis burden of each mouse lung. The primary MG tumors in mice Nos. 1 through 3 and 6 through 8 mainly consisted of ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells, respectively. The lung metastasis burdens developed in mice Nos. 6 through 8 were significantly more severe than that in mice Nos. 1 through 3 (\**P* < 0.05 by one-way ANOVA test). (C) The percentages of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells in the advanced MG tumors at week 27 were positively and negatively correlated with the lung metastasis burdens, respectively.

and 60% ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells (Fig. 4A and *SI Appendix, Fig. S7B*). The xenograft tumors with predominantly ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells produced the most lung metastases within ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> nodules, while the ones with mostly ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells developed the fewest lung metastases. The xenografts with mixed ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cells produced the second most lung metastases with nodules that consisted of mainly ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells (Fig. 4B). We did not find any ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells in the lung metastases of all examined mice (*SI Appendix, Fig. S8*). These results demonstrate that: 1) ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells originating from ER $\alpha$ <sup>+</sup> MGECS are nonmetastatic; 2) ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells originating from ER $\alpha$ <sup>-</sup> MGECS are weakly metastatic; and 3) ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells that derived from ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells after

losing ER $\alpha$  are extremely metastatic. Accordingly, these findings defined an interesting hierarchy for metastatic capacity that is determined by both ER $\alpha$  expression status and origin of the BrC cell lineage.

**The ERK1/2 MAPKs Are Activated in ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> Tumor Cells but Not in ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> Tumor Cells.** We compared the transcriptomes of ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells and identified 230 up-regulated and 143 down-regulated transcripts in ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cells (*SI Appendix, Fig. S9A and Table S1*). Gene set enrichment analysis revealed several cancer-related pathways, including Ras, cell adhesion, and PI3K-AKT signaling pathways (*SI Appendix, Fig. S9B*). The increased levels of Rasgrf1 and Fgf13 expression in the Ras pathway and Prlr, LamC3, and

**Fig. 4.** ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> cancer cells were much more metastatic than ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup> cancer cells. (A) RFP<sup>+</sup> and RFP<sup>-</sup> tumor cells were isolated from MG tumors at week 27 after viral infection and orthotopically inoculated into female SCID mice as sketched. Xenografts were collected 8 wk after inoculation. Five tissue pieces from different regions of each tumor were sampled for preparing sections. Double IF for ErbB2 and RFP was performed on sections of all tissue pieces to determine the percentage of RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells to RFP<sup>-</sup>ErbB2<sup>+</sup> tumor cells. \* $P < 0.05$ , and \*\* $P < 0.01$  by Student's  $t$  test.  $n = 8, 6$ , and 6 assayed tumors for *Upper, Middle, and Lower* bar graphs, respectively. (B) H&E staining and double IF for ErbB2 and RFP were performed with sets of serial sections prepared from each lung of SCID mice bearing RFP<sup>+</sup>ErbB2<sup>+</sup> ( $n = 8$  mice), RFP<sup>-</sup>ErbB2<sup>+</sup> ( $n = 6$  mice), and 1:1 mixture ( $n = 6$  mice) xenografts. Stained sections were imaged by scanning. The lung tissue and the RFP<sup>+</sup>ErbB2<sup>+</sup> and RFP<sup>-</sup>ErbB2<sup>+</sup> cancer cell areas (pixels) in all section sets were measured using ImageJ software. The percentage of tumor cell area compared to lung area is presented as lung metastasis burden. \* and \*\* $P < 0.05$  and  $P < 0.01$  by one-way ANOVA test. (C) A model depicting dynamic changes of the relative ratios of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>, ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup>, and ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cell populations during primary MG tumor growth, progression, and lung metastasis, and estimating lung metastasis capacity for each cancer cell lineage. Our quantitative data suggest that the relative lung-metastatic potencies of ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup>, ER $\alpha$ <sup>-</sup>RFP<sup>-</sup>ErbB2<sup>+</sup>, and ER $\alpha$ <sup>-</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells could be assigned as 0, 1, and 14 folds, respectively.

Itga7 expression in the PI3K-AKT pathway were validated in ER $\alpha$ -RFP<sup>+</sup>ErbB2<sup>+</sup> cells versus ER $\alpha$ -RFP<sup>-</sup>ErbB2<sup>+</sup> cells by RT-qPCR assays (SI Appendix, Fig. S9C). The PI3K-AKT pathway and the Ras pathway that activates MAPK ERK1/2 are known to promote cancer growth and metastasis. We found that the expression levels of AKT and ERK1/2 mRNAs as well as the phosphorylated active AKT showed no changes in these cells. However, levels of phosphorylated ERK1/2 were high in ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> and ER $\alpha$ -RFP<sup>+</sup>ErbB2<sup>+</sup> cells in 13-wk hyperplasia and in ER $\alpha$ -RFP<sup>+</sup>ErbB2<sup>+</sup> cells in 27-wk tumors, but were detected only in a very small proportion of ER $\alpha$ -RFP<sup>-</sup>ErbB2<sup>+</sup> cells in tumors at both stages (SI Appendix, Figs. S10 and S11). ERK1/2 phosphorylation activates these kinases to translocate into the nucleus where they phosphorylate nuclear targets. Our results suggest that the high ERK1/2 activity is associated with the ER $\alpha$ <sup>+</sup> tumor cell lineage, which may be responsible in part for the fast-proliferating and strong-metastatic capabilities of the subsequent ER $\alpha$ -RFP<sup>+</sup>ErbB2<sup>+</sup> cancer cells. Further future studies are needed to understand why the slow-proliferating and nonmetastatic ER $\alpha$ <sup>+</sup>RFP<sup>+</sup>ErbB2<sup>+</sup> tumor cells also have high ERK1/2 activities.

In summary, overexpression of ErbB2 can transform ER $\alpha$ <sup>+</sup> and ER $\alpha$ <sup>-</sup> mouse MGECs into BrCs. ER $\alpha$ <sup>+</sup>ErbB2<sup>+</sup> tumor cells from the ER $\alpha$ <sup>+</sup> cell lineage have high ERK1/2 activities, but proliferate slowly and do not metastasize if they maintain ER $\alpha$  expression. However, due to decreased FoxA1 and GATA3 expression and ER $\alpha$  promoter methylation, these cells with high ERK1/2 activities progressively lose ER $\alpha$  to become fast-proliferating and highly metastatic ER $\alpha$ <sup>-</sup>ErbB2<sup>+</sup> cancer cells. ER $\alpha$ <sup>-</sup>ErbB2<sup>+</sup> tumor cells from the ER $\alpha$ <sup>-</sup> cell lineage proliferate fast, but have much weaker metastatic capability compared to ER $\alpha$ <sup>-</sup>ErbB2<sup>+</sup> cancer cells with an ER $\alpha$ <sup>+</sup> origin (Fig. 4C). These findings indicate that cell lineage origin and ER expression status are crucial factors contributing to the heterogenous growth and metastasis features of HER2<sup>+</sup> BrCs. A future BrC treatment objective could be to prevent the transformation of ER $\alpha$ <sup>+</sup>ErbB2<sup>+</sup> cancer cells into aggressive ER $\alpha$ <sup>-</sup>ErbB2<sup>+</sup> cancer cells with an ER $\alpha$ <sup>+</sup> origin while treating ER $\alpha$ <sup>+</sup>ErbB2<sup>+</sup> cancers. Our results also suggest that the ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> human BrCs that are currently treated

as a single type can consist of a more aggressive ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> subtype with an ER $\alpha$ <sup>+</sup> origin and a less aggressive ER $\alpha$ <sup>-</sup>HER2<sup>+</sup> subtype with an ER $\alpha$ <sup>-</sup> origin. A new objective then should involve the discovery of molecular markers specific to each subtype for a more distinguished diagnosis. Indeed, our findings warrant future studies to develop inherent molecular markers for these two BrC subtypes and to identify subtype-specific molecular targets for precision therapy.

## Materials and Methods

**Mouse Models.** ER $\alpha$ -F2A-Cre mice were cross-bred with Rosa26-LoxP-STOP-LoxP-tRFP and MMTV-TVA mouse lines (17–19) to generate heterozygous trigenic ER<sup>Cre</sup>RFP-T mice. Mouse genotypes were assayed by PCR using allele-specific oligonucleotide primers as described previously (17–19). RCAS-ErbB2HA virus was produced in DF-1 chicken fibroblasts, and 1 million viral particles were introduced into the ductal lumina of every fourth MG in 9-wk-old female ER<sup>Cre</sup>RFP-T mice as described previously (19, 20). After viral infection, these female ER<sup>Cre</sup>RFP-T mice were maintained to allow MG tumor development. For xenograft models, flow cytometry-sorted mouse tumor cells were injected into the fourth pair of MG fat pads of 8-wk-old female SCID mice. Each fat pad received  $5 \times 10^5$  cells in 100  $\mu$ L Matrigel (354230, Corning). Tumor growth, histopathology, and lung metastasis were examined as described previously (20, 26). The animal protocol was approved by the Institutional Animal Care and Use Committee of Baylor College of Medicine.

Tissue collection, H&E staining, immunohistochemistry, immunofluorescence (IF), DNA methylation assay, flow cytometry, transcriptome analysis, RT-qPCR, and statistical analysis were performed as described in SI Appendix, Supplemental Methods.

**Data Availability.** The FASTQ file for RNA-Seq data has been deposited in the BioProject category of the NCBI Sequence Read Archive database, accession no. PRJNA713819 (27). All other study data are included in the article and/or supporting information.

**ACKNOWLEDGMENTS.** We thank Dr. David Lonard for discussion and Jarrod Martinez, Mu Yang, Suoling Zhou, and Wen Bu for experimental assistance. We thank the Cytometry and Cell Sorting Core at Baylor College of Medicine for assisting with cell sorting and Zhongming Zhao, Xian Chen, and Chunying Yang in the Cancer Genomics Center at the University of Texas Health Science Center for RNA-Seq. This study is partially supported by NIH grant CA193455 (to J.X.). J.X. is also partially supported by the Gordon Cain Endowed Professorship in Cell Biology at Baylor College of Medicine.
