

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Mortality

ABSTRACT

Background: The variability of coronavirus disease 2019 (COVID-19) illness severity has puzzled clinicians and has sparked efforts to better predict who would benefit from rapid intervention. One promising biomarker for in-hospital morbidity and mortality is cardiac troponin (cTn).

Methods: A retrospective study of 1331 adult patients with COVID-19 admitted to the Rush University System in Illinois, USA was performed. Patients without cTn measurement during their admission or a history of end stage renal disease or stage 5 chronic kidney disease were excluded. Using logistic regression adjusted for baseline characteristics, pre-existing comorbidities, and other laboratory markers of inflammation, cTn was assessed as a predictor of 60-day mortality and severe COVID-19 infection, consisting of a composite of 60-day mortality, need for intensive care unit, or requiring non-invasive positive pressure ventilation or intubation.

Results: A total of 772 patients met inclusion criteria. Of these, 69 (8.9%) had mild cTn elevation (> 1 to < 2x upper limit of normal (ULN)) and 46 (6.0%) had severe cTn elevation (\geq 2x ULN). Regardless of baseline characteristics, comorbidities, and initial c-reactive protein, lactate dehydrogenase, and ferritin, when compared to the normal cTn group, mild cTn elevation and severe cTn elevation were predictors of severe COVID-19 infection (adjusted OR [aOR] aOR 3.00 [CI: 1.51 – 6.29], $P < 0.01$; aOR 9.96 [CI: 2.75 – 64.23], $P < 0.01$, respectively); severe cTn elevation was a predictor of in-hospital mortality (aOR 2.42 [CI: 1.10 – 5.21], $P < 0.05$) and 60-day mortality (aOR 2.45 [CI: 1.13 – 5.25], $P < 0.05$).

Conclusion: In our cohort, both mild and severe initial cTn elevation were predictors of severe COVID-19 infection, while only severe cTn elevation was predictive of 60-day mortality. First cTn value on hospitalization is a valuable longitudinal prognosticator for COVID-19 disease severity and mortality.

1. Introduction

COVID-19 is responsible for a global pandemic with greater than 100 million cases and 2.3 million deaths worldwide as of February 2021 [1].

* Funding: The authors received no financial support for the research, authorship, or publication of this manuscript.

☆☆ Disclosures: The authors have no conflicts of interest to disclose

E-mail address: Max.Ruge@jefferson.edu (M. Ruge).

Due to the wide spectrum in severity of presentation ranging from completely asymptomatic to acute hypoxic respiratory failure, a large body of research has focused on predictors of poor outcomes in an attempt to risk stratify patients. While comorbidities and chest imaging can provide valuable prognostic information, laboratory biomarkers would provide a quantitative method that is overall easier to obtain and less expensive than imaging [2–5]. To date, multiple biomarkers have been found to be helpful in prognosticating poor outcomes in patients with COVID-19 including hematologic markers (e.g., lymphocyte count and platelet count), inflammatory markers (e.g., interleukin-6 and C-reactive protein [CRP]), biochemical markers (e.g., lactate dehydrogenase [LDH] and creatinine kinase [CK]), and markers of coagulopathy

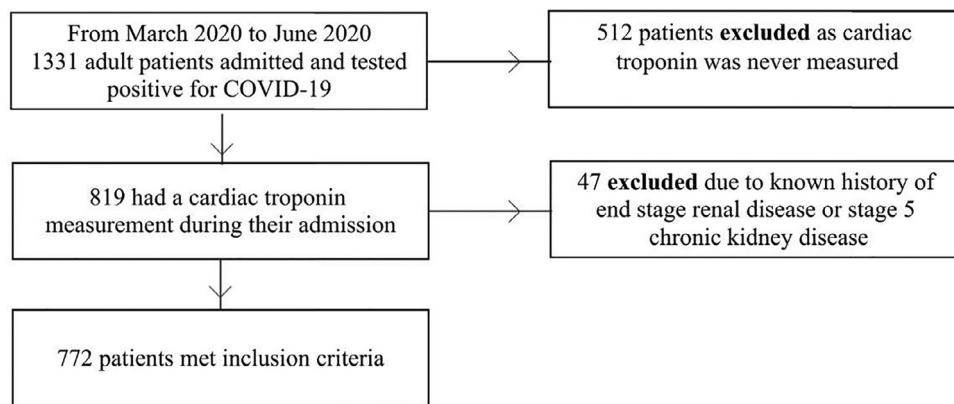

Fig. 1. Inclusion criteria to define study population.

(e.g., prothrombin time and D-Dimer) [6–9]. A variety of molecular changes have also been associated with the SARS-CoV-2 virus, and subsequently, novel biomarkers are also being tested [9,10].

Cardiac injury, one of multiple cardiovascular complications of COVID-19, occurs in 8 to 28% of patients and is known to increase overall mortality, which makes cardiac biomarkers a particular area of interest [11–14]. A meta-analysis of cardiac biomarkers found that cardiac troponin (cTn) and creatinine kinase (CK) levels were higher in non-survivors versus survivors of COVID-19, while no significant difference was found in the levels of brain natriuretic peptide (BNP) between these two groups [15]. In this study, cTn emerged as a particularly promising cardiac biomarker as it was elevated in the combined outcome of critical illness and mortality, which was not the case for CK [15].

The data supporting the prognostic role of cTn is robust as summarized by another meta-analysis of twenty-one studies and 6297 patients that found those with cardiac injury are 16.79 times more likely to suffer all-cause mortality [11,13,16–20]. Despite this mounting evidence, some have been hesitant in recommending its use in risk stratification likely due to its long-standing association with ischemic disease rather than as a biomarker for critical illness [21,22].

This retrospective study sought to add to the body of literature regarding the utility of cTn as a biomarker. Specifically, we wanted to compare COVID-19 disease severity, 60-day mortality, and 60-day complications in those with normal versus elevated cTn levels. We then sought to assess these outcomes by level of cTn elevation to further probe the potential benefits of cTn as a biomarker.

2. Methods

We conducted a retrospective cohort study of adult patients \geq 18 years old with polymerase chain reaction confirmed COVID-19 between March to June 2020 who were admitted to Rush University System for Health (RUSH), which includes Rush University Medical Center, a 664-bed tertiary academic medical center; Rush Oak Park Hospital, a 201-bed affiliated community hospital; and Rush Copley Medical Center, a 210-bed suburban affiliated community hospital in Illinois, US. A combination of automatic and manual data extraction data collection was performed. Patient's medical records were followed and reviewed for a minimum of 60 days after the date of their initial COVID-19 admission through chart review of several local hospitals.

Those without a cTn measurement were excluded (Fig. 1). When multiple cTns were measured, only the first cTn measurement was used. The cTn assay used at our institution is Troponin I with normal values of 0.00 - 0.09 ng/mL. Cardiac injury was defined as a cTn value greater than this upper limit of normal (ULN).

Patients were additionally subcategorized into normal cTn level, mild cTn elevation (> 1 to $< 2x$ ULN), and severe cTn elevation ($\geq 2x$ ULN).

Prior studies have suggested that the standard laboratory cutoff for various cardiac biomarkers should be redefined to enhance prognostic ability for COVID-19. ²³ Specifically, Qin *et al.* found that reducing the cutoff for high sensitivity cTn by 49.0% improved mortality prediction [23]. To test this further, a subcategory was created for light cTn elevation, defined as $cTn > 0.5x$ to $\geq 1x$ ULN. Normal cTn was redefined as $\leq 0.5x$ ULN, but this was only used when light cTn elevation was specifically being analyzed.

Additionally, those with end stage renal disease and stage 5 chronic kidney disease (CKD) were excluded as renal disease is a known to influence cTn measurement (Fig. 1) [24].

The primary outcome was 60-day mortality. Two secondary outcomes of particular interest were in-hospital mortality and a composite outcome for severe infection that consisted of 60-day mortality, intensive care unit (ICU) requirement, and need for non-invasive positive pressure ventilation or intubation. Other secondary outcomes included readmission, intubation, extracorporeal membrane oxygenation (ECMO), tracheostomy, vasopressor requirement, and inotrope requirement.

Patient charts were also reviewed for pre-selected major adverse events (MAE) up to 60 days from their hospital admission, which included life-threatening arrhythmia, deep venous thrombosis, symptoms of acute HF, acute renal failure requiring renal replacement therapy, stroke, and pulmonary embolism. During this subsequent chart review, data was also collected on hospital readmission and mortality.

3. Statistical analysis

All data analysis, including statistical analyses, was performed using RStudio version 1.3 (Boston, Massachusetts). Kaplan-Meier survival estimates were generated and plotted with the survival and `survminer` packages, respectively.

Continuous variables are reported with mean and standard deviation for normally distributed variables and with median and interquartile range for variables not normally distributed. Categorical variables are reported as counts and proportions. Continuous variables were compared with t-tests or Wilcoxon rank-sum test, and categorical variables with the Pearson chi-square test.

Logistic regression was performed between the level of cTn elevation as a predictor variable for severe infection and 60-day mortality, respectively. All logistic regression models were adjusted for baseline characteristics of age, sex, and body mass index, pre-existing history of coronary artery disease, atrial fibrillation, chronic obstructive pulmonary disorder, and diabetes mellitus, and

the initial values of CRP, LDH, and ferritin during the index hospitalization. Odds ratios (OR) with 95% confidence intervals (CI) are reported for logistic regression. The threshold for statistical significance was set to a p-value < 0.05.

4. Results

Of the 1331 patients available in our dataset, 772 met inclusion criteria. Only 3 patients (0.4%) in our cohort had a cardiac catheterization during their hospitalization. Two of these patients were diagnosed with acute coronary syndrome with one having an ST-elevation myocardial infarction with percutaneous coronary intervention and the other having a type I non-ST segment elevation myocardial infarction with visible plaque rupture on the angiogram. The last patient's angiogram revealed chronic stable coronary artery disease requiring no intervention.

The median cTn level was 0.02 with a first and third quartile of 0.00 and 0.04, respectively. The overall distribution was heavily skewed to higher values (range: 0.00 to 68.86).

A total of 115 patients (14.9%) in our cohort had an elevated cTn level. Of these, 69 patients (60.0%) had mild cTn elevation, and 46 patients (40.0%) had severe cTn elevation.

Compared to the baseline characteristics of patients with normal cTn levels, those with increased cTn measurements were older and have a variety of comorbidities including a history of atrial fibrillation, coronary artery disease, hypertension, chronic kidney disease, cancer, ventricular arrhythmia, stroke, acute myocardial infarction, and prior deep venous thrombosis or pulmonary embolism (Table 1). Additionally, the elevated cTn group had higher measured values of white blood cells, creatinine, CRP, ferritin, and LDH but lower hemoglobin and temperature measurements.

5. Primary survival outcome

In our cohort, 135 (17.5%) patients suffered 60-day mortality with the median time of death of day 12 after hospitalization (interquartile range [IQR] 6 – 22). Compared to those without cTn elevation, patients with cTn elevation were significantly more likely to suffer 60-day mortality (adjusted OR [aOR] 1.73 [CI: 1.00 – 2.94]; $P < 0.05$) (Fig. 2).

When subclassifying cTn by the level of elevation, 91 (13.9%), 20 (29.0%), and 24 (52.2%) patients died within 60 days in the normal, mild cTn elevation, and severe cTn elevation groups, respectively. Those with severe cTn elevation (aOR 2.45 [CI: 1.13 – 5.25]; $P < 0.05$), but not those with those with mild cTn elevation (aOR 1.35 [CI: 0.68 – 2.60]; $P = 0.38$), were at increased risk for 60-day mortality compared to those with normal cTn levels (Fig. 2, Table 2). When compared to those with mild cTn elevation, patients with severe cTn elevation were at no higher risk of 60-day mortality (aOR 2.05 [CI: 0.74 – 5.78]; $P = 0.17$).

6. In-Hospital mortality outcome

The in-hospital mortality rate was 13.6% (105 of 772). The odds of in-hospital mortality was 1.93 times higher in patients with elevated versus normal cTn (aOR 1.93 [CI: 1.09 – 3.36]; $P < 0.05$).

In analyzing by level of cTn elevation, 69 (10.5%), 16 (23.2%), and 20 (43.5%) patients suffered in-hospital mortality in the normal, mild cTn elevation, and severe cTn elevation groups, respectively. Patients in the severe (aOR 2.42 [CI: 1.10 – 5.21]; $P < 0.05$) cTn elevation group were at increased risk of in-hospital mortality when compared to those with normal cTn levels; no statistically increased risk was found in those with mild cTn elevation compared to those with normal cTn levels (aOR 1.62 [CI: 0.79 – 3.22]; $P = 0.17$). When only analyzing those with elevated cTn levels, patients with severe cTn elevation were no more likely to suffer in-hospital mortality (aOR 1.53 [CI: 0.57 – 4.09]; $P = 0.40$) versus those with only mild cTn elevation.

7. Composite outcome for severe infection

A total of 379 (49.1%) patients in our cohort had a severe COVID-19 infection as defined by the composite outcome. Those with cTn elevation were significantly more likely to have a severe COVID-19 infection compared to those a normal initial cTn level (aOR 3.99 [CI: 2.16 – 7.76]; $P < 0.001$).

When subclassifying cTn by the level of elevation, 288 (43.7%), 49 (71.0%), and 43 (93.5%) patients suffered severe infection in the normal, mild cTn elevation, and severe cTn elevation groups, respectively. Both those with mild cTn elevation (aOR 3.00 [CI: 1.51 – 6.29]; $P < 0.01$) and those with severe cTn elevation (aOR 9.96

ULN = upper limit of normal; ICU = intensive care unit; ECMO = extracorporeal membrane oxygenation; MAE = major adverse events; PE = pulmonary embolism; DVT = deep vein thrombosis; HF = heart failure

[CI: 2.75 – 64.23]; $P < 0.01$) were at increased risk for the composite outcome compared to those with normal cTn levels (Table 2). When compared to those with mild cTn elevation, patients with severe cTn elevation (aOR 5.97 [CI: 0.97 – 72.35]; $P = 0.09$) were not at increased risk of severe infection. The incidence of the individual components of the composite outcome by level of cTn elevation is shown in Supplemental Table 1.

8. Secondary outcomes by presence/absence of cTn elevation

When compared to those with normal cTn levels, patients with elevated cTn were more likely to be intubated (57.4% vs 25.7%, $P < 0.001$), require tracheostomy (9.6% vs 3.2%, $P < 0.01$), need ECMO (5.3% vs 1.5%, $P < 0.05$), have a pressor requirement (56.5% vs 24.2%, $P < 0.001$), have an inotrope requirement (13.0% vs 1.5%, $P < 0.001$), and require admission to the ICU (63.5% vs 21.8%, $P < 0.001$) or ICU level of care during their hospitalization (76.5% vs 40.6%, $P < 0.001$) (Table 3). Those with elevated cTn also had a higher incidence of a combined outcome of in-hospital mortality or readmission compared to those with normal cTn levels (41.7% vs 21.6%, $P < 0.001$). There was no significant difference in the rates of readmission alone between the groups.

The median time of the first MAE was 5 days after hospitalization (IQR 1 – 12). Those with elevated cTn levels were more likely to suffer a MAE in general compared to those with normal cTn measurement (49.6% vs 15.8%, $P < 0.001$). For individual MAE, elevated cTn was associated with increased rates of pulmonary embolism (10.4% vs 2.6%, $P < 0.001$), deep venous thrombosis (9.6% vs 2.4%, $P < 0.001$), acute kidney injury requiring renal replacement therapy (21.7% vs 6.4%, $P < 0.001$), life-threatening arrhythmia (20.9% vs 6.5%, $P < 0.001$), and acute heart failure exacerbation (8.7% vs 1.4%, $P < 0.001$). There was no significant difference between the groups in the incidence of stroke.

9. Secondary outcomes by level of cTn elevation

Those with severe cTn elevation were more likely to be intubated (71.7% vs 47.8%, $P < 0.05$), require the intensive care unit on admission (76.1% vs 55.1%, $P < 0.05$) or at some point during the hospitalization (89.1% vs 68.1%, $P < 0.05$), and need vasopressor (76.1% vs 43.5%, $P < 0.01$) and inotropic agents (23.9% vs 5.8%, $P < 0.05$) (Table 4). Significant differences between the mild and severe cTn groups were not present in the incidence of readmission, ECMO, tracheostomy, or a composite of both in-hospital mortality or readmission.

There were also no significant differences between the incidence of MAE between the severe and mild cTn groups.

10. Light cTn elevation

In this cohort, 64 patients (8.3%) had light cTn elevation. When compared to cTn $\leq 0.5x$ ULN, those with light cTn elevation were more likely to have severe COVID-19 infection (61.5% vs 41.8%, $P < 0.01$), in-hospital mortality (18.5% vs 9.6%, $P < 0.05$), and 60-day mortality (24.6 vs 12.6%, $P < 0.05$).

11. Comparing those with vs without cTn measurement

The 820 patients who had cTn measured during their hospitalization were compared with the 512 patients without measurement regardless of chronic kidney disease status. In comparing baseline characteristics, the cTn group was more likely to be older and male with a higher median body mass index (Supplemental Table 2). Patients with cTn measured were also more likely to have a prior history of most comorbidities tested including atrial fibrillation, coronary artery disease, hypertension, and prior myocardial infarction ($P < 0.001$). The cTn group also had significantly higher incidence of 60-day mortality (17.1% vs 3.1%, $P < 0.001$) and severe COVID-19 infection (48.9% vs 19.9%, $P < 0.001$) when compared to those with no cTn measurement during their index hospitalization.

12. Comparing initial to maximum cTn measurement

A total of 218 patients had multiple cTn measurements during their hospitalization. The median delta of the maximum cTn value minus the initial cTn value was 0.040 (IQR 0.016 – 0.323). On average, the maximum cTn value was obtained on hospital day 4 (IQR 1 – 9). No statistical analysis was performed using the delta or the maximum cTn value as the focus of this study was on the prognostic role of initial cTn measurement.

13. Discussion

To date, prior studies have demonstrated the prognostic role of cTn level measurement in predicting COVID-19 severity and mortality [11,13,16–20]. However, many of these studies only measured complications and mortality during a patient's hospitalization without post-discharge follow up [13,16,17]. Our study supports prior work and provides additional longitudinal outcomes with our 60 day follow up post hospital discharge.

Table 4
Secondary Outcomes by Level of Cardiac Troponin Elevation

	Mild cTn Elevation, > 1 to < 2x ULN	Severe cTn Elevation, ≥ 2x ULN	P -value
n	69	46	
Readmitted (%)	10 (14.5)	2 (4.3)	0.152
In-Hospital Mortality or Readmission (%)	26 (37.7)	22 (47.8)	0.375
Admitted to ICU (%)	38 (55.1)	35 (76.1)	0.036
Required ICU During Admission (%)	47 (68.1)	41 (89.1)	0.017
ECMO (%)	3 (4.3)	3 (6.7)	0.910
Tracheostomy (%)	8 (11.6)	3 (6.7)	0.585
Required Pressors (%)	30 (43.5)	35 (76.1)	0.001
Required Inotropes (%)	4 (5.8)	11 (23.9)	0.011
Total 60-Day MAE (%)	30 (43.5)	27 (58.7)	0.159
PE (%)	5 (7.2)	7 (15.2)	0.290
DVT (%)	4 (5.8)	7 (15.2)	0.174
Renal Replacement Therapy (%)	11 (15.9)	14 (30.4)	0.106
Life-threatening Arrhythmia (%)	12 (17.4)	12 (26.1)	0.373
Stroke (%)	0 (0.0)	0 (0.0)	1.000
Acute HF Exacerbation (%)	4 (5.8)	6 (13.0)	0.311

cTn = cardiac troponin; ULN = upper limit of normal; ICU = intensive care unit; ECMO = extracorporeal membrane oxygenation, MAE = major adverse event; PE = pulmonary embolism; DVT = deep venous thrombosis

Supplemental Table

1: Individual Components of the Composite Outcome for Severe COVID-19 Infection by Level of Cardiac Troponin Elevation

	Normal cTn, ≤ 1x ULN	Mild cTn Elevation, > 1 to < 2x ULN	Severe cTn Elevation, ≥ 2x ULN	P -value
n	658	69	46	
60-Day Mortality (%)	91 (13.8)	20 (29.0)	24 (52.2)	<0.001
Need for ICU (%)	268 (40.7)	47 (68.1)	41 (89.1)	<0.001
NIPPV (%)	40 (6.1)	1 (1.4)	6 (13.0)	0.039
Mechanical Ventilation (%)	170 (25.8)	33 (47.8)	33 (71.7)	<0.001
Overall Composite (%)	288 (43.8)	49 (71.0)	43 (93.5)	<0.001

cTn = cardiac troponin; ULN = upper limit of normal; ICU = intensive care unit; NIPPV = non-invasive positive pressure ventilation

Supplemental Table

2: Comparison of baseline characteristics, comorbidities, and outcomes in patients with and without cardiac troponin measurement

	No cTn Measured	cTn Measured	P-value
n	512	820	
Age (median [IQR])	54.00 [42.00, 66.00]	59.50 [47.00, 72.00]	<0.001
Male (%)	254 (49.6)	485 (59.1)	0.001
BMI (median [IQR])	27.10 [23.15, 31.70]	28.00 [24.10, 33.45]	0.004
<i>Comorbidities</i>			
Atrial Fibrillation (%)	42 (8.2)	141 (17.2)	<0.001
Coronary Artery Disease (%)	87 (17.0)	241 (29.4)	<0.001
Hypertension (%)	283 (55.3)	540 (65.9)	<0.001
Chronic Kidney Disease (%)	102 (19.9)	225 (27.4)	0.002
COPD (%)	22 (4.3)	67 (8.2)	0.008
Diabetes Mellitus (%)	215 (42.0)	389 (47.4)	0.059
Asthma (%)	66 (12.9)	105 (12.8)	1.000
Cancer (%)	47 (9.2)	92 (11.2)	0.275
Stroke (%)	52 (10.2)	126 (15.4)	0.008
Myocardial Infarction (%)	38 (7.4)	145 (17.7)	<0.001
Venous Thromboembolism (%)	48 (9.4)	121 (14.8)	0.005
<i>Outcomes</i>			
60-Day Mortality (%)	16 (3.1)	140 (17.1)	<0.001
Severe COVID-19 Infection (%)	102 (19.9)	401 (48.9)	<0.001

cTn = cardiac troponin; IQR = interquartile range; BMI = body mass index; COPD = chronic obstructive pulmonary disorder

In our cohort, both severe and mild cTn elevation were significant predictors of severe COVID-19 infection compared to those with normal cTn levels. Additionally, severe cTn elevation, but not mild cTn elevation, was also predictive of both in-hospital and 60-day mortality. Those with an elevated cTn level were also at increased risk for 60-day MAE in virtually every individual outcome including pulmonary embolism, deep venous thrombosis, life-threatening arrhythmia, and acute heart failure exacerbation. The role of cTn as a biomarker in predicting in-hospital mortality and morbidity has been elucidated in earlier studies [11,17,18]. Our

study takes this further by establishing cTn's role in longitudinal prognostication of patients hospitalized with COVID-19 disease, up to 60 days after initial presentation regardless of medical comorbidities or other markers of inflammation including CRP, LDH, and ferritin [23].

In patients who have recovered from acute COVID-19 infection, the majority will have the persistence of at least one symptom with a significant fraction even having post-infection pulmonary or extrapulmonary organ dysfunction [25,26]. While there is still much to learn about the long-term effects of COVID-19 infection,

some hospitals have established outpatient COVID-19 clinics to address the volume and unique needs of this group of patients [26]. While previous studies have focused on cTn's prognostic role for in-hospital events, our data on 60-day mortality and 60-day MAE indicates that the prognostic value of initial cTn measurement appears to extend beyond the acute COVID-19 hospitalization. Therefore, those with elevated cTn levels represent a high-risk group that should be closely followed even after their index hospitalization.

Our cohort does have key differences from previously published cTn data. Our positive cTn percentage (14.9%) was less than that found in Majure *et al.* in New York (30%) and Shah *et al.* in Georgia (37.5%) but within published estimates from China (7–28%) [16,19]. Furthermore, the mean age of our cohort (59) was younger than both Majure *et al.* (66) and Shah *et al.* (63) [16,19]. Our hospital also checked cTn on a greater percentage of those admitted with COVID-19 than did Majure *et al.* (61% vs 56%)[19].

The data is mounting that the role of cTn should be expanded beyond the previous engrained notion as a test for myocardial ischemia. Even prior to COVID-19, cTn has been found to be a predictor of both in-hospital and long-term mortality in intensive care unit patients with acute respiratory disease [27]. In addition to myocardial infarction, the possible causes of elevated cTn in COVID-19 are multiple including chronic disease-causing myocardial injury, acute non-ischemic cardiac injury, and acute non-ischemic non-cardiac injury such as sepsis or pulmonary embolism [22].

As advances continue to be made in the therapeutic options for COVID-19 treatment, it is essential to continue building stronger risk stratification methods to rapidly determine who would most benefit from these therapies [28–31]. Further studies should be focused on prospectively verifying the role of cTn as a predictor, and if those results support the current literature, cTn should be more aggressively considered as a routine prognostic lab in COVID-19 patients.

14. Study limitations

In this cohort study, a significant limitation is the selection bias of those who had cTn measured during their hospitalization. When tested, those with cTn measurement had increased frequency of most baseline comorbidities tested and an increased incidence of both severe COVID-19 infection and 60-day mortality when compared to those without cTn measurement who were excluded from our study. Additionally, while those with end-stage kidney disease or CKD Stage V were excluded, those with lesser degree of chronic kidney disease (CKD stages 1–4) were included. Given that any degree of renal dysfunction can affect cTn level, this could have affected cTn assessment to a certain level. Furthermore, our institution does not use high sensitivity cTn, which serves as an even more promising biochemical biomarker for COVID-19 due to the assay's ability to detect even smaller changes in cTn level. Lastly, as this study was conducted within the centers of the Rush University System for Health (RUSH) alone, it is possible that some post-discharge complications and deaths were not collected in our dataset as we only had access to local area hospitals that used the EPIC electronic medical record.

15. Conclusion

In our cohort, both mild and severe initial cTn elevation were predictors of severe COVID-19 infection, while only severe cTn elevation was predictive of 60-day mortality. First cTn value on hospitalization is a valuable longitudinal prognosticator for COVID-19 disease severity and mortality.
