Abstract: The treatment of hepatocellular carcinoma (HCC) has witnessed radical changes over the last few years, with the introduction of immune checkpoint inhibitors (ICI) in clinical practice, namely the combination of atezolizumab plus bevacizumab as the standard of care for first-line treatment of advanced HCC. The immunosuppressive microenvironment of the chronically inflamed liver makes HCC a fertile ground for the use of ICI. This review focuses on anti-programmed cell death-1 (PD-1) monoclonal antibodies (mAb), which have been extensively studied, as monotherapy, in combination with other ICI or with antiangiogenic agents. Currently, anti-PD-1 agents are approved by the United States Food and Drug Administration for second-line treatment in advanced HCC: nivolumab, alone or in combination with ipilimumab, and pembrolizumab. Lack of demonstration of survival benefit in first and second line led to the investigation of PD-1 agents in combination with multi-kinase inhibitors, with a number of first-line treatment regimens being actively investigated. Mounting evidence suggests a potential role of PD-1 blockade as adjuvant or neoadjuvant therapies. A key challenge remains the identification of biomarkers of response, since only a minority of patients appear to benefit from ICI.

Keywords: liver cancer, immunotherapy, advanced, immune checkpoint inhibition, PD-1, angiogenesis

Introduction

Liver cancer accounts for 830.180 deaths in the world every year and ranks 6th as most frequently diagnosed cancer and third as most frequent cause of cancer-related deaths.¹ Hepatocellular carcinoma (HCC) represents the majority of cases of primary liver cancer. It arises most frequently in the context of an underlying liver disease, such as chronic viral hepatitis (hepatitis C virus [HCV] being the predominant etiological factor in Western countries and hepatitis B virus [HBV] in East Asia), alcoholic cirrhosis, non-alcoholic steatohepatitis (NASH), non-alcoholic fatty liver disease (NAFLD), and exposure to toxic agents such as aflatoxin. In particular, the incidence and the prevalence of NAFLD-related HCC are expected to increase, especially in the US, with NAFLD likely to become the most frequent etiology in the upcoming years.² If diagnosed in the early phases, HCC can be potentially cured with surgical resection, liver transplantation, or loco-regional approaches. However, most of the patients are diagnosed with an advanced disease, and systemic agents represent the treatment of choice.^{3,4}

The most frequently used staging system for HCC is the Barcelona Clinic Liver Cancer (BCLC) classification, and systemic treatment is indicated for patients

classified as BCLC C or BCLC B not deemed amenable to further loco-regional treatments. For more than a decade, multikinase inhibitors (MKIs) targeting the angiogenesis pathway have been the mainstay for advanced HCC treatment, with sorafenib being the only available first-line treatment,^{5,6} until another MKI, lenvatinib, was proven non-inferior to sorafenib in the Phase III REFLECT trial.⁷ For patients progressing on or intolerant to sorafenib, several agents have been proven effective as second-line treatment. In particular, two MKIs, regorafenib and cabozantinib, achieved a significant survival advantage for sorafenib-pretreated patients in the phase III RESORCE and CELESTIAL trials, respectively.^{8,9} Of note, cabozantinib is the only agent showing a benefit as third-line treatment, since 27% of the enrolled patients in the CELESTIAL trial had received two previous lines of treatments. Ramucirumab, an anti-VEGF monoclonal antibody (mAb), represents the only example of biomarker-driven therapy for HCC, since it showed to significantly prolong survival compared to placebo in sorafenib-pretreated patients with a baseline alpha-fetoprotein (AFP) ≥ 400 ng/mL.¹⁰

However, the landscape of HCC treatment has dramatically changed in the last few years with the use of immune checkpoint inhibitors (ICI). The modulation of

the immune system via the blockade of the programmed death-1 (PD-1)/PD-ligand 1 (PD-L1) and/or via the combined blockade of the cytotoxic T-lymphocytes antigen-4 (CTLA-4) has been approved for several cancer types, becoming the current standard of care in different lines of treatment. The implementation of ICI for HCC treatment has met several challenges, due to the fact that the presence of a chronic HBV or HCV infection has been classically considered as a contraindication to the use of immunotherapy, due to the fear of a viral reactivation. However, the presence of a largely immunotolerant environment in the liver makes the use of immunomodulatory agents for HCC particularly intriguing.¹¹ The United States (US) Food and Drug Administration (FDA) approved the use of the combination of atezolizumab, an anti-PD-L1 mAb, plus bevacizumab, an anti-vascular endothelial growth factor (VEGF) mAb, as first-line treatment of unresectable or metastatic HCC, after the positive results of the phase III IMbrave150 trial, where the combination outperformed sorafenib in terms of survival and response.^{12,13} For further lines of treatment, in sorafenib-pretreated patients, the FDA has approved the use of nivolumab, an anti-PD-1, alone or in combination with ipilimumab, an anti-CTLA-4 mAb, and pembrolizumab, another anti-PD-1 agent (Table 1).

This review will focus on the use of PD-1 inhibitors for the treatment of advanced HCC, with a special focus on the possible future application in earlier phases of the disease.

The PD-1/PD-L1 Pathway as a Therapeutic Actionable Driver of Anti-Cancer Immunity in HCC

PD-1 and its ligand PD-L1 compose a widely studied checkpoint regulating the adaptive immune response. While PD-1 is a glycoprotein expressed on the cell membrane of tumor-infiltrating immune cells, PD-L1 is constitutively expressed on several lineages of immune cells and it is further upregulated upon their activation. It can also be expressed by tumor cells and by a number of somatic cells when exposed to proinflammatory cytokines, namely vascular endothelial cells, fibroblastic reticular cells, epithelia, pancreatic islet cells, astrocytes, and neurons.¹⁴ The PD-1/PD-L1 axis leads to a negative feedback on immune response, by blocking the T-cell receptor (TCR) and CD28 signaling.^{15,16} Immune escape is one of the hallmarks of cancer,¹⁷ and tumor cells often overexpress PD-L1 as a resistance mechanism, in order to hijack the PD-1/PD-L1 immunosuppressive pathway. For this reason, the development and the use of anti-PD-1 and anti-PD-L1 mAb has changed the treatment paradigm of many cancer types. HCC provides a particularly fertile ground to use ICI, since the underlying chronic disease induces an immune-tolerant microenvironment, where tumor cells can escape from immunological surveillance. An important function of the liver is to act as an “immunological gatekeeper” since it receives and metabolizes a number of immunologically active substances from the gut: in particular, patients with a liver disease are characterized by a “leaky gut”, and the liver receives microbial components from the gut microbiota, including bacterial nucleic acid, lipopolysaccharides (LPS), and toxins, collectively referred to as microbial-associated molecular patterns (MAMPs) or pathogen-associated molecular patterns (PAMPs).¹⁸ HCC is known to escape from immune response thanks to aberrant expression of neoantigens and dysfunctional antigen presentation through the major histocompatibility complex.¹¹ The impaired recruitment of CD4+ and cytotoxic CD8+ cells, combined with the expansion of tolerogenic dendritic cells and regulatory T cells (T-regs), contribute to the liver immune tolerance. Also, a number of cell lines play in role in the

immunosuppressive microenvironment, namely myeloid-derived suppressor cells (MDSCs), hepatic stellate cells, and tumor-associated macrophages (TAMs).¹¹ Despite some initial fears that ICI could cause a viral flare in case of HCV or HBV-related HCC, the first pivotal trials unequivocally confirmed the safety of ICI in these patients,¹⁹ paving the way for the subsequent efficacy testing of immunotherapy in HCC. The first anti-PD-1 agent used in HCC was nivolumab, a fully human IgG4 mAb blocking PD-1 interaction with PD-L1 and its other ligand PD-L2, and then others followed, namely pembrolizumab, sintilimab, and tislelizumab.

In order to tackle the multiplicity of resistance mechanisms within the cancer-immunity interface, anti-PD-1 agents were tested in combination with other anti-tumor classes, such as anti-CTLA-4 mAb and antiangiogenic drugs. Double checkpoint blockade has showed to exert a synergistic anti-tumor effect across malignancies, in particular malignant melanoma²⁰ and renal cell carcinoma.²¹ CTLA-4 is a receptor on the membrane of activated T cells and it is constitutively expressed on the membrane of CD4+ CD25+ regulatory T cells (T-regs). It binds to ligands of the B7 family (CD80/CD86) on antigen-presenting cells (APCs) and downplays the adaptive immune response, counteracting CD28 activating signal.²² The combined inhibition of PD-1 and CTLA-4 enhances CD8+ T cell-mediated tumoral killing, activating a broader gene response than with the single agents.²³

Another avenue tested to promote synergistic efficacy is inhibition of the VEGF pathway, a master regulator of angiogenesis, immune tolerance and driver of poor prognosis in HCC. Anti-PD-1 agents have also been investigated in combination with anti-VEGF mAb, such as bevacizumab, or with MKI with an antiangiogenic mechanism of action. The VEGF pathway is known to exert an immunosuppressive effect via a pleiotropic range of mechanisms, mainly involving the promotion of immunomodulating cell types (immature dendritic cells, myeloid-derived suppressor cells, tumor-associated macrophages, and T-regs) and the downregulation of CD8+ T cells activity.²⁴ Moreover, VEGF promotes aberrant angiogenesis and local hypoxia, which is a known mechanism of tumor immune escape in HCC.²⁵ Preclinical data show that the use of anti-VEGF agents can revert these immunosuppressive effects, and the concomitant use of ICI can enhance the immune-mediated tumoral killing.²⁶ Furthermore, the inhibition of the neoangiogenesis can restore the normal delivery of ICI in tumor

tissues and can reduce the hypoxia-induced PD-L1 overexpression.²⁷

The presence of this strong preclinical rationale has paved the way for using ICIs as monotherapy or in combination in clinical practice for HCC treatment, translating into a significant benefit for cancer patients.

Clinical Evidence for the Use of PD-1 Inhibitors in Advanced HCC

Anti-PD-1 ± Anti-CTLA-4 for Advanced Disease

Nivolumab used as monotherapy was approved by the FDA for sorafenib-pretreated patients on the basis of the results of the phase I/II CheckMate-040 study.²⁸ This was a multi-center, non-comparative, open-label trial testing the safety and efficacy of nivolumab in 48 patients for the dose-escalation and 214 for the dose-expansion phase. Patients were stratified according to viral and non-viral etiology and a Child-Pugh score up to B7 was allowed. The majority of patients had already been treated with sorafenib (182 out of 262, 69.5%). The recommended dose for the expansion phase was 3 mg/kg every 2 weeks, after exposing patients in the dose escalation phase to a dose from 0.1 mg/kg to 10 mg/kg without dose-limiting toxicities. In the dose-expansion group, nivolumab achieved an objective response rate (ORR) of 20% (95% confidence interval [CI], 15–26) and a disease control rate (DCR) of 64% (95% CI, 58–71) per Response Evaluation Criteria in Solid Tumors (RECIST) 1.1 criteria, similar across the prespecified subgroups, and a 9-month overall survival rate of 74% (95% CI, 67–79) (Table 1). The experimental drug showed no unexpected safety signal, and in particular no viral flares in patients suffering from HCV and HBV hepatitis. Of note, nivolumab was proven a safe and effective option also in patients with a Child-Pugh B7 liver function, with a comparable rate of treatment-related adverse events (TRAEs) and treatment discontinuation due to an AE than in the general population.²⁹ This pivotal trial paved the way for the CheckMate-459 trial, the multicenter phase III randomized trial testing the superiority of nivolumab in first line against the previous standard of care sorafenib.³⁰ However, the study did not meet its primary endpoint: median OS did not significantly differ between the nivolumab arm (16.4 months [95% CI, 13.9–18.4]) and the control arm (14.7 months [CI 95%, 11.9–17.2]), with an HR of 0.85 (95% CI, 0.72–1.02; $p=0.0752$). Notably, both drugs achieved unprecedented results in terms of survival: nivolumab reached the highest median OS compared to the previous phase III first-line trials,

and sorafenib obtained a much longer survival than in the SHARP⁵ and in the Asia-Pacific⁶ trial, possibly reflecting a better patient selection and an improved AEs management.³¹ The authors highlighted a potential clinical benefit of nivolumab, with regard to ORR (15% versus 7% for nivolumab and sorafenib, respectively), grade 3–4 (G3–4) TRAEs (22% versus 49%), and quality of life (QoL) in a further analysis.³² However, in view of the lack of survival advantage, nivolumab cannot be considered an alternative to sorafenib in first line.

The role of nivolumab in HCC was also explored in combination with ipilimumab. The double immune checkpoint blockade was investigated in the cohort 4 of the CheckMate-040 trial in patients who progressed on or were intolerant to sorafenib.³³ The combination was tested at different dosing regimens: the best results were obtained in the arm A of this cohort, where 49 patients received nivolumab 1 mg/kg plus ipilimumab 3 mg/kg every 3 weeks for four doses, followed by single-agent nivolumab 240 mg every 2 weeks. This regimen achieved an ORR of 32% (95% CI, 20–47) per RECIST 1.1, including 4 complete responses (CR), and a median duration of response (DOR) not reached (NR) (Table 1). Also, the regimen in arm A outperformed the other arms in terms of survival, with a median OS of 22.8 months (95% CI, 9.4–NR) versus 12.5 months (95% CI, 7.6–16.4) and 12.7 months (95% CI, 7.4–33.0) in arm B and C, respectively. In arm A, 53% patients experienced a G3–4 TRAE, with the most frequent causes of treatment discontinuation being hepatitis (6%), pneumonitis (6%), colitis (4%). Interestingly, researchers did not observe any recurrence of immune-related AE (irAE) when patients suffering from an irAE were rechallenged with nivolumab or ipilimumab. Based on these results, the US FDA approved the use of the combination of nivolumab plus ipilimumab at the regimen tested in the arm A after sorafenib discontinuation. Also, this regimen is currently under investigation in the phase III CheckMate 9DW trial (NCT04039607), where it is tested in first line against sorafenib (Table 2). Another PD-1 inhibitor, pembrolizumab, received the FDA approval for sorafenib-pretreated patients after the positive results of the Phase II KEYNOTE-224 trial.³⁴ The trial met its primary endpoint, with an ORR of 17% (95% CI, 11–26), and prepared the ground for the subsequent randomized phase III KEYNOTE-240 trial.³⁵ This trial randomized 413 patients who had failed prior sorafenib in a 2:1 ratio to pembrolizumab or to placebo. Due to the statistical design, which established a prespecified boundary of $p=0.0174$ for OS, the primary endpoint, median OS, was not met: pembrolizumab achieved a median OS of 13.9 months

Table 2 Ongoing Phase III Trials with Anti-PD-1 Agents for First-Line Advanced Disease

Notes: ^aA radiological diagnosis according to the American Association for the Study of Liver Diseases (AASLD) criteria is admitted in LEAP-002 trials for cirrhotic patients; ^bnon inferiority trial; references are reported in square brackets.

Abbreviations: HCC, hepatocellular carcinoma; BCLC, Barcelona Clinic Liver Cancer; ECOG PS, Eastern Cooperative Oncology Group Performance Status; iv, intravenously; q3w, every 3 weeks; OS, overall survival; ORR, objective response rate; PFS, progression-free survival; DOR, duration of response; TTP, time to progression; HRQoL, health-related quality of life; DCR, disease control rate; CBR, clinical benefit rate; RECIST 1.1, response evaluation criteria in solid tumors version 1.1; mRECIST, modified response evaluation criteria in solid tumors; q4w, every 4 weeks; TTSD, time to symptom deterioration.

(95% CI, 11.6–16.0) versus 10.6 months (95% CI, 8.3–13.5) with placebo (HR 0.78; 95% CI, 0.611–0.998; $p=0.0238$), while median progression-free survival (PFS) was 3.0 months (95% CI, 2.8–4.1) versus 2.8 months (95% CI, 1.6–3.0) with pembrolizumab and placebo, respectively (HR, 0.72; 95% CI, 0.570–0.904; $p=0.0022$, where the prespecified boundary was $p=0.002$) (Table 1). Despite the consistency of these findings with the previous phase II study, this trial was formally negative. After the disappointing findings of anti-PD-1 mAbs as monotherapy, it will be of high interest to analyze the data from the phase III non-inferiority trial (RATIONALE 301: NCT03412773)³⁶ currently testing tislelizumab (BGB-A317), another anti-PD-1 mAb, against sorafenib in first line, after the promising results obtained in a previous phase Ia/b trial³⁷ (Table 2).

Anti-PD-1 Plus Antiangiogenic Agents

Following the success of the combination of atezolizumab and bevacizumab in the IMBrave150 study,¹² another combination was proven effective in treatment-naïve HCC patients. The ORIENT-32 was a phase II/III trial testing the

superiority of the combination of sintilimab, an anti-PD-1 mAb, and a bevacizumab biosimilar against sorafenib as first-line treatment in a Chinese, HBV-predominant population.³⁸ The trial reached its primary endpoints, both median OS (not estimable [NE] versus 10.4 months; HR 0.57; 95% CI, 0.43–0.75; $p < 0.0001$) and median PFS (4.6 versus 2.8 months; HR 0.56; 95% CI 0.45–0.7; $p < 0.0001$), thus making the combination a possible new standard of care for Chinese patients. Earlier phase studies tested the combination of anti-PD-1 mAb and MKI with a known antiangiogenic spectrum. Pembrolizumab plus lenvatinib was administered in a phase Ib study to 100 untreated HCC patients, with an ORR of 46.0% (95% CI, 36.0–56.3) and a DCR of 88.0% (95% CI, 80.0–93.6) per modified RECIST (mRECIST) criteria by independent review.³⁹ Based on these results, a phase III trial is currently testing the combination in a large population against sorafenib⁴⁰ (Table 2). Lenvatinib has been successfully combined with nivolumab in another phase Ib study conducted in 30 Japanese patients, where the combination obtained a promising ORR of 76.7% per mRECIST criteria.⁴¹ Moreover, a third phase Ib trial

tested the combination of pembrolizumab plus regorafenib on 32 treatment-naïve patients, with an interesting ORR of 28% and a manageable safety profile.⁴² Another anti-PD-1 agent, camrelizumab, was combined with apatinib (anti-VEGFR-2 MKI) in the phase II RESCUE trial, where the combination was tested both in first and second line, achieving an ORR of 34% for untreated patients and 22.5% as second line.⁴³

Clinical Evidence for the Use of PD-1 Inhibitors in Earlier Phases

Anti-PD-1 as Adjuvant Therapy for HCC

Currently, no treatment has proved to be effective in the adjuvant setting for HCC, after surgical resection, liver transplantation, or loco-regional treatment. These approaches can be performed for patients diagnosed with early-stage disease with a curative intent; however, tumor recurrence affects long-term survival, with relapse rates of up to 70% and 5-year OS <50%.⁴⁴ Early relapse involves the recurrence of the primary tumor, while late relapse involves the appearance of a new primary tumor in the context of a chronically damaged liver. The only phase III trial testing a possible adjuvant treatment for HCC was the STORM trial, failing to demonstrate an advantage in relapse-free survival with sorafenib.⁴⁵ Anti-PD-1 mAb have already proved effective in the adjuvant setting in other cancer types, such as melanoma⁴⁶ and gastroesophageal cancer,⁴⁷ showing a significant survival advantage. For HCC, several immunotherapy strategies have already been tried, such as cancer vaccines⁴⁸ and lymphocyte infusions,⁴⁹ without conclusive evidence. Currently, large phase III clinical trials are investigating the role of anti-PD-1 mAb in the adjuvant setting after curative resection or ablation, in particular nivolumab (CheckMate 9DX: NCT03383458) and pembrolizumab (KEYNOTE-937: NCT03867084). However, due to the high risk of acute graft rejection and due to the need of a chronic immunosuppressive therapy, it is not possible to design a trial with an adjuvant ICI after a liver transplantation.⁵⁰

Anti-PD-1 as Neoadjuvant Therapy

Most of HCC patients are diagnosed at a late stage of the disease, when it is not possible to offer a potentially curative treatment, such as surgical resection, liver transplantation or local ablation. For this reason, the use of a systemic therapy as a bridge to downstage the disease and to make it susceptible of a loco-regional approach is an appealing

strategy. If this strategy was difficultly viable in the past, given the low ORR obtained by MKI, the more robust responses seen in the ICI clinical trials bring the spotlight on the neoadjuvant approach for HCC. Furthermore, the use of ICI in the neoadjuvant setting offers a unique possibility of observing the *in vivo* response to the checkpoint blockade, thus providing precious tissue samples for biomarker studies. Currently, no clinical data are available of the efficacy of anti-PD-1 in this setting, but several phase I/II clinical trials are currently testing nivolumab (NCT03630640), cemiplimab (NCT03916627), and toripalimab (NCT03867370). Moreover, a phase II study (NCT03630640) and the phase Ib PRIME-HCC trial⁵¹ (NCT03682276) are investigating the use of the combination of nivolumab and ipilimumab prior to surgical resection, and the latter will provide a thorough biomarker study on biological samples.

Anti-PD-1 in Combination with Loco-Regional Treatments

Loco-regional treatments are the treatment of choice for early and intermediate stage HCC.³ Besides their classic ablative action, a growing evidence points at the possible immunomodulatory role of these techniques, thus suggesting a potential synergism with immune checkpoint blockade. In particular, radiofrequency ablation (RFA) and microwave ablation (MWA), used for early-stage HCC, are known to influence the tumor microenvironment via the release of tumor neoantigens, thus promoting local infiltration of CD8+ T cells and the systemic CD8+ T cell-mediated response.⁵² Also, the well-known abscopal effect induced by radiotherapy (RT) has not been characterized yet in HCC, but, considering the growing use of stereotactic body RT in early-stage HCC, the combination with ICI could be of high interest.⁵³ Trans-arterial chemoembolization (TACE) is the treatment of choice for BCLC B stage HCC. The ischemic damage caused by the arterial occlusion induces the production of the hypoxia inducible factor (HIF)-1 α , a known modulator of PD-L1 expression. Furthermore, TACE can act on tumor microenvironment by decreasing the percentage of Tregs and increasing the CD4+/CD8+ ratio, thus suggesting a possible positive interaction with ICI anti-tumor activity.⁵⁴ This rationale guided the design of trials testing the combination of TACE and anti-PD-1 mAb, for instance the phase I/II PETAL study is investigating the safety and preliminary efficacy of pembrolizumab after TACE in intermediate

stage HCC (NCT03397654), while another study is testing the combination of nivolumab plus drug eluting bead-TACE (deb-TACE) (NCT03143270).

Biomarkers of Response

Despite the major advances in the use of immunotherapy for HCC, only a minority of patients respond to ICIs. The causes beneath the lack of response are not fully understood, and the search for biomarkers of response has become an area of high unmet need.⁵⁵ Biomarkers associated with ICI efficacy in other cancer types appear to have little utility in HCC. For instance, microsatellite instability (MSI) is a widely recognized biomarker of response to ICI, and FDA granted pembrolizumab a site-agnostic accelerated approval for any MSI-high (MSI-H) or mismatch-repair deficient (dMMR) unresectable or metastatic cancer type, based on the response rates in the KEYNOTE-016 study.⁵⁶ However, the percentage of MSI-H among HCC patients is low (<3%)⁵⁷ and, despite some anecdotal evidence,^{58,59} the testing for MMR status as biomarker of response for ICI in HCC would be of low impact. Tumor mutational burden (TMB) over ten mutations per megabase (defined as TMB-high [TMB-H]) was found to be associated with a response to ICI in the KEYNOTE-158 study,⁶⁰ leading the FDA to grant pembrolizumab its second site-agnostic approval for the treatment of unresectable or metastatic TMB-H cancer regardless of its primary site. However, the study did not include any HCC patient, and HCC itself normally arises in an immunosuppressive microenvironment, with cases of TMB-H HCC being infrequent.⁶¹ PD-L1 expression, measured with different immunohistochemistry assays either on tumor cells as tumor proportional score (TPS) either on tumor and surrounding immune cells as combined positive score (CPS), is a predictive biomarker of response in several cancer types.⁶² However, the efficacy of ICIs in HCC does not seem to be related to PD-L1 expression. For instance, in the CheckMate-040 trial, the PD-L1 expression on tumor cells was assessed as secondary endpoint, but response to nivolumab was comparable across subgroups (PD-L1 < or \geq 1%).²⁸ However, in a preplanned exploratory analysis of the KEYNOTE-224 trial, the response to pembrolizumab seemed to be linked to PD-L1 expression quantified with CPS, but not with TPS,³⁴ suggesting that further, prospective studies are needed to clarify the issue. Currently, the FDA approvals for ICIs HCC do not take into account the PD-L1 expression: the measure of PD-L1 is not performed in clinical practice and

the lack of PD-L1 expression is not an exclusion criterion for the administration of ICIs. On the other hand, a more integrated evaluation of tumor microenvironment and immune phenotypes could be crucial to better predict ICI response.^{63,64} A post-hoc biomarker analysis performed on the tissues of patients treated with nivolumab within the dose-escalation and dose-expansion phases of the CheckMate-040 identified a possible role of a 4-gene signature as predictor of response to ICI.⁶⁵ This analysis further highlighted the limitation of considering PD-L1 expression as a sole biomarker, since responses to nivolumab were registered regardless of PD-L1 expression, even if ORR were numerically higher in PD-L1 \geq 1% patients.

Recent data show that response to ICI could depend on HCC aetiology. In particular, patients who develop HCC on the background of NASH etiology have been found to harbour an enriched population of exhausted CD8+PD1+ T cells.⁶⁶ These aberrant cells are linked to an impaired immune surveillance, leading to a lack of response to ICI. This preclinical observation has been further corroborated by a meta-analysis of three randomized phase III clinical trials investigating ICI in advanced HCC, showing that survival of non-viral HCC patients was not improved by immunotherapy.⁶⁶ Prospective evaluation of these mechanisms is warranted; however, immunotherapy still remains a valid treatment regardless of the underlying aetiology.⁶⁷

Additional data will be provided by the biomarker analyses planned within the ongoing phase III immunotherapy trials, both on tumor samples and other biological samples to overcome the problem of biopsy availability, trying to disentangle the complicated issue of ICI response in HCC.

Open Challenges

In 2017, the first results of the CheckMate-040 trial showed that anti-PD-1 inhibitors could radically change the natural history of HCC, challenging the dominance of MKI in the treatment algorithm.²⁸ These pivotal findings paved the way, a couple of years later, to the unquestionable success of the anti-PD-L1 mAb atezolizumab in combination with bevacizumab in the IMbrave150 study.¹² However, the disappointing data coming from the use of nivolumab³⁰ and pembrolizumab³⁵ as monotherapy raise an intricate question: is there still a place for anti-PD-1 agents in HCC? Undoubtedly, despite the trial not reaching its primary endpoint, Checkmate-459 highlighted the good safety profile of nivolumab, and its better

tolerability compared to sorafenib.³² We can speculate that a possible role of anti-PD-1 agents as monotherapy could be based on the favorable impact on QoL. Based on the trial results, nivolumab cannot be considered as standard of care for first line treatment. Perhaps a non-inferiority trial focused on adverse events and QoL could carve out a niche for PD-1-based immunotherapies in the complex treatment landscape of HCC. However, the number of patients required for a large non-inferiority trial and the issues related to this type of trial could discourage from planning one.⁶⁸ Currently, a phase III non-inferiority trial (RATIONALE 301: NCT03412773) is testing an anti-PD-1 mAb, tislelizumab, against sorafenib.³⁶ Whilst atezolizumab plus bevacizumab have become standard of care, the results of the trial may still change first-line treatment choices. PD-1 monotherapy holds the benefit of being safe and be characterized by a lower proportion of long-term adverse events such as diarrhea, skin toxicity and fatigue typical of MKIs, which may limit patient's QoL. Also, nivolumab is the only agent proved safe and effective in Child B patients in clinical trials²⁹ and post-registration studies,⁶⁹ so further, prospective data on larger populations could provide important clinical data on the positioning of anti-PD-1 therapy agent in this more fragile segment of HCC patients, for which no approved therapy exists. The continued use of pembrolizumab as a second-line therapy is also debatable in view of atezolizumab and bevacizumab having become standard of care in first line and lack of survival benefit proven in the KEYNOTE-240 trial. It appears unlikely that pembrolizumab will be approved outside FDA territory in view of lack of OS benefit.⁷⁰ This is unfortunate as a number of patients who may not be eligible to atezolizumab and bevacizumab could still benefit from PD-1 inhibition as a second-line therapy. An area of active investigation is the a priori identification of the subset of patients benefitting from pembrolizumab after sorafenib failure. However, clinical trial datasets have been unhelpful in answering this question. Some hints could possibly come from the identification of molecular signatures predicting response to immunotherapy-based approach. For instance, nearly 25% of HCC fall into the "immune class" category, showing the markers of a potential better response to ICIs.⁶⁴ On the other side, negative biomarkers found in preclinical models could also be highly useful to exclude patients from unnecessary and potentially toxic treatments.⁷¹ It is therefore likely that anti-PD-1/PD-L1 blockade will keep its position in the HCC treatment algorithm in combination with other

agents, since the preliminary results of the phase I/II studies^{39,41,42} are highly promising and the phase III trials on their use in first line are currently ongoing. Furthermore, the possible applications of anti-PD-1 agents in earlier stages of the disease, as in the neo-/adjuvant setting or in combination with loco-regional treatments, is intriguing and could expand the domain of immunotherapy use in HCC.^{72,73} In particular, the immunomodulatory role of ablation, SBRT, and TACE makes the results of the ongoing studies focusing on the combination with ICI eagerly awaited. In case of a relapse after early use of anti-PD-1 agents, it will be challenging to address the role of atezolizumab plus bevacizumab or other combinations in advanced/relapsed disease, since the evidence supporting the use of ICI in immunotherapy-pretreated patients is growing for other solid tumors^{74,75} but still lacking for HCC. The growing number of phase III clinical trials due to report in the next few years will be crucial in further reshaping the treatment landscape of HCC. While cancer immunotherapy continues to expand in clinical research and routine practice, the revolutionizing role of anti-PD-1/PD-L1 agents as a backbone to novel immunotherapeutic combination approaches is undoubted. As such, their clinical use, with different indications and in combination, is likely to expand.

Journal of Hepatocellular Carcinoma

Dovepress

Publish your work in this journal

The Journal of Hepatocellular Carcinoma is an international, peer-reviewed, open access journal that offers a platform for the dissemination and study of clinical, translational and basic research findings in this rapidly developing field. Development in areas including, but not limited to, epidemiology, vaccination, hepatitis therapy, pathology

and molecular tumor classification and prognostication are all considered for publication. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
