Abstract

What are the clinical features, severity, and rate of progression of lung disease in women with tuberous sclerosis and lymphangioleiomyomatosis and how do they differ from patients with sporadic lymphangioleiomyomatosis?

Data from 94 tuberous sclerosis and lymphangioleiomyomatosis and 460 sporadic lymphangioleiomyomatosis women were compared. Forty tuberous sclerosis/lymphangioleiomyomatosis and 40 sporadic lymphangioleiomyomatosis patients were age- and lung function-matched, and changes in volume occupied by cysts (cyst score) and pulmonary function occurring over 6.5 years were evaluated.

Tuberous sclerosis/lymphangioleiomyomatosis patients had better lung function than sporadic lymphangioleiomyomatosis patients, but no difference was observed from sporadic lymphangioleiomyomatosis patients in yearly rates of change in FEV_1 (-1.9 ± 2.7 vs. -1.9 ± 1.9 % predicted, p=0.302), DL_{CO} (-2.1 ± 2.8 vs. -1.9 ± 2.7 % predicted, p=0.282), or cyst scores ($+1.0\pm1.3$ vs. $+1.4\pm1.7$ %, p=0.213). However, the proportion of patients with abnormal lung function and higher rates of FEV_1 decline was greater in sporadic lymphangioleiomyomatosis. Some young tuberous sclerosis/lymphangioleiomyomatosis patients (mean age=25.7 ± 3 years) progressed rapidly from minimal to severe lung disease.

Tuberous sclerosis/lymphangioleiomyomatosis patients may experience abrupt declines in lung function. Consequently, women with tuberous sclerosis found to have lung cysts should undergo

periodic functional and radiologic testing to follow disease progression and determine need for therapy.

Summary

While the natural history is variable, some women with TSC and LAM may quickly progress to disabling respiratory disease.

Keywords

Lymphangioleiomyomatosis in Tuberous Sclerosis Complex

INTRODUCTION

Lymphangioleiomyomatosis (LAM), a multisystem disease affecting predominantly women, is characterized by cystic lung destruction, abdominal angiomyolipomas, lymphatic tumors, and chylous effusions [1-3]. The pathological features of LAM are caused by proliferation of a neoplastic smooth muscle-like LAM cell that has characteristics of both smooth muscle cells and melanocytes [1,4]. An inherited form of LAM occurs in patients with tuberous sclerosis complex (TSC), an autosomal dominant disorder which occurs in one of 6,000 live births and is caused by mutations in the tuberous sclerosis complex 1 (*TSC1*) or 2 (*TSC2*) genes [5-6]. A second form, sporadic LAM, is an uncommon disease affecting 3 to 5 per million of women in the general population, and is caused by mutations of the *TSC2* gene [5,7-9]. Loss of heterozygosity of *TSC2* has been reported in LAM lesions from lung and kidney angiomyolipomas, and LAM cells isolated from lung, blood, and chyle [5,8,10-12]. The metastatic nature of LAM is supported by the presence of identical mutations in lung and kidney lesions, and evidence of de-novo invasion of transplanted donor's lungs by the recipient LAM cells, suggesting migration from the kidney, lymphatic system or uterus, to the lungs [13-15].

The prevalence of clinically significant LAM in TSC was thought to be low, ranging from 0.6 to 2.3 % of TSC patients [16-19]. Subsequent cross-sectional studies however, showed that the prevalence of lung cysts in women with TSC ranged from 26 to 49 % and that the extent of cystic disease increases with age [20-25]. Clinically significant cystic disease is almost exclusively seen in women.

Although the clinical and physiologic features of sporadic LAM have been described, there are large gaps in our knowledge of the natural history of TSC-LAM, especially whether the prognosis of TSC-LAM is similar to that of sporadic LAM and whether a few lung cysts on a computed tomography scan of a woman with TSC and normal lung function may progress to clinically significant lung disease [1,26,27]. We also wanted to determine whether the rates of change in lung function and lung volume occupied by cysts [28] in patients with TSC-LAM were different from those with sporadic LAM. To answer these questions, we reviewed the clinical and physiologic characteristics and high resolution computed tomography (HRCT) scans, of TSC-LAM patients seen at the NIH Clinical

Research Center over a period of 16 years and compared their features with those of patients with sporadic LAM.

MATERIAL and METHODS

Patient population.

Between 1996 and 2012, 637 women were referred to NIH for participation in a natural history and pathogenesis protocol (NHLBI Protocol 95-H-0186), and a lung disease screening protocol (NHLBI Protocol 82-H-0032) which were approved by the Institutional Review Board of the National Heart, Lung, and Blood Institute. Patients were either self-referred or referred through individual physicians. All subjects gave written informed consent before enrollment. Of the 637 patients, 554 had LAM. History and physical examination, laboratory tests, and pulmonary function tests were obtained at the time of each visit. Cardiopulmonary exercise tests, computed tomography (CT) scans of the thorax and abdomen, and magnetic resonance imaging of the brain were obtained once a year. Data from some of these patients have been reported previously [1,26,29].

Pulmonary function testing.

Lung function was measured (Master Screen PFT, Erich Jaeger; Wuerzburg, Germany system) according to standard methods [30,31].

Cardiopulmonary exercise testing.

Patients exercised on a bicycle ergometer and a computerized metabolic cart (Vmax 229 Cardiopulmonary Exercise System; Sensormedics, Yorba Linda, CA) using incremental protocols [32].

Radiologic Methods.

Forty TSC-LAM patients were selected based on the suitability of CT scan studies for a computer analysis that estimates the volume of lung occupied by cysts (cyst scores) and lung texture changes in areas adjacent to cysts [28]. Once this was accomplished, from the sporadic LAM cohort we selected patients who not only had suitable CT scans for analysis but also matched each TSC-LAM patient by age, lung function and follow-up time. Then, we estimated their cyst scores, rate of progression of cystic lesions, and rates of decline in lung function.

Statistical Methods.

For comparisons of demographic data, lung function, and exercise tests between TSC-LAM and sporadic LAM patients, Student's t test was employed. The data set contained clinical data and multiple pulmonary function and exercise measurements for most patients. The yearly rate of change (slope) was calculated from a linear regression for pulmonary function and exercise data [26], and an adjusted analysis was then performed using mixed effects models. All available data were used to compare TSC-LAM and sporadic LAM patients using a t-test for continuous variables and a chi-squared test for categorical variables. A binary outcome of whether a subject had TSC-LAM or sporadic LAM was compared

to predictor variables such as age, time of first symptom, length of follow-up, dyspnea, hemoptysis, lymphatic system involvement, angiomyolipomas, pulmonary function tests and variables related to cardiopulmonary exercise tests. Variables that resulted in p-values of less than 0.15 were used in a multivariate logistic regression model to predict factors that were associated with TSC-LAM. The level of statistical significance was set at p<0.05 for variables to remain in the final model. The odds ratios (OR) and their 95% confidence intervals were also derived. For comparison of proportions of TSC and TSC-LAM patients with lung function abnormalities we employed the Chi-square test. The Wilcoxon-Mann-Whitney test was used to compare the proportions of rates of lung function decline between TSC and sporadic LAM patients. Analysis of variance and the Tukey/Kramer procedure was employed to compare initial and final cyst scores for both TSC-LAM and sporadic LAM patients.

All data, except the estimated yearly rate of change in lung function and cyst scores, are shown as means (±SD).

RESULTS

Patient characteristics.

Of 554 patients with LAM, 94 had TSC-LAM and 460 had sporadic LAM (Figure 1). Demographic features of the 94 patients with TSC-LAM are shown on the online supplement Table 1S. Sixty-one of the 94 patients were diagnosed with TSC (mean age=18.3±14.7 years) before being diagnosed with LAM (mean age=36±10 years). In 26 patients, the diagnosis of TSC (mean age=41.6 ±10.6 years) was made after the diagnosis of LAM; fourteen of the 26 had a lung biopsy. The mean age at the time of the diagnosis of LAM was 37±10.4 years. Twenty two of the 26 patients were diagnosed with TSC at NIH. In seven of the 94 patients the diagnosis of TSC and LAM were made at the same time (mean age=37.4±12 years). The diagnosis of TSC was based on the presence of at least two major criteria or one major and one or more minor features [6].

Thirty-eight of the 94 patients were brought to NIH under a screening protocol for TSC and were subsequently found to have LAM. Five of these patients had lung biopsies; the remaining patients were diagnosed by CT scan. All but seven patients, had respiratory symptoms. The remaining 56 patients were brought in because of cystic lung disease and TSC or cystic lung disease and no prior diagnosis of TSC. Twenty-five of the 56 underwent tissue biopsies; the remaining 31 were diagnosed by CT scan [33]. Seven of the 56 patients referred no respiratory symptoms.

Table 1 shows age of first LAM-related symptoms, age of diagnosis and enrollment in our study, method of diagnosis, mode of presentation and other features, for the 554 patients. In 37 TSC-LAM patients the diagnosis of LAM was made by tissue biopsy, and in the remaining 57, by the presence of lung cysts and angiomyolipomas in the setting of TSC [33]. Of the 460 sporadic LAM patients, 308 were diagnosed by tissue biopsy and the remaining 152 were diagnosed by clinical and radiologic criteria [33].

Pulmonary function studies.

Initial pulmonary function data for TSC-LAM and sporadic LAM patients are shown on Figure 2, panel A, and in the online supplement, Table S2. Thirty three percent (n=31) of the TSC-LAM patients had airflow obstruction (Table 3). Overall, 40 percent (n=38) of the 94 patients had abnormal DL_{CO}. Forty three percent (n=40) had normal lung function.

Data for an average follow-up of 5.1 ± 3 years were available for respectively, 73 LAM-TSC and 319 sporadic LAM patients (Figure 1) (initial data given in Table S3, online supplemental data). Although FEV_1 and DL_{CO} were significantly higher in TSC-LAM patients than sporadic LAM patients, no statistically significant differences were observed between the two groups in rates of decline of any of the respiratory variables (Figure 2, panel B). The yearly rates of decline in percent-predicted FEV_1 for TSC-LAM and sporadic LAM were respectively, 1.7 ± 0.4 % predicted (69.6 ± 12.2 ml) and 2.2 ± 0.2 % predicted (81.5 ± 6.4 ml) (p=0.302); the rates of yearly decline in DL_{CO} were respectively, 2.8 ± 0.6% predicted (0.78 ± 0.14 ml/min/mmHg) and 2.1 ± 3.9 % predicted (0.57 ± 0.04 ml/min/mmHg) (p=0.282).

To further study differences between TSC-LAM and sporadic LAM patients we performed two additional types of analysis. First, we compared the proportions of patients showing airflow obstruction, diffusion impairment, or normal lung function and found that greater proportions of sporadic LAM patients had functional abnormalities than TSC-LAM patients and the difference between both groups was statistically significant (Table 2).

In addition, we stratified the rates of yearly changes in FEV_1 and DL_{CO} for TSC-LAM and sporadic LAM patients and performed a statistical analysis of the data. This analysis showed that the proportion of patients with higher rates of FEV_1 decline was significantly greater in sporadic than in TSC-LAM (Table 3).

Cardiopulmonary exercise testing.

Results from the initial cardiopulmonary exercise tests (CPET) of 76 TSC-LAM patients and 340 sporadic LAM patients are shown on Figure 2, panel C, and in the online supplement, Table S4. Eighteen (23.6 %) of the 76 TSC-LAM patients experienced a drop in oxygen saturation (SaO2) equal or greater than 4 % (mean=7.0 ± 2.7 %). Seventeen TSC-LAM patients failed to reach anaerobic threshold (AT). Seven of these patients had profound hypoxemia and four had decreased breathing reserve. Analysis of the initial CPET data showed that TSC-LAM patients had greater breathing reserve (BR) and lower peak minute ventilation (VE max) and ventilatory equivalent for CO2 (VE/VCO2) at AT than sporadic LAM patients (Figure 2, panel C). There were no other statistically significant differences in exercise variables between TSC-LAM and sporadic LAM patients. Longitudinal CPET data comprising approximately four years of follow-up were available for 60 TSC-LAM and 236 sporadic LAM patients, respectively (Figure 2, panel D). We found a greater decrease in percent-predicted peak heart rate in sporadic LAM than TSC-LAM patients (-1.4 ± 0.2 versus -0.14 ± 0.31 %, p=0.002) and a greater decline in percent-predicted peak minute ventilation (VE max) in sporadic LAM than TSC-LAM patients (-0.6 ± 0.4 versus 0.9 ± 0.7 %, p=0.011)

Predictors of TSC-LAM and disease severity.

A multivariate model was employed to estimate the odds of a patient having TSC-LAM instead of sporadic LAM (Table 4). This analysis showed that only the age of diagnosis (p=0.017), age of first respiratory symptoms (p=0.007), and the presence of angiomyolipomas (p=0.003), or lymphangioleiomyomas (p<0.001), were significantly different between patients with TSC-LAM and those with sporadic LAM (Table 4). An odds-ratio analysis (Table 4) showed that the presence of lymphangioleiomyomas decreased the odds of having TSC-LAM by 74%. The presence of angiomyolipomas increased the odds of having TSC-LAM by two and one half times. Finally, for each additional year in age at the time of diagnosis of LAM, the odds of having TSC-LAM decreased by 3.8% (Table 4).

Because the frequency of lymphangioleiomyomas was greater in sporadic LAM, we questioned whether this manifestation of extrapulmonary LAM was related to the severity of lung disease. A multivariate analysis showed that patients with lymphangioleiomyomas (n=143) had lower DL_{CO} than patients without lymphangioleiomyomas: 66.0±23.4 % predicted (13.9±5.0 ml/min/mmHg) versus 78.6±25.0 % predicted (16.8±5.8 ml/min/mmHg) (p<0.001). A lower DL_{CO} was observed in patients with lymphangioleiomyomas regardless of the co-occurrence of angiomyolipomas. A similar analysis restricted to TSC-LAM patients was not performed because only 12 TSC-LAM patients had lymphangioleiomyomas.

Rate of progression of lung disease in TSC-LAM.

We compared changes in cyst scores and lung function of 40 TSC-LAM with 40 age and lung function-matched sporadic LAM patients followed for about six and one half years (Table 5). A reading of the first and last imaging studies showed that in 21 TSC-LAM patients the average number of cysts increased from 26±25 to 50±43. Cyst scores increased from 5.3±5.9 to 11.8±9.6 % (p<0.05). We further analyzed the TSC-LAM CT scan data focusing on 11 young TSC-LAM patients (mean age=25.7 ± 3 years, range=18-30) for whom we had data spanning 4.3±3.8 years. Yearly rates of decline in FEV_1 and DL_{CO} were 4.1±3.6 and 4.3±3.8 % predicted, respectively. Visual review of CT scans showed progression of disease from minimal or mild, to moderate to severe. In six patients there was quick progression to severe disease. Yearly rates of decline in in FEV_1 and DL_{CO} were 5.9±3.0 and 5.4±3.6 % predicted and the percentage of lung volume occupied by cysts increased from 8.1±6.9 to 27.6±5.8 %. CT scans of two of these patients are shown on Figure 3.

In 18 of the 40 sporadic LAM patients, over the period of observation, the average number of cysts increased from 66±40 to 94±60. Cyst scores increased from 5.6±5.2 to 15.3±9.8 % (p<0.05) (Table 5). There was no significant difference between TSC-LAM and sporadic LAM patients in both initial and final cyst scores. There was also no significant difference in the rate of change in cyst scores for TSC-LAM and sporadic LAM patients: 1.0±1.3 versus 1.4±1.7 %, p=0.213 (Table 5). Supplemental online data Table S5 and Figure S1 show changes in cyst scores for each TSC-LAM and sporadic LAM patient.

DISCUSSION

Our study shows that compared to sporadic LAM patients, TSC-LAM patients were diagnosed with LAM at an earlier age and were more likely to have fewer respiratory symptoms. The presence of angiomyolipomas increased the odds of a LAM patient having TSC-LAM. Conversely, the presence lymphangioleiomyomas decreased the odds of a patient having TSC-LAM. A greater proportion of TSC-LAM patients presented with normal lung function than sporadic LAM patients. Furthermore, although there was no statistically significant difference in FEV_1 and DL_{CO} rates of decline between TSC-LAM and sporadic LAM patients, stratification of rates of functional decline according to grade showed that more TSC-LAM patients had lesser rates of FEV_1 decline than sporadic LAM patients.

These differences in disease severity at the time of presentation and subsequent functional decline could be explained by recruitment bias. Indeed, 38 TSC-LAM patients were referred to NIH under a screening protocol and only later were found to have LAM. It is likely that such a cohort would have milder lung disease than a population of TSC-LAM patients presenting with respiratory symptoms. This referral bias may have resulted in more TSC-LAM patients having milder lung disease than sporadic LAM patients. In agreement, we found that patients diagnosed with LAM after being diagnosed with TSC, tended to have higher FEV_1 (83 ± 27 versus 75 ± 26 % predicted) and DL_{CO} (82 ± 29 versus 77 ± 23 % predicted) at the time of the first NIH visit than patients in whom the diagnosis of LAM preceded the diagnosis of TSC, although the difference was not statistically significant.

The finding that a relatively large number of TSC patients presenting with LAM only belatedly were diagnosed with TSC, is consistent with data from a prior study showing that 45 (59 %) of a total of 79 TSC patients were only diagnosed with TSC in adulthood. Thirty of the 45 (66 %) patients reported clinical features consistent with TSC that antedated the eventual diagnosis of TSC by a median time of 21.5 years [33]. In summary, our TSC-LAM population consisted of a mix of patients presenting as LAM and another presenting as TSC. We propose that the make-up of our cohort corresponds to the most frequent presentation of TSC patients, either as TSC or LAM.

A lower frequency of lymphatic involvement observed in TSC-LAM patients could have accounted for their lesser severity of lung disease. We found that patients with lymphangioleiomyomas had a lower DL_{CO} than patients with less lymphatic involvement, and our study showed that lymphangioleiomyomas are more prevalent in sporadic LAM. Lymphatic disease in LAM is known to be associated with increased blood levels of vascular endothelium growth factor D (VEGF-D), and data from the MILES trial have shown that increased levels of VEGF-D are associated with more severe lung function abnormalities, less exercise tolerance and greater oxygen requirements [34]. It is possible that lymphatic involvement with LAM cell infiltration may obstruct lymphatic flow from the lungs causing impairment of gas exchange, which is reflected by diminished DL_{CO} and hypoxemia. This hypothesis is consistent with reports that lymphangioleiomyomas and pulmonary infiltrates resolve after treatment with sirolimus, resulting in improvement in lung function [35-37]. However, there are no data regarding the potential value of measurement of serum VEGF-D

levels in predicting the prognosis of a woman with TSC who has been diagnosed with LAM. Of the available methods of assessing the prognosis of LAM, measuring the rates of decline in lung function over time and quantitatively grading CT scans remain the most practical and useful tools.

Initial cardiopulmonary exercise testing data are consistent with the differences in degree and frequency of pulmonary function abnormalities in TSC-LAM and sporadic LAM patients. Breathing reserve was higher in TSC-LAM than sporadic LAM patients. Peak VEmax and VE/VCO2 at AT were higher in sporadic LAM reflecting a greater ventilatory response to exercise. Because TSC-LAM patients had better lung function, their ventilatory response to exercise was less, resulting in a lower VE/VCO2, lower VEmax and greater breathing reserve.

One of the questions that we wanted to address in this study was whether the detection of a few lung cysts on a CT scan of women with TSC equates to the presence of LAM, and whether such patients eventually develop clinically significant lung disease, their course is similar to that seen in sporadic LAM. We found that the presence of a few lung cysts and normal lung function in a woman with TSC does not necessarily predict a good outcome. In fact, we identified eleven young TSC-LAM patients with few lung cysts and normal lung function who rapidly progressed to moderate to severe lung disease, reflected by high rates of lung function decline and increased percentage of lung volume occupied by cysts. These findings suggest that, as in sporadic LAM, lung disease in TSC-LAM patients may worsen rapidly with age and run a course similar to sporadic LAM.

Our data are consistent with the results of a study involving women with TSC, showing that the risk of LAM was age-dependent, increasing from 27% in subjects under the age of 21, to 81% in subjects above the age of 40 [25]. A European Respiratory Society consensus statement recommended screening of TSC patients by CT scans at 18 years of age and repeating the study when 30 years old [33]. A more recent statement regarding surveillance of women with TSC and demonstrable lung cysts also recommended CT scans every two to three years and annual pulmonary function tests [37]. In our study, we report longitudinal physiologic and computed tomography data showing that, although TSC-LAM patients, as a group, tended to have milder and less progressive lung disease than sporadic LAM patients, individual patients, specifically women between the ages of 18 and 30 years, may experience rapid declines in lung function. Any approach other than close monitoring of respiratory symptoms, lung function and exercise tolerance, along with imaging studies, in TSC women in that age group, would fail to detect the presence of clinically significant cystic lung disease before the age of 30. Thus, close medical follow-up of all women with TSC and lung cysts, including pulmonary function tests and computed tomography, is recommended. This approach is justified by evidence that treatment of LAM with sirolimus is effective in slowing progression of lung disease [37,39].

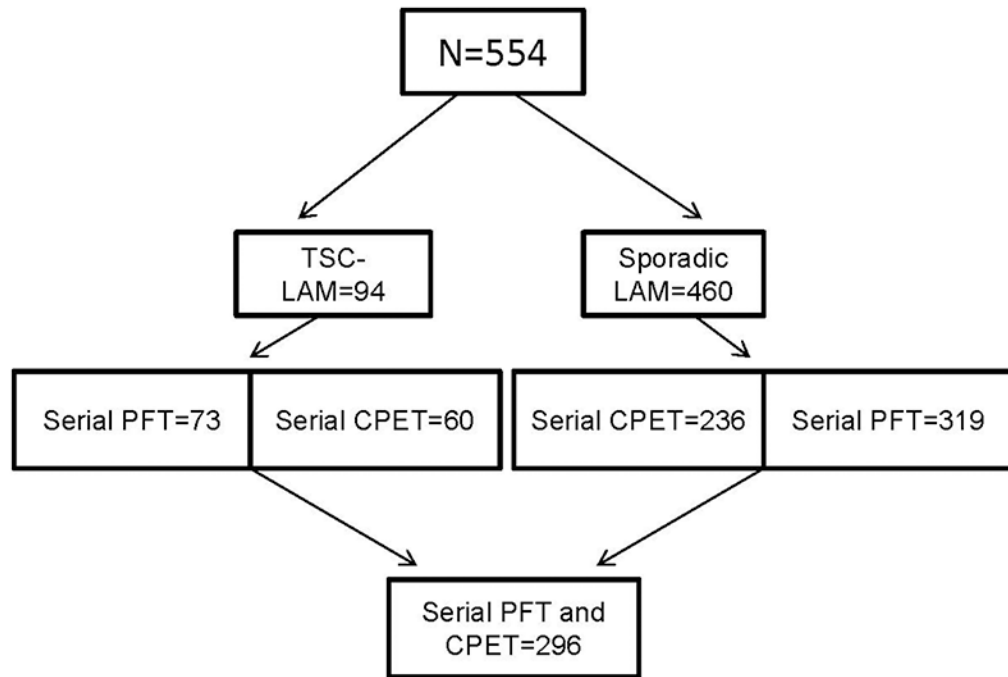

Figure 1.
Flow diagram showing the numbers of TSC-LAM and sporadic LAM patients seen initially and those who had pulmonary function tests (PFT) and cardiopulmonary exercise tests (CPET) spanning several years.
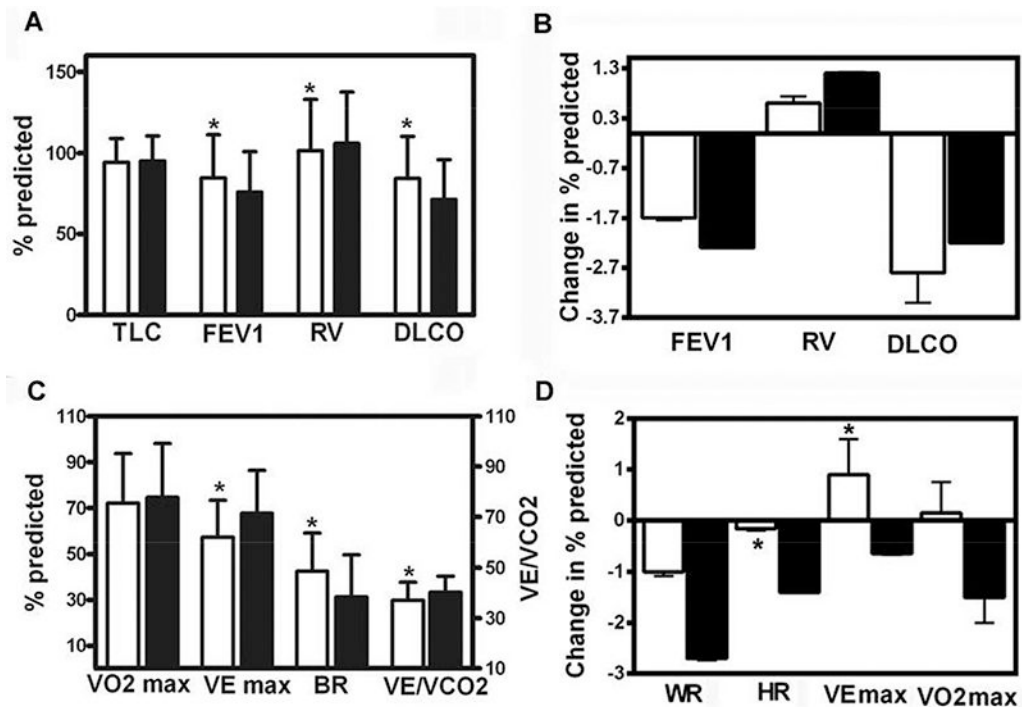

Figure 2.
Panel A: Pulmonary function data in 94 TSC-LAM (white bars) and 460 sporadic LAM (black bars) patients obtained at the time of the first visit to NIH. Overall TSC-LAM patients have significantly higher FEV_1 and DL_{CO} and lower RV than sporadic LAM patients. Panel B: Yearly changes in percent-predicted FEV_1, RV, and DL_{CO}, in 73 patients with TSC-LAM (white bars) and 319 patients with sporadic LAM (black bars) followed for over five years, expressed as mean ±SEM. No statistically significant differences were observed between TSC-LAM and sporadic LAM patients. Panel C: Initial cardiopulmonary exercise data in 76 TSC-LAM (white bars) and 340 sporadic LAM patients (black bars) obtained at the time of the first visit to NIH. TSC-LAM patients have significantly higher BR and lower VE max and lower VE/VCO2 than sporadic LAM patients. Panel D: Yearly changes in exercise variables in 60 TSC-LAM (white bars) and 236 sporadic LAM patients (black bars) followed for approximately four years, expressed as mean ±SEM. There was a statistically significant difference in the rates of change in peak heart rate and peak minute ventilation between TSC-LAM and sporadic LAM patients.

Abbreviations used are: TLC: total lung capacity; FEV_1: forced expiratory volume in the first second; RV: residual volume; DL_{CO}: diffusion capacity for carbon monoxide; VE max: minute ventilation at peak exercise; VO2 max: peak oxygen consumption; HR: heart rate; BR: breathing reserve; VE/VCO2: ventilatory equivalent for carbon dioxide. * $p < 0.05$, significantly different from sporadic LAM patients.
Figure 3.
Panel A. Lung computed tomography scan of a 19 year-old woman with TSC-LAM showing minimal cystic changes. Panel B. Five years later, the computed tomography scan shows severe disease. Panel C. Lung computed tomography scan of a 25 year-old woman with TSC-LAM showing minimal cystic changes. Five years later, the computed tomography scan shows more severe disease.

Table 1.

Demographic features of 554 patients with lymphangioleiomyomatosis

Demographics	TSC-LAM	Sporadic LAM
Number of patients	94	460
White	79 (84%)	397 (86.3%)
Black	7 (7.4%)	26 (5.6%)
Hispanic	5 (5.3%)	10 (2.1%)
Asian	2 (2.1%)	25 (5.4%)
Other	1 (1.0%)	2 (0.4%)
Age of LAM Diagnosis	36.4±10.4 *	41.1±9.4
Age, first symptom	33.2±9.9 *	37.0±9.9
Age, first visit to NIH	39.1±10.2 *	43.9±9.2
Death during study	14 (14.8%)	70 (15.2%)
Lung transplantation during study	4 (4.2%)	51 (11%)
Initial Symptoms		
Dyspnea	35 (37 %)	222 (42 %)
Cough	None	19 (4 %)
Pneumothorax	38 (40 %) †	13 (2.8 %)
Hemoptysis	3 (3 %)	44 (10 %)
Chylous effusions	10 (11 %)	33 (7 %)
Abdominal, pelvic or back pain	8 (9 %)	59 (13 %)
No respiratory symptoms	19 (19 %)	8 (2 %)
Extrapulmonary Findings		
Lymphangioleiomyomas	12 (12.8 %)	177 (38 %)
Angiomyolipomas	90 (95.7 %)	190 (41.3 %)
Bilateral angiomyolipomas	80 (85.1%)	61 (13.2%)
Chylous effusions, any time	13 (13.8 %)	93 (20 %)
Mode of Diagnosis of LAM		
Tissue biopsy	37 (39 %)	308 (67 %)
Clinical data and computed tomography	57 (61 %)	152 (33 %)
Bronchodilator response	107 (23%)	14 (15%)
Post-menopausal	16 (17%)	105 (22.8%)
Therapies received		
Progesterone/leuprolide	47 (51 %)	207 (45%)
Sirolimus	8 (8.5%)	41 (8.9%)

*
p<0.05. Significantly different from sporadic LAM

†
p<0.01. Significantly different from sporadic LAM

Table 2.

Proportions of TSC and sporadic LAM patients with functional abnormalities

	TSC-LAM	Sporadic LAM	p-value
Number of patients	94	460	
Airflow obstruction	31 (32.9 %)	234 (50.8 %)	0.002
Diffusion abnormality	38 (40.4 %)	282 (61.3 %)	<0.001
Airflow obstruction and diffusion abnormality	25 (26.5 %)	194 (42.1 %)	0.005
Normal pulmonary function	40 (42.5 %)	122 (26.5 %)	0.002

*
Using a chi-square test

Table 3.

Proportion of rates of functional decline in lung function in 73 patients with TSC-LAM and 319 patients with sporadic LAM [a]

	TSC-LAM	TSC-LAM	Sporadic LAM	Sporadic LAM
Number of patients	73	73	319	317
Decline in % predicted	FEV_1	DL_{CO}	FEV_1 [*]	DL_{CO}
>10 %	1 (1.3 %)	4 (5.4 %)	11 (3.4 %)	14 (4.3 %)
8-10 %	3 (4.1 %)	2 (2.7 %)	9 (2.8 %)	10 (3.1%)
6-8 %	5 (6.8 %)	8 (10.9 %)	19 (5.9 %)	12 (3.7%)
4-6 %	2 (2.7 %)	4 (5.4 %)	32 (10.0%)	38 (11.9%)
2-4 %	13 (17.8 %)	15 (20.5 %)	87 (27.2 %)	84 (26.3%)
0-2 %	31 (42.4 %)	27 (36.9 %)	95 (29.7 %)	90 (28.2 %)

[*] p=0.048, using Wilcoxon-Mann-Whitney test

[a] Patients were followed for 5.1±3 years

Table 4.

Multivariate analysis and odds ratio estimates for distinguishing clinical features of TSC-LAM and sporadic LAM

A. Multivariate analysis	TSC-LAM	Sporadic LAM	p-value
Number	73	319	
Age of diagnosis	38.0±10.7	41.5±9.2	0.017
Age of first symptoms	34.2±10.3	38.0±9.5	0.007
Angiomyolipoma	89%	36%	0.003
Lymphangioleiomyoma	15%	41%	<0.001
B. Odds ratio estimates	**Odds ratio**	**95 % confidence level**	**p-value**
Angiomyolipomas	2.54	1.372, 4.701	0.017
Lymphangioleiomyomas	0.237	0.101, 0.554	0.003
Age	0.962	0.931, 0.993	<0.001

Table 5.

Demographic, physiologic and radiologic findings in 40 patients with TSC-LAM and 40 patients with sporadic LAM

Demographics	TSC-LAM	Sporadic LAM
Age	40.1±9.9	39.9±8.1
Follow-up time (years)	6.5±2.7	6.5±3.2
Deaths	2 (5%)	3 (7.5%)
Lung function		
FEV$_1$ (liters)	2.6±0.5	2.6±0.5
% predicted FEV$_1$	96.8±18.9	93.8±15.9
DL$_{CO}$ (ml/min/mmHg)	20.4±3.9	20.5±4.2
% predicted DL$_{CO}$	95.4±19.1	94.8±16.7
% predicted decline in % FEV$_1$	1.9±2.7	1.9±1.9
% predicted decline in DL$_{CO}$	2.1±2.8	1.9±2.7
Cardiopulmonary exercise testing		
Work rate (% predicted)	99±25	109±24
Peak heart rate (% predicted)	89±8	91±8
Peak VE max (% predicted)	57±16	62±16
BR (%)	44±16	38±20
Peak VO2 max (% predicted)	80±15	86±21
VE/VCO2 at AT	32±7	34±6
Volume occupied by cysts		
Initial cyst scores (%)	5.3±5.9	5.6±5.2
Final cyst scores (%)	11.8±9.6[*]	15.3±9.8[*]
Yearly change in cyst scores (%)	1.0±1.3	1.4±1.7

[*] Statistically significant from initial cyst score (by ANOVA). Abbreviations used: FEV$_1$: forced expiratory volume in the first second; DL$_{CO}$: diffusion capacity for carbon monoxide; VE max: minute ventilation at peak exercise; BR: breathing reserve; VO2 max: peak oxygen consumption; VE/VCO2: ventilatory equivalent for carbon dioxide; AT: anaerobic threshold.
