## ABSTRACT

Throughout the COVID-19 pandemic, many have worried that the additional burden of seasonal influenza would create a devastating scenario, resulting in overwhelmed healthcare capacities and further loss of life. However, many were pleasantly surprised: the 2020 Southern Hemisphere and 2020–2021 Northern Hemisphere influenza seasons were entirely suppressed. The potential causes and impacts of this drastic public health shift are highly uncertain, but provide lessons about future control of respiratory diseases, especially for the upcoming influenza season.

The COVID-19 pandemic has altered almost every aspect of public health since its global spread in early 2020. One such consequence of COVID-19 has been altered circulation of other respiratory pathogens, like influenza. Seasonal influenza causes 3–5 million cases of severe illness and kills 260,000–650,000 people globally each year [44]. The added strain of even a mild influenza season to a healthcare system already pushed beyond its limits by the COVID-19 pandemic was a devastating prospect that worried many. Fortunately, influenza cases were unprecedentedly low in the 2020 influenza season in the Southern Hemisphere and in the 2020–2021 influenza season in the Northern Hemisphere [26,34,39,40]. The lack of additional healthcare burden due to influenza left healthcare capacity to be focused towards the continued surge of COVID-19, likely preserving many lives. With some distance now from the last influenza season, we must heed the many lessons learned and relearned about influenza dynamics and control over the last year so we can be better prepared for future influenza outbreaks.

At the outset of the COVID-19 pandemic in early 2020, the Northern Hemisphere 2019–2020 influenza season was still in full force in the US, but rapidly declined during March 2020. Some have proposed that the pandemic and the ensuing nonpharmaceutical interventions led to this decrease in influenza transmission [34].

While this is a possible explanation, behavioral data now available for the first months of 2020 show little change from baseline during this period (Figure S2). Instead, unusual viral dynamics could explain the early and rapid decline of the 2019–2020 flu season, in which unusually high and early flu B circulation was followed by a wave of flu A circulation [4]. This sits in contrast to the routine pattern of initial influenza A circulation followed by low flu B circulation which brings a gradual end to most flu seasons (Figure S3). In fact, we find that if the influenza A wave is considered independently and controlled for changes in healthcare-seeking, the US 2019–2020 flu season did not deviate significantly from expectations after the declaration of the COVID-19 emergency (Figure S1).

While the Northern Hemisphere 2019–2020 influenza season may not have been affected by the COVID-19 pandemic, for the influenza season starting in 2020, countries in the Southern Hemisphere, which typically experience their influenza season in May–October, reported drastically reduced influenza circulation [34]. The Northern Hemisphere has also remarkably experienced almost no influenza during the typical timing of the 2020–2021 season, with the US and EU reporting only 0.15–0.2% of samples as positive for flu (compared to around 18–23% in 2019–2020) [8,17]. As a comparative case study, we can consider the US, France, Australia: 3 countries that are socially similar, have high data availability and experience similar influenza seasons by hemisphere [12]. All three settings suppressed the influenza season in 2020–2021, and a

number of explanations may be behind this. One potential explanation for this pattern is viral competition between SARS-CoV-2 and influenza. This competition could occur through multiple mechanisms, such as immune interactions, viral competition and a reduced susceptible pool due to isolation [32,38].

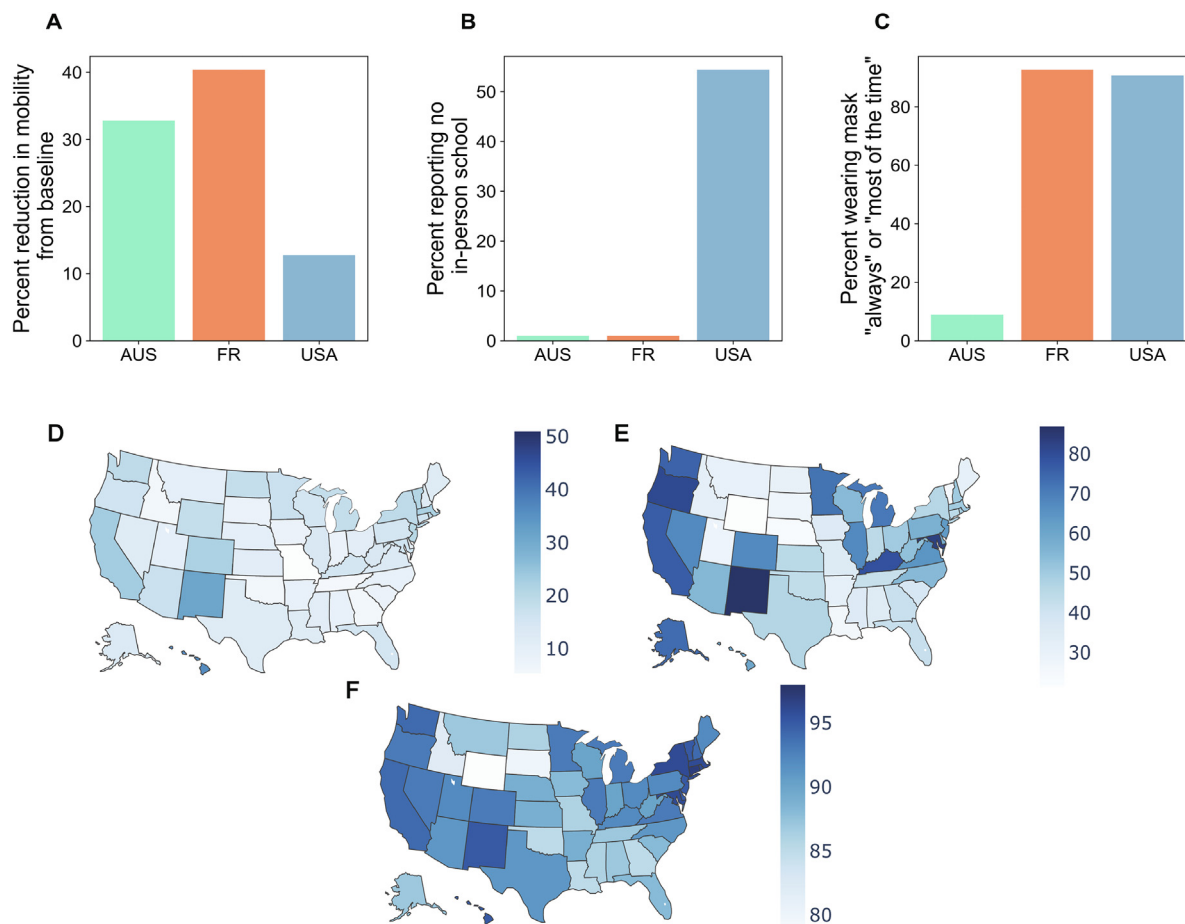

Another potential explanation for the decrease in the 2020 influenza burden is increased influenza vaccination. In order to respond to the pandemic, many countries increased and accelerated the distribution of influenza vaccine doses: a 36% increase in Australia, a 13% increase in France, and an 11% increase in the United States [7,23]. However, this increase in distributed doses may not have necessarily translated to an increase in vaccine coverage. In France and other European countries, exceptionally high demand in the early phase of the flu vaccination campaign reportedly led to shortages of vaccine doses [5,37]. Social distancing measures in the US and Europe at the start of the winter wave may have disrupted access to routine vaccination settings such as primary care providers, workplaces and schools, or increased demand due to disease awareness may have limited the protection of vulnerable groups. Even if high vaccine coverage was achieved on average, stark heterogeneities exist spatially, by age group (e.g. the US state of Iowa estimates a 20 percent decline in flu vaccination in the 65 + age group [24]), and by race and ethnicity (e.g. it is estimated that flu vaccination coverage among Black, non-Hispanic children in the US decreased 8 percentage points from the previous year [10]). This heterogeneous patchwork of influenza vaccine protection makes populations vulnerable and will further exacerbate existing health disparities amplified by the COVID-19 pandemic [2,46].

While viral competition and increased vaccination may have contributed, we propose that the most influential process in suppressing the influenza epidemic of 2020–2021 were the significant behavioral interventions in place due to the COVID-19 pandemic. Nonpharmaceutical interventions such as closures of schools and non-essential businesses, telework, restriction on gathering size, and mask-wearing have been key public health tools for limiting the impact of the COVID-19 pandemic [16,22]. Given the shared transmission route between SARS-CoV-2 and influenza, the same protective behaviors could greatly limit influenza transmission [11,13,40]. In fact, far less mitigation effort is required to control a disease with a lower  $R_0$ , or a less transmissible disease, like flu ( $R_0 = 1-2$ ), compared with a disease with a higher  $R_0$ , like COVID-19 ( $R_0 = 2-5$ ) [3,35]. Many non-pharmaceutical interventions, like stay-at-home orders and remote work guidelines, reduce mobility and contact, diminishing transmission potential. Both Australia and France had stringent social distancing policies in place at the typical start of their influenza seasons, resulting in drastic reductions in mobility (Fig. 1A). The US, however, showed mobility levels that were close to a pre-pandemic baseline at the start of the influenza season. Similarly, pandemic-related school closures may have affected influenza transmission. Since school-aged children are of particular importance for influenza transmission, school closures are thought to have significant impact on influenza dynamics by reducing contacts of children and homogenizing mixing across age groups [6,14,18,29]. The US had widespread school closures and distance learning throughout the 2020–2021 influenza season (Fig. 1B). Conversely, France and Australia did not: some areas of Australia implemented distance learning in April, but resumed in-person schooling prior to the typical start of the influenza season [30], and France also maintained in-person schooling during the entire influenza season. Another measure that many have taken to reduce the spread of COVID-19 that impacts all respiratory-transmitted viruses is mask-wearing. Mask-wearing data shows that both the US and France had high uptake of mask-wearing during the start of their influenza seasons, however, Australia had much lower levels (Fig. 1C).

Each of the case study countries- the US, France, and Australia- exhibited no influenza season, but implemented different non-pharmaceutical interventions with varying levels of adherence. Reported variations partly stem from differences in strategic policies adopted to control the COVID-19 pandemic, aiming towards SARS-CoV-2 elimination (Australia) vs. mitigation (the US, France) [33]. Additionally, for all three interventions (restrictions on mobility, school closure, mask use), uptake were also spatially heterogeneous (Fig. 1D-F), driven by variation in policy strength and policy response [20,42]. This scenario presents an opportunity to better understand the relative effects of individual interventions and the role of layering multiple partially-efficacious interventions to suppress influenza and other respiratory diseases. It will be crucial for such studies to be conducted at a fine spatial scale to capture spatial heterogeneities in infection dynamics as well as variation in human behavior [27,31], and simultaneously to consider global dynamics to capture the shift in viral circulation and lack of viral introductions normally mediated by human mobility.

As we all breathe a collective sigh of relief for the dodged influenza season, it's important to look ahead beyond this temporary respite. Given the lower transmission potential of influenza and significant population immunity from past infections or vaccination, we know that less collective action is necessary to stop flu transmission than COVID-19. The pandemic has demonstrated the effectiveness of several policies and social norms that should be sustained to continue to reduce influenza and other respiratory infections. Universal paid sick leave, particularly in the US, should be a focus for policy; facilitating infected individuals to remain home is shown to reduce future respiratory-disease transmission [36,43,46]. Additionally, during the pandemic, many workplaces have created structures that allow for remote work for non-essential jobs and flexible work schedules; maintaining this flexibility could be a means to reduce overall contact and thus reduce transmission during influenza season. The pandemic has improved acceptance of mask-wearing, increased understanding of the importance of vaccination, and increased awareness and adherence to protective behaviors which could be leveraged for disease control efforts in the future. On the other hand, the sustained behavioral changes during the pandemic or recent COVID-19 vaccination may increase apathy towards social distancing measures, fear of social stigma against mask-wearing, or hesitancy towards vaccination for influenza [41]. While some hygienic behaviors recommended during the 2009 H1N1 influenza pandemic remained as a residual effect once the pandemic was over, overall adoption of preventive measures sharply declined during the first post-pandemic seasonal influenza [19], and a similar effect was observed after the SARS outbreak in 2003 [28].

Beyond behavioral intervention, we must remain vigilant given the significant perturbation to influenza viral dynamics and host ecology. As COVID-19 cases become suppressed through vaccination and behavioral interventions are lifted, the risk of other respiratory infections will be restored. Indeed, an uptick in cases of respiratory syncytial virus has already been observed in the US [9]. The lack of natural immunity during the last influenza season also means a shift in the immune landscape and a buildup of susceptible individuals, with potential consequences for the timing and severity of future outbreaks [1]. Complicating matters further, influenza vaccine strains are typically based on viral surveillance from past influenza circulation in both hemispheres. A lack of influenza circulation last season will reduce our confidence in the strains that are likely to circulate next season, potentially resulting in strain mismatch between the vaccine and circulating strains [45]. Despite these challenges in vaccine composition which may result in a low efficacy influenza vaccine, encouraging widespread vaccine uptake in fall 2021 will be our best bet to reduce both influenza disease burden and antigenic evolution [25,47]. In gen-

**Fig. 1.** Australia (green), France (orange), and the US (blue) implemented different behavioral interventions with different levels of adherence during the timeframe of their typical influenza seasons. A) Mobility data collected by Google, based on Google application-based location services that shows how location visits differ compared to a pre-pandemic baseline [21], demonstrates that Australia and France had a high percent reduction in mobility to retail and recreation locations, compared to the baseline, while the US showed a more modest reduction in the same mobility, during April–June 2020 for Australia and November–mid-December 2020 for France and the US, capturing the start of their respective influenza seasons. B) A social media survey of Facebook users across over 200 countries starting in 2020 demonstrated that approximately half of US respondents with school-aged children were participating in no in-person schooling from November 1–mid-December 2020 [15]. Australia and France did not have widespread school closures at the start of their influenza seasons. C) The Facebook survey also demonstrated that France and the US had high levels of mask-wearing during November 1–mid-December 2020. Australia had much lower mask-wearing uptake at the start of the influenza season in April–June 2020. Adherence to protective behaviors was spatially heterogeneous across the US as measured by (D) Google mobility data showing the percent reduction in mobility to retail and recreation locations from November–mid-December 2020; (E) the Facebook survey data showing that reports of no in-person schooling; and (F) the Facebook data showing reports of wearing a mask “always” or “most of the time”. eral, the influenza virus promises unpredictability over all else in the transformed post-pandemic viral landscape and we must be prepared.
