Summary

Interpretation of the function of non-coding risk loci for neuropsychiatric disorders and brain-relevant traits via gene expression and alternative splicing quantitative trait locus (e/sQTL) analyses is generally performed in bulk post-mortem adult tissue. However, genetic risk loci are enriched in regulatory elements active during neocortical differentiation, and regulatory effects of risk variants may be masked by heterogeneity in bulk tissue. Here, we map e/sQTLs, and allele-specific expression in cultured cells representing two major developmental stages, primary human neural progenitors ($n = 85$) and their sorted neuronal progeny ($n = 74$), identifying numerous loci not detected in either bulk developing cortical wall or adult cortex. Using colocalization and genetic imputation via transcriptomewide association, we uncover cell-type-specific regulatory mechanisms underlying risk for brain-relevant traits that are active during neocortical differentiation. Specifically, we identified a progenitor-specific eQTL for CENPW co-localized with common variant associations for cortical surface area and educational attainment.

Introduction

Genome wide association studies (GWASs) have identified many common non-coding variants associated with risk for neurodevelopmental disorders, or inter-individual variability in brain structure and other brain-related traits. $1-7$ However, it is challenging to determine the mechanism of these non-coding variants because, in general, (1) the genes impacted by non-coding risk variants are unknown, (2) the cell type(s) and developmental period(s) where the variants have an effect are not known, and (3) there may be limited availability of cells or tissue representing the causal developmental stage and cell type.

One potential mechanism by which non-coding genetic variation can influence brain traits is through alterations in gene expression or expression quantitative trait loci (eQTLs). Genetic variation also impacts transcript splicing, $8-10$ and several studies have implicated genetically mediated alterations in splicing as important risk factors for neuropsychiatric disorders. $11-13$

Most current efforts to explain the function of these risk loci rely on mapping local expression and splicing quantitative trait loci (e/sQTLs) in bulk adult brain tissue, which has been a fruitful approach. $14,15$ $14,15$ However, neuropsychiatric disorder genetic risk loci are enriched in cell types relevant for neocortical differentiation that are not

present in the adult brain.^{[16](#page-18-4)[,17](#page-18-5)} e/sQTL studies performed on human fetal brain bulk cortical tissue have demonstrated the importance of developmental stage and cell composition, by identifying thousands of fetal brain-specific $e/sQTLs$ ^{[18–20](#page-18-6)} However, these studies necessarily focus on one developmental time point for each individual and heterogeneity in bulk tissue may mask cell-type-specific allelic effects.[21–24](#page-18-7)

Utilizing a cell-type-specific in vitro model system including neural progenitors ($n_{\text{donor}} = 85$) and their virally labeled and sorted neuronal progeny ($n_{\text{donor}} = 74$) derived from a multi-ancestry population, here we investigated how common genetic variants impact brain-related traits through gene expression and splicing during human neurogenesis. We discovered 2,079/872 eQTLs in progenitors and neurons and 5,900/4,396 sQTLs in progenitors and neurons, respectively. Importantly, 66.1%/47% of eQTLs and 79.3%/73.4% of sQTLs in progenitor/neuron were unique and not found in fetal bulk brain e/sQTLs from a largely overlapping sample^{[19](#page-18-8)} or in adult bulk e/sQTL data from GTEx.^{[25](#page-18-9)} We showed both eQTLs and sQTLs colocalized with known GWAS loci for neuropsychiatric disorders and other brain-relevant traits in a cell-type-specific manner. By integrating the dataset generated here with cell-type-specific chromatin accessibility from the same cell lines^{[17](#page-18-5)} and brain structure GWAS, 4 we propose a

regulatory mechanism whereby genetic variation influences educational attainment, a proxy for human intelligence, across multiple levels of biology. Furthermore, we genetically imputed cell-type-specific and temporal specific gene expression and alternative splicing associated with brain-relevant traits and neuropsychiatric disorder risk using transcriptome-wide association studies (TWASs).

Material and methods

Cell culture

Generation of human neural progenitor cells was previously described.^{[17](#page-18-5)[,26](#page-18-10)} Briefly, human fetal brain tissue was acquired from the UCLA Gene and Cell Therapy Core following IRB regulations from approximately 14–21 gestation weeks (inferred to be 12–19 post conception weeks). The tissue was derived from voluntary terminations of pregnancy. We excluded known trisomy 21 cases. We were not aware of any fetal anomalies in any body system. For a small subset of intact samples, cortical tissue was dissected to generate primary human neural progenitor cells (phNPCs). For most samples that were non-intact, flat and sheetlike pieces of brain tissue that were presumed to originate from the cortex were selected to generate phNPCs. The tissue was then dissociated and cultured as neurospheres as previously described.^{[26](#page-18-10)} Neurospheres were plated on laminin/fibronectin and polyornithine-coated plates for an average of 2.5 ± 1.8 SD passages, and cryopreserved.

Cryopreserved phNPCs were transferred to UNC Chapel Hill, after material transfer agreement, where all downstream culture and analyses were completed. Donors processed for ATAC-seq (described previously 17) and RNA-seq (described here) were cultured simultaneously. The overall design of the experiment and media used for culture was previously described.^{[17](#page-18-5)} Briefly, we cultured 89 unique donors for subsequent RNA-seq library preparation. We first randomly assigned the approximately 8–9 donors into 12 rounds for a feasible cell culture workload. We thawed one round every 3 weeks. To reduce batch effects, we processed each round on the same day of the week and designated the same person to do each task as much as possible. Cells were isolated at two time points: progenitor and their differentiated and virally labeled neuronal progeny. Progenitors were cultured in proliferation media including growth factors for 3 weeks (see Liang et al.¹⁷), and we lifted them with trypsin to prepare RNA-seq libraries. Differentiation in the absence of growth factors was performed for 5 weeks, after which the culture was transduced with AAV2-hSyn1-eGFP virus, that specifically expresses a reporter gene in neurons without integrating into the genome, at 20,000 multiplicity of infection (MOI) and then differentiated for another 3 weeks. FACS sorting (using either BD FACS Aria II or Sony SH800S) at 56 days (8 weeks) post-differentiation was used to isolate EGFP-labeled neurons [\(Figure S1A](#page-17-2)). After cells were isolated as either progenitors or neurons, we added Qiazol and stored the mixture at -80° C for randomized RNA isolation to reduce batch effects.

Immunofluorescence labeling and imaging

At the progenitor stage or after 8 weeks of differentiation, we fixed the cells by incubating them in 4% PFA and performed permeabilization with 0.4% Triton in PBST. We used 10% goat serum dissolved in PBST for blocking. We incubated blocked samples with

primary antibodies dissolved in PBST solution with 3% goat serum at 4°C overnight followed by washing 3 times with PBST. Samples were subject to incubation in fluorophore-conjugated secondary antibodies, for 1 h at room temperature, then they were stained with DNA-binding dye DAPI with 10 min incubation. We used antibodies with concentrations listed as follows: SOX2 (1:400, rabbit, Millipore #AB5603), Ki67 (1:1,000, rat, Invitrogen #14- 5698-82), HOPX (1:1,000, Sigma-Aldrich, Catalog#:HPA030180, Lot#: C105752), TUJ1 (1:2,000, mouse, Biolegend #801202), GFP (1:500, Millipore, Catalog#: AB16901, Lot#:2712295), Alexa Fluor 568 (1:1,000, goat anti-rabbit, Invitrogen #A11036), Alexa Fluor 647 (1:1,000, goat anti-rat, Invitrogen #A21247), Alexa Fluor 488 (1:1,000, goat anti-mouse, Invitrogen #A11001).

RNA-seq library preparation

We isolated RNA from progenitors and neurons using the QIAGEN miRNeasy Minelute kit, quantified RNA concentration with a Qubit 2.0 fluorometer, and assessed RNA integrity via eRIN scores using the Agilent Tapestation. We prepared libraries for sequencing using Kapa Biosystems KAPA Stranded RNA-seq with Riboerase (HMR) kit by loading 50 ng of total RNA into the initial reaction. We followed the manufacturer's instructions for fragmentation and PCR steps. To obtain \sim 350 bp average insert size, we fragmented cDNA at 85° C for 6 min. Final library concentrations were determined using Qubit 2.0 fluorometer and pooled to a normalized input library. Pools were sequenced on a NovaSeq S2 flowcell using 150 bp PE reads with an average read depth of 99.8M \pm 29.8 SD read pairs per sample.

RNA-sequencing data processing

We merged fastq files from the same library when sequenced on multiple flow cells and trimmed the adapters using sequences provided by Illumina with Cutadapt/1.15. 27 27 27 Quality control of each library was performed with FastQC. For alignment, we first integrated the sequence of AAV2-hSyn1-eGFP plasmid used for labeling neurons into GRCh38 release92 reference genome. Then, we aligned the fastq files to this combined reference genome by implementing STAR/2.6.0a aligner.²⁸

We processed aligned data further with different steps based on downstream analyses. To estimate gene expression levels, we quantified reads with the union exon based approach using featureCounts, where for each gene, all overlapping exons were merged to form union exons, and the reads mapped to those union exons with the same strandedness were counted.²⁹ Gene models were identified using the GTF file Homo_sapiens.GRCh38.92 merged with AAV2-hSyn1-eGFP plasmid.

For allele-specific expression and splicing quantification, we remapped the aligned data with WASP software $(v2018-07)^{30}$ $(v2018-07)^{30}$ $(v2018-07)^{30}$ to reduce reference mapping bias. First, we identified reads overlapping with bi-allelic SNPs within our acquired genotype data. Following this, the genotype of any reads overlapping with a SNP was swapped with the other allele, and re-mapped. WASP discarded re-mapped reads that did not map to the same genomic position. As a final step, we implemented the rmdup.py script provided in the WASP software which removes duplicate reads randomly, regardless of their mapping score.

Mycoplasma contamination test

Adaptor trimmed reads (see above) were mapped using STAR to a combined reference including the GRCh38 release 92 human reference genome, AAV2-hSyn1-eGFP plasmid, and more than 1,400 mycoplasma genomes. Alignment parameters allowed for simultaneous mapping of reads to one or more human and mycoplasma genomes. No sample exceeded 0.11% of total reads mapping to any mycoplasma genome, indicating none of our cultures were contaminated with mycoplasma. This mapping strategy was only used for mycoplasma contamination analysis and not for subsequent analyses.

Genotype processing

We performed genotyping using Illumina HumanOmni2.5 or HumanOmni2.5Exome platform and exported SNP genotypes to PLINK format following the procedure previously described.^{[17](#page-18-5)} Briefly, we converted SNP marker names from Illumina KGP IDs to rsIDs using the conversion file provided by Illumina. We performed quality control with PLINK v.1.90b3 software 31 as follows. We filtered out SNPs with the following criteria: variant missing genotype rate >5% (–geno 0.05), deviations from Hardy-Weinberg equilibrium at p $< 1 \times 10^{-6}$ (–hwe 10^{-6}), minor allele frequency $<$ 1% (-maf 0.01). We also filtered out individuals with missing genotype rate >10% (–mind 0.10). We obtained 1,760,704 directly genotyped variants surviving our QC procedure. Lastly, we called sex from genotype data using PLINK v.1.90b3 software based on heterozygosity on the X chromosome. When there was an ambiguity for sex assessment based on genotype data, we checked XIST expression. We estimated the population structure of our study cohort by implementing multidimensional scaling (MDS) for genotype data of our samples and genotype data from HapMap3, following the protocol from the ENIGMA consortium. By plotting MDS1 versus MDS2, we visually show each donor's ancestry relative to known populations [\(Figure S2B](#page-17-2)).

Imputation

After filtering genotype data, we pre-phased the data with SHAPEIT v.2.837.^{[32](#page-18-16)} For our imputation reference panel, we used 1000 Genomes Project Phase 3 that contains a total of 37.9 million SNPs in 2,504 individuals with multiple ancestries, including those from West Africa, East Asia, and Europe.^{[33](#page-19-0)} Imputation was implemented using Minimac4 software³⁴ (v.1.0.0). On the X chromosome, we separately performed pre-phasing and imputation steps for the pseudoautosomal region and non-pseudoautosomal regions. Following imputation, we retained any variants with missing genotype rate lower than 0.05, Hardy-Weinberg equilibrium p value greater than 1×10^{-6} , and minor allele frequency (MAF) bigger than 1%. We retained SNPs with sufficient imputation quality ($\mathbb{R}^2 > 0.3$), and obtained approximately 13.6 million SNPs in total.

Sample quality control

One library with missing eRIN score and one library with missing final cDNA concentration from neurons were removed. In order to detect sample swaps or mixing between samples, we evaluated consistency of genotypes called from the RNA-seq and genotyping array via VerifyBamID v.1.1.3. 35 We removed the RNA-seq libraries file with [FREEMIX] > 0.04 or [CHIPMIX] > 0.04 ($n_{\text{library}} = 14$). Also, we corrected samples where we detected swaps ($n_{\text{library}} =$ 8). After quality control, we retained 85 unique donors for progenitors, and 74 unique donors for neurons for subsequent analyses.

Replicate correlation and determination of technical factors correlating with gene expression

Quantified RNA-seq reads with featureCounts were imported to generate a gene count matrix in DESeqDataSet format from

DESeq2 R package.³⁶ We filtered out the lowly expressed genes (those where fewer than 10 read counts of a gene were observed in fewer than 5% of samples), and normalized the data via variance stabilizing transformation (vst()) function from DESeq2 R package. 36 We included genes on the X and Y chromosomes and genes transcribed from mitochondrial DNA meeting the expression criteria. We subset the normalized gene expression matrix into progenitor- and neuron-specific samples. To identify major axes of variation in gene expression across samples, we computed principal components of gene expression with prcomp() function from stats R package for each cell type separately and reported the proportion of variance explained by each component.

We recorded biological and technical variables for each sample which may potentially impact gene expression: cell type, postconception week, sex, tissue acquisition date, researcher extracting RNA and preparing libraries, RNA input amount, index number and bases, final cDNA concentration, BioAnalyzer run date, average fragment size of BioAnalyzer cDNA, sequencing pool, cell input, Qiazol lot number and addition date, eRIN, RNA extraction date, RNA tapestation date, QIAGEN extraction kit lot number, FACS sorting date and time, total live cells during sorting, FACS machines used, researcher performing FACS sorting, papain lot number and addition date, differentiation rank (a qualitative assessment of cell health evaluated under the microscope), well location in the 6-well plate, date to plate for differentiation, researcher washing and differentiating cells and date, virus addition date, researcher adding virus, PBS lot number used for cell proliferation and differentiation, laminin, polyornithine lot numbers used for proliferation and differentiation, donor ID, round, media lot numbers used for proliferation, passage number, split dates, researcher performing each split, rank for proliferation (qualitative assessment of cell health), trypsin lot number used for splitting cells, and fibronectin lot number. To identify technical covariates impacting expression levels, we assessed whether any recorded biological or technical variables were significantly correlating with the first 10 expression PCs separately for each cell type. We observed that different FACS machines (Sony SH800S with $n_{donor} = 8$; FACS Aria II with $n_{donor} = 66$) used to isolate GFP-labeled neurons had a strong impact on global gene expression in neurons (PC1: $r = 0.59$, p value $= 1.782e-08$; PC2: $r =$ $(0.58, p$ value $= 3.972e-08)$ [\(Figure S2D](#page-17-2)). To remove the impact of sorter on global neuron expression profiles prior to differential expression analysis, we implemented limma::removeBatchEffect function. 37 Then, we combined the gene expression matrix from batch-corrected neurons with progenitors gene expression data.

We cultured 20 donors multiple times during the course of the experiment in order to quantify cell culture-induced noise. We calculated Pearson's correlation of gene expression between libraries from the same donors ($n_{\text{library-library pairs}} = 15$ in progenitors and $n_{\text{library-library pairs}} = 12$ in neurons), and between each library across donors in a pairwise manner ($n_{\text{library-library pairs}} = 11,556$ for progenitors; $n_{\text{library-library pairs}} = 9,312$ for neurons). For neurons, we used gene expression values after batch correction with the limma R package for the sorter type, as described above. We performed an unpaired two-sided t test for statistical assessment of mean difference between these two categories after fisher's z transformation of correlation r values [\(Figure S1C](#page-17-2)).

Differential gene expression analysis

We identified differentially expressed genes between progenitors and neurons by using vst normalized expression values corrected

Figure 1. Study design and cell-type-specific expression

(A) Study design illustrating the fetal brain tissue derived cell-type-specific system used to perform eQTL and sQTL analysis. (B) Immunofluorescence of the cells showed that undifferentiated progenitors were SOX2 (in red) and PAX6 (in green) positive, and 8 week differentiated neurons labeled with AAV2-hSyn1-EGFP were positive for EGFP (in green) (scale bar is 100 μ m, DAPI in blue). (C) Principal component analysis of progenitor (purple) and neuron (green) transcriptomes from each donor indicates cell-type-specific clustering.

(D) MA plot showing differentially expressed genes in progenitor versus neurons. $log_2FC > 0$ and adjusted p value < 0.05 indicates genes upregulated in neurons shown in green (neuron up), $log_2FC < 0$ and adjusted p value < 0.05 indicates genes upregulated in progenitors shown in purple (progenitor up) and genes not significantly differentially expressed between two cell types are shown in gray. Blue lines indicate $|log_2FC| > 1.5$.

for sorter with limma R package.^{[37](#page-19-4)} We retained the genes if at least 10 counts of the gene were present inmore than 5% of the samples from either one of the cell types. To perform a paired differential gene expression analysis, which inherently controls for donor-related differences, we established the following design matrix: model.ma $trix(\sim\text{CellType} + as.factor(DonorID) + RIN, data)$. Following this, we adjusted p values for each gene via multiple test correction with the Benjamini-Hochberg procedure³⁸ and defined significant differentially expressed genes as adjusted p value < 0.05.

Gene Ontology analysis

We performed gene ontology enrichment analysis by using the gprofiler2 package as the R interface to the g:Profiler tools by using GO:BP database.³⁹ For differentially expressed genes, after performing DGE analysis, we categorized the genes into two groups as upregulated in progenitors ($log{\rm FC}<-1.5$ and adjusted p value $<$ 0.05) and upregulated in neurons (logFC $>$ 1.5 and adjusted p value < 0.05) ([Figure 1](#page-3-0)D). For each enrichment analysis, we applied multiple test correction and considered only pathway enrichments with adjusted p value lower than 5% false discovery rate as statistically significant.

Transition mapping (TMAP)

To evaluate the transcriptomic similarity between our in vitro culture system and the in vivo brain, we performed transition mapping analysis as described in previous work. $26,40$ $26,40$ To evaluate transcriptomic similarity to cortical laminae in the developing brain, we used previously published laminar expression data from laser capture microdissections of prenatal human brain⁴¹ (H376.IIIB.02. female, 16 pcw, brainspan.org). In our comparison, genes were retained which showed expression in either cell type and were present on the array in which the in vivo data were acquired. We used gene symbols to find ensemblIDs and used ensemblIDs to match with in vitro data. When multiple probes were present for a given gene on the array, the probe with the highest expression per gene was used. We quantile normalized the gene expression and we performed in vivo differential gene expression via limma between every two laminae. Similarly, we performed differential expression analysis in our in vitro cultures as described above. We applied transition mapping via RRHO2 R package with ''stratified approach'' to avoid misinterpretation of the discordant overlaps.⁴² In this algorithm, first genes were ranked based on their degree of differential expression (DDE) (i.e., $-\text{log}10(p \text{ value}) \times \text{signed}$ effect size) separately for in vivo and in vitro data. Following ranking, a hypergeometric test was applied to assess enrichment for each overlap between two datasets for a series of arbitrary step sizes. By employing a stratified algorithm, we computed the degree of overlap. Finally, we visualized the hypergeometric test -log10(p values) as a heatmap ([Figure S1](#page-17-2)G).

Cell-type-specific local eQTL mapping

To perform local eQTL analysis, we conducted an association test between gene expression (retaining genes if at least 10 counts of the gene were present in more than 5% of the samples of that cell type, resulting in 24,778 and 27,649 genes for progenitors and neurons, respectively) with genetic variants within ± 1 Mb window of gene TSS for both autosomal chromosomes and X chromosome, for progenitors and neurons separately. Each gene TSS was defined as the transcription start site of the gene isoform with the most upstream exon based on GTF file Homo_sapiens.GRCh38.92.

We removed variants of low allele frequency in order to prevent one donor from strongly influencing association results. For variant selection, PLINK v.1.90b3 software function was implemented to obtain donor counts per genotype group for each variant. We included only variants with at least two heterozygous donors and no homozygous minor allele donors, or at least two minor allele homozygous donors for autosomal chromosomes, and for X chromosome we retained the variants with at least two haploid allele counts in addition to this criteria.

For eQTL mapping, we used a linear mixed effects regression model to control for population stratification and cryptic relatedness with EMMAX software.^{[43](#page-19-10)} To compute the kinship matrix, we implemented emmax-kin -v -h -d algorithm creating the identity by state (IBS) kinship matrix by excluding all genetic variants located on the same chromosome as the tested variant from non-imputed genotype data for each single variant association test (MLMe method; see Yang et al. 44). We used additional ancestry control by including the first ten MDS components from the genotype data as covariates.^{[45](#page-19-12)} In order to control for unmeasured technical variables impacting gene expression, we computed global gene expression PCs. To optimize eQTL discovery, we sequentially added gene expression PCs and re-ran the genetic associations via EMMAX. For neurons, we included a covariate for FACS sorter for each run given its strong impact on gene expression.

The full association model for neurons was:

expression \sim SNP + 10 MDS of global genotype + kinship matrix

 $+$ FACS sorter $+$ PCs of global gene expression

The full model for progenitors was:

expression \sim SNP + 10 MDS of global genotype + kinship matrix $+$ PCs of global gene expression

For each run, we adjusted nominal values of all gene variant associations, and defined significant associations with nominal p value lower than 5% false discovery rate (FDR). 38 We found that 10 PCs and 12 PCs of gene expression resulted in a maximum number of eGenes discovery in progenitors and neurons, respectively ([Figure S2](#page-17-2)E). Our final eQTL model was:

Neuron:

expression \sim SNP + 10 MDS of global genotype + kinship matrix

 $+$ FACS sorter $+$ 12 PCs of global gene expression

Progenitors:

expression \sim SNP + 10 MDS of global genotype + kinship matrix $+10$ PCs of global gene expression

In order to stringently control our association results for both number of variants and genes tested, we further implemented a hierarchical correction procedure called eigenMT-FDR 46 for the models optimized above. Using this method, as step 1, we adjusted the nominal p values of the all *cis* SNPs separately for each gene to compute locally adjusted p values with the eigenMT method that resulted in the estimation of effective number of independent tests from the genotype correlation matrix including *cis* SNPs.^{[47](#page-19-14)} In step 2, locally adjusted minimum p values for all genes were then subjected to FDR procedure to obtain globally adjusted p values. In step 3, we defined eGenes as genes with globally adjusted p value lower than 0.05. Then, to find other independent SNPs for those eGenes, we set the significance threshold as the maximum nominal p value from step 1 that had corresponding globally adjusted p value lower than 0.05.

We performed conditional analysis by using this threshold p value gathered from the eigenMT-FDR multiple correction method to identify independent significant eQTLs. To identify conditionally independent eQTLs, for each eGene (a gene significantly associated with at least one variant), we iteratively included the hard call genotype of the variant with the strongest association with eGene as a covariate and re-ran the regression model specified above ([Figure S3](#page-17-2)A). We defined a variant as "conditionally independent'' from the variant conditioned on, if the association of the variant with the eGene was still significant based on the initial threshold p value. Then, we conditioned on those variants that met threshold p value condition at the first round plus the primary variant and identified third conditionally independent eQTLs. We applied this procedure iteratively until no additional significant eQTLs remained.^{[48](#page-19-15)[,49](#page-19-16)}

Bulk fetal brain eQTL mapping

We utilized bulk fetal cortical wall eQTL data described previ-ously.^{[19](#page-18-8)} We re-analyzed data in this study with the following modifications to harmonize with the eQTL approach implemented in this study: (1) we controlled for population stratification using a linear mixed effects model as described above and (2) we included 23 additional donors which were genotyped after the publication of the previous manuscript. We used rRNA-depleted RNA-seq data from flash frozen human fetal brain cortical wall tissues derived from 240 donors at 14–21 gestation weeks (inferred to be 12–19 post conception weeks). We excluded 4 donors for sample swap and contamination based on verifyBAMID analysis, and 1 donor with sex ambiguity, resulting in 235 unique donors for eQTL analysis (35 of unique donors shared with cell-type-specific data). Gene-based annotations of the genome were derived from Homo sapiens gene ensembl v.92 (GRCh38) for eQTLs. We included only genes with at least 10 counts in 5% of donors. We normalized the data with the VST method to be used as phenotype in eQTL analysis. We also extracted genomic DNA from the same donors and performed genotyping on a dense array (Illumina Omni $2.5 +$ Exome) and imputation to a common reference panel (1000 Genomes Phase 3; described above). Variants were retained in the analysis if there were at least two heterozygous donors and no homozygous minor allele donors, or if there were at least two minor allele homozygous donors as for cell-type-specific eQTLs, as described above.

We performed local eQTL analysis to test the association between each gene's expression and variants within the ± 1 Mb window of the transcription start site of each gene. We applied linear mixed model association software $EMMAX⁴³$ $EMMAX⁴³$ $EMMAX⁴³$ to control for population stratification and cryptic relatedness (as described above for cell-type-specific eQTL analysis). We used the linear mixed effects regression model testing association between expression of each gene and nearby genetic variants, controlling for ten MDS genotype components, ten PCs of gene expression, and a kinship matrix as random effect excluding the chromosome genotypes testing with the MLMe approach.⁴⁴ After association, nominal p values were corrected for hierarchical multiple testing using the eigenMT-FDR method as described above, and we obtained independent eQTLs performing conditional analysis as described for cell-type-specific eQTLs above.

Enrichment of eQTLs within functional genomic annotations

To identify enrichment of eQTLs and sQTLs within functionally annotated genomic regions, we implemented GARFIELD software to control for the distance to TSS, LD, and minor allele frequency (MAF) of QTLs.^{[50](#page-19-17)} We used functional genomic annotations from 25 chromatin states given in the ChromHMM BED files of Roadmap Epigenomics project from human male fetal brain $51,52$ $51,52$ lifted over from hg19 to hg38. For all eQTLs, we extracted the p value from the strongest association for each variant (with minimum p value) in the case that one variant was associated with multiple genes. To create annotation files, we considered a variant overlapping with a functional element if the variant itself or any of the variants in high LD within 500 kb ($r^2 > 0.8$) overlapped with each of the annotation categories. LD pruning 50 was performed at $r^2 > 0.01$ within GARFIELD software. Following this, a logistic regression model controlling for the distance to TSS of the gene with the strongest association to the tested SNP, LD proxies, and MAF binned for five quantiles was performed with GARFIELD software for enrichment at eigenMT-FDR p value thresholds defined in

eQTL analysis. The effective number of annotations were estimated and multiple testing adjusted p values were computed by the software to identify enrichment of eQTLs within defined annotations.

Enrichment of eGenes within likely in vitro artifacts

To determine whether eQTL discovery was driven by in vitro artifacts, we performed an enrichment analysis via fgsea software 53 to test whether discordant genes between in vivo laminar expression data 41 and our cell-type-specific in vitro data were enriched among cell-type-specific eGenes. To define discordant genes, we used two lists of differentially expressed genes from in vivo oSVZ versus SP (selecting these regions as the most overlapping with our cell types in [Figure S1](#page-17-2)G) and separately from in vitro progenitor versus neurons as described for TMAP analysis. We defined the discordant genes as genes with adjusted p value lower than 0.01 and opposing sign of log fold change. Then, for each cell type, we tested for enrichment of discordant genes among all eGenes ranked by their ascending *m*-value (from low values for cell-typespecific to high values for shared effect size).

Allele-specific expression analysis pipeline

To identify sites with allele specific expression (ASE), we initially extracted uniquely mapped reads from the RNA-seq data remapped with WASP to reduce mapping bias and to discard duplicate reads; then, we applied the ASEReadCounter algorithm from GATK tools.^{[54](#page-19-21)} For each donor, we counted allele-specific reads overlapping with bi-allelic variants identified in the genotypeVCF files. We retained only variants with at least five heterozygous donors and at least ten counts from either allele (at least two counts supporting each allele). ASE can be falsely called when genotyping errors are present in the dataset. We used two approaches to identify and remove potential genotyping errors. (1) We detected wrongly called variant genotypes by assessing concordance be-tween genotypes called by DNA versus RNA.^{[55](#page-19-22)} We removed variants that were called homozygous based on the genotype data when at least ten counts of the alternate allele were present in the RNA-seq data, and (2) we discarded variants where at least seven heterozygous donors based on genotype data have zero counts for one of the alleles, which may indicate a donor falsely called as heterozygote when in truth the donor is a homozygote (given that $(1/2)^7 = 0.008$, meaning that probability of having all donors receiving an imprinted allele from either mother or father is low). Because ASEReadCount does not disambiguate the strandedness of reads, it is not possible to confidently assign reads overlapping with multiple gene annotations to a specific gene. 54 Therefore, if a variant overlapped with more than one gene annotation, we removed the variant by implementing findOverlaps function from IRanges R package^{[56](#page-19-23)} for genes based on their genomic coordinates defined GTF file Homo_sapiens.GRCh38.92.

To evaluate allelic imbalance, we used DESeq2 with the design: $design = ~0 + RNAid + Allele. Excluding homozygous donors, we$ computed the log2 fold change of non-reference allele counts over reference allele counts and used a Wald test to detect allelic imbalance by setting fitType $=$ "mean" after visual inspection of dispersion. Multiple test correction was performed with the Benjamini and Hochberg method, and we defined significant ASE sites as those with adjusted p values lower than 0.05.

To compare eQTLs with ASE sites ([Figures 2](#page-6-0)B, [S4F](#page-17-2), and S4G), we extracted eQTLs associations with the variants tested for ASE analysis (at least 5 heterozygous donors and overlapping with at least 10 RNA-seq reads). We also extracted eGenes (defined based on significant eigenMT-FDR global p value) with at least 10 counts per donor. To calculate allelic fold change (aFC) for the eQTLs in this list, we applied aFC software⁵⁷ using VST normalized genes and controlling for the same fixed effect covariates used for eQTL analysis.

Quantification of intron excisions

To identify alternatively excised introns, separately for each cell type, we extracted exon-exon junctions from uniquely mapped reads from WASP-mapped RNA-seq data in BAM format via regtools function where reads map to a minimum of 6 nt of each exon.⁵⁸ Next, we processed those junctions that are called *intron* excisions or exon-exon junctions with the pipeline provided by Leaf-Cutter software.⁵⁹ First, intron excisions with shared splice junctions were clustered together applying an iterative procedure until each cluster has at least 50 reads across donors and introns with maximum 50 kb length, separately for progenitors and neurons. For differential splicing analysis, we performed clustering by combining exon-exon junctions files from each cell type. For each cluster, intron excisions supported by at least one count in more than five donors were retained (within each set of donors contributing to the three different sQTL analyses for that cell type [progenitor, neuron] or tissue class [fetal brain bulk]; or for differential splicing analysis across donors from both cell types used [progenitor $+$ neuron]). We further calculated intron excision ratios and filtered out introns represented in less than 40% of donors (within each set of donors contributing to the three different sQTL analyses for that cell type [progenitor, neuron] or tissue class [fetal brain bulk]; or for differential splicing analysis across donors from both cell types used [progenitor $+$ neuron]) with prepare_phenotype_table.py. We referred to each intron excision ratio as percent spliced in (PSI) that corresponds to the usage of each intron compared to other introns in the same cluster. Standardized and quantile normalized intron excision ratios, and global alternative splicing PCs computed with those ratios were used for downstream analysis.

Differential splicing analysis

To perform differential splicing analysis, we used quantile normal-ized PSI values as input to the limma package.^{[37](#page-19-4)} Identical to differential expression analysis, neuron splice ratios were corrected for batch including FACS machine used for sorting with limma::removeBatchEffect function. Batch corrected neuron splice ratios were combined with progenitor data. We implemented a paired differential splicing analysis inherently controlling donor-related differences with the design matrix: model.matrix(\sim CellType $+$ as.fac $tor(DonorID)$ + RIN, data). We defined intron junctions with adjusted p values via multiple test correction with Benjamini-Hochberg procedure^{[38](#page-19-5)} lower than 0.05 as significant differentially spliced introns.

Splicing QTL mapping

We performed cell-type-specific splicing QTL analysis by testing the association of PSI with the genetic variants located within the ± 200 kb window from starting and end points of the splice junctions for autosomal chromosomes and the X chromosome. Identical to local eQTL analysis, we used only genetic variants that met the following criteria: if there were at least two heterozygous donors and no homozygous minor allele donors, or if there were at least two minor allele homozygous donors.

Figure 2. Cell-type-specific eQTL analysis

(A) Enrichment of progenitor eSNPs (left) and neuron eSNPs (right) within chromatin states in the fetal brain from chromHMM listed on the y axis. The x axis shows the effect size of enrichment with 95% upper and lower confidence interval and the plot is color-coded based on -log10(p value) value from enrichment analysis. Significant enrichments are shown with an asterisk. Enrichment was tested using eQTLs thresholded at the eigenMT-FDR p value.

(B) Comparison of the effects of shared ASE sites and eQTLs in progenitors (left in purple) and neurons (right in green). Nonsignificant ASE sites are shown as darker colors for both cell types, and significant ASE sites are shown as lighter colors. Correlation coefficient (r) values are indicated in colors for each category and the red dashed line indicates $y = x$.

(C) Overlap percentage of cell-type-specific eSNP-eGene pairs shared with fetal bulk eQTLs in progenitors and neurons at m-value > 0.9. Odds ratio (OR) test p values are shown.

(D) The fraction of progenitor/neuron primary eGene-eSNP pairs that are true associations (π_1) in fetal bulk eQTLs. 95% upper and lower confidence interval are shown.

We used standardized and normalized intron excision ratios (percent spliced in) calculated by LeafCutter as the phenotype for sQTL mapping. $EMMAX^{43}$ $EMMAX^{43}$ $EMMAX^{43}$ was used to test for association between SNPs within a *cis*-region of ± 200 kb of the intron cluster and intron ratios within cluster. We controlled for population stratification and cryptic relatedness as described above for eQTL mapping. Also, we controlled for unmeasured technical variables impacting alternative splicing via computed global splicing PCs. Similar to eQTL analysis, we optimized sQTL discovery by sequentially adding global splicing PCs to the genetic associations via EMMAX. Again for neurons, we additionally controlled for FACS sorter for each run given its strong impact on splicing.

The full model for neurons was:

PSI \sim SNP + 10 MDS of global genotype + kinship matrix + FACS sorter $+$ PCs of global splicing

The full model for progenitors was:

PSI \sim SNP + 10 MDS of global genotype + kinship matrix + PCs of global splicing

For every run, we adjusted nominal values of all PSI variant associations and defined significant associations with lower than at 5% false discovery rate (FDR). 38 We found that 1 PC and 1 PC across the PSI matrix resulted in a maximum number of intron excisions with at least one significant association in progenitors and neurons, respectively [\(Figure S6](#page-17-2)B). Our final sQTL model was:

Neuron:

PSI \sim SNP + 10 MDS of global genotype + kinship matrix + FACS sorter $+1$ PCs of global splicing

Progenitors:

PSI \sim SNP + 10 MDS of global genotype + kinship matrix + 1 PCs of global splicing

Implementing the same hierarchical correction procedure as for eQTLs (eigenMT-FDR⁴⁶) first, we adjusted the p values of the all *cis* SNPs strongest association separately for each intron excision to compute locally adjusted p values with the eigenMT method, 47 and then locally adjusted minimum p values for all intron excisions were subjected to the BH procedure giving globally adjusted p values. Intron excision with corresponding global p value lower than 0.05 were considered as significant alternative splicing events. In order to find other independent significant sQTLs in addition to the ones associated with lowest p values, we applied conditional analysis at eigenMT-FDR p value threshold as described for eQTL analysis.

For bulk fetal cortical tissue sQTL mapping, we applied the same strategy used for cell-type-specific sQTLs and found the following model maximized significant intron junctions discovery:

PSI \sim SNP + 10 MDS of global genotype + kinship matrix + 6 PCs of global splicing

After calculating eigenMT-FDR threshold p value, we performed conditional analysis to define independent significant sQTLs.

To find genes overlapping with intron excision, we annotated intron junctions by using LeafCutter based on genomic coordinates and gene model provided in GTF file Homo_sapiens.GRCh38.104. Intron junctions assigned as cryptic 5', cryptic 3', or novel annotated pair were considered as novel splicing events for the genes overlapped with junctions including unannotated splice sites for the ARL14EP.

RNA binding protein motif analysis

We performed enrichment of sSNPs in RNA binding protein binding sites via GARFIELD as described above with the only difference being controlling for the distance to the intron with the strongest association to the tested SNP. In this analysis, we used BED files including RNA binding protein sites from a CLIP-seq database as annotation files 60 and assessed significant enrichment of celltype-specific sQTLs for binding sites of each RBP.

Comparison of QTL association methods

To determine the impact and reproducibility of a linear mixed effects model as compared to a standard linear regression on QTL results, we applied the FastQTL 61 method in nominal pass mode for different models to run eQTL analysis on autosomal chromosomes. To test for impacts on population stratification, we performed FastQTL (1) without controlling either for population structure or technical confounders, (2) controlling for only technical confounders, (3) controlling for 10 MDS of global genotype and global gene expression PCs. Following this analysis, we compared genomic inflation factors (λ_{GC}) across those three groups to our data where we controlled for 10 MDS of global genotype and global gene expression, as well as the cryptic relatedness with kinship matrix.

We also compared autosomal eGenes/significant introns and primary eGene-eSNP/intron-sSNP pairs detected via either EM-MAX or FastQTL. For EMMAX analysis, eGenes/significant introns and primary eGene-eSNP/intron-sSNP pairs were defined using the eigenMT-FDR approach with 5% FDR. For FastQTL, eGenes/ significant introns and primary eGene-eSNP/intron-sSNP pairs were defined by fitting nominal p values of the most highly associated pairs extrapolated from a beta distribution to adaptive permutations with the setting –permute 1000 10000 as previously described.^{[62](#page-19-29)} Then, Storey's q value method⁶³ was applied on permutation p values derived from beta approximation across genes/introns for multiple correction with 5% FDR.

QTL sharing

We estimated *m*-values to assess cell type specificity of SNP-gene or SNP-intron excision pairs with Metasoft.^{[64](#page-20-1)} Prior to software implementation, we extracted e/sQTLs from the neuron data corresponding to primary progenitor eSNP-eGene/sSNP-introns junction pairs to determine overlap of sharing significant progenitor e/sQTLs with neuron eQTLs. Similarly, we extracted e/sQTLs from the progenitor data corresponding to neuron primary eSNP-eGene/sSNP-introns junction pairs to determine overlap of sharing significant neuron eQTLs with progenitor e/sQTLs. We estimated standard errors by dividing beta estimates from EMMAX by t-statistics for each association p value. We defined associations shared across different QTLs as m -value > 0.9 . Similarly, in order to find significant progenitor/neuron e/sQTLs shared with fetal bulk e/sQTLs, we extracted e/sQTLs from the fetal bulk data corresponding to progenitor/neuron primary eSNP-eGene/sSNP-introns junction pairs and defined shared QTLs at m -value > 0.9 .

We also applied the π_1 statistic⁶³ to quantify QTL sharing for progenitor versus neuron and progenitor/neuron versus fetal bulk primary eSNP-eGene pairs/sSNP-intron junction pairs using the R qvalue package. 65 To find the fraction of progenitor/neuron primary eSNP-eGene pairs that are true associations in neuron/ progenitor eQTLs (π_1) , we extracted nominal p values from neuron/progenitor eQTLs for corresponding progenitor/neuron primary eSNP-eGene pairs. Using the qvalue() function by setting lambda seq (0.2,0.8,0.1), we computed the π_0 value and defined the π_1 as $1 - \pi_0$. The previously described π_1 statistic requires the gene to be detectable in both cell types, which may underestimate cell type specificity. To account for this, in a separate analysis, when a SNP-gene pair was not tested in a cell type, we assigned a random p value (sampled from a uniform distribution). We applied the same strategy to find the fraction of progenitor/ neuron primary sSNP-intron junction pairs that are true associations in neuron/progenitor sQTLs. Similarly, in order to find the fraction of progenitor/neuron primary eSNP-eGene or sSNPintron junction pairs that are true associations in fetal bulk eQTLs or fetal bulk sQTLs, we used nominal p values from fetal bulk eQTLs or sQTLs for corresponding progenitor/neuron primary eSNP-eGene or sSNP-intron junction pairs to compute the π_1 value.

We considered an LD-based overlap of e/sQTLs between two datasets when the index e/sSNPs were in LD ($r^2 > 0.8$ where LD was calculated in our sample population) and the eSNP-eGene/sSNPintron pairs were shared. To determine the total number of eSNP-eGene/sSNP-intron pairs as the universe for enrichment analyses, we pruned all variants associated with each gene per gene for $r^2 > 0.01$ by using PLINK command plink –indep-pairwise 50 5 0.01. To determine whether different proportions of sharing were observed between two cell types, we performed an odds ratio test described here.^{[66](#page-20-3)}

To test for temporal specificity of cell-type-specific e/sQTL data, we downloaded GTEx adult brain e/sQTL data.²⁵ We called loci from the two datasets as colocalized when (1) index adult brain e/sQTLs are found within LD buddies of cell-type-specific e/sQTLs at LD $r^2 > 0.8$ (where LD is calculated using either the European population from 1000 Genomes or our study's population) and (2) the cell-type-specific e/sQTL data conditioned on index adult brain e/sQTLs, the cell-type-specific index e/sQTL no longer survives the global significance threshold.

LD-thresholded colocalization with brain disorders and traits GWAS

To find eQTLs and sQTLs colocalized with index GWAS loci, we performed LD-thresholded colocalization analysis for each cell type separately.⁶⁷ We used summary statistics of GWASs for schizophrenia $(SCZ)^1$ $(SCZ)^1$ (MIM: 181500), major depression disorder $(MDD)^{68}$ $(MDD)^{68}$ $(MDD)^{68}$ (MIM: 608516), bipolar disorder (BP)² (MIM: 125480), educational attainment (EA), 69 neuroticism, 70 70 70 IQ, 5 5 5 cognitive performance (CP) ,⁶⁹ attention-deficit/hyperactivity disorder $(ADHD)^6$ (MIM: 143465), Alzheimer disease $(AD)^{71}$ $(AD)^{71}$ $(AD)^{71}$ (MIM: 104300), Parkin-son disease (PD)^{[72](#page-20-9)} (MIM: 168600), insomnia,^{[73](#page-20-10)} epilepsy⁷⁴ (MIM: 600669), autism spectrum disorder $(ASD)^{75}$ (MIM: 209850), and cortical thickness and surface area from the ENIGMA project.⁴ We used liftover to convert the positions of variants in GWAS summary statistics from hg19 to hg38 with liftOver function from R rtracklayer package.⁷⁶ Variant rsids were assigned with dbSNP151 based on positions of variants in summary statistics data. To define index GWAS SNPs at genome-wide significant threshold p value

 (5×10^{-8}) , we implemented a clumping procedure, where we defined two LD-independent GWAS signals so as to have pairwise LD r^2 < 0.5 based on LD matrix computed with European population of 1000 Genomes (1000G European phase 3). Prior to clumping, duplicated rsIDs in 1000G EUR genotype files were assigned with unique names, and BIM files were modified for each chromosome. Following a unique id assignment, BIM files were merged back to BED and FAM files with –bmerge function of PLINK1.9 software (plink –bfile BED file –bmerge modified_BIM file). Since all GWASs we leveraged in our colocalization analysis have been conducted in populations of European ancestry, and our study population is multi-ancestry, we computed LD r^2 separately within these two different populations. We considered the index eQTL or sQTL SNP coincident with the index GWAS SNP if the pairwise LD r^2 between them was greater than 0.8 based on either the LD matrix computed via either European 1000 Genomes Phase 3 data or our study population. Following that, we performed a conditional eQTL/sQTL analysis by conditioning on the coincident index GWAS SNP. If the association of index QTL and gene expression or intron excision was no longer significant based on p value thresholds defined with eigenMT-FDR method for each dataset, we identified that cell-type-specific and fetal bulk eQTL/sQTL as a colocalized loci with the given GWAS trait. Since GTEx raw data are not available publicly, conditional analysis was not performed to infer colocalization.

Transcription factor motif analysis

We used motifbreakR to detect the disruption of the transcription motif binding site where there was a variant within a chromatin accessibility peak [\(Figure 4D](#page-13-0)). 77 77 77

TWAS analysis

We performed transcriptome-wide association analysis for progenitor and neurons separately with FUSION software.⁷⁸ First, we obtained a set of variants shared between the genotypes from 1000 Genomes European phase 3^{33} 3^{33} 3^{33} and our study population restricted to variants described for eQTL analysis and removed monomorphic variants within European genotype data. We estimated cisheritability of genes (including variants within ± 1 MB window of the TSS) and intron junctions (including variants within ± 200 kb window of two ends of intron junctions) with GCTA soft-ware^{[79](#page-20-16)} by controlling for the same covariates for global gene expression/splicing and 10 PCs of global genotypes used in e/ sQTL analysis. VST normalized gene expressions were further subject to quantile normalization for heritability estimation. 1,703/ 973 genes and 6,552/6,578 intron junctions were significantly cis -heritable in progenitors/neurons for heritability p value \lt 0.01. To determine the method to be used to estimate the genetic component of gene expression/splicing (weights), we performed leave-one-out cross validation 80 for the prediction models including LASSO regression, 81 Elastic-net regression 82 and EM- $MAX⁴³$ within FUSION software. We used the weights computed from the prediction model with the highest cross validation \mathbb{R}^2 (the highest performance) per gene/intron junction for downstream analysis for progenitor, neuron, and fetal bulk brain tissue. To evaluate the reproducibility of TWAS analysis, we pseudorandomly (maintaining similar proportions of donor ancestry) down-sampled the fetal bulk eQTL data to the sample size of progenitor ($n_{\rm donor} = 85$) and neuron ($n_{\rm donor} = 74$) data twice per cell type, and calculated weights. For adult brain bulk tissue data, we obtained the weights of genes and intron junctions from CommonMind Consortium study.⁸³ Also for the reproducibility of TWAS analysis, we used the weights of genes from GTEx adult frontal cortex (BA9) v.7 model. 62

Before running TWAS analysis, we prepared GWAS summary statistics for schizophrenia $(SCZ)_1$ $(SCZ)_1$ ¹ major depression disorder (MDD) ,^{[68](#page-20-5)} educational attainment (EA) ,^{[69](#page-20-6)} neuroticism,^{[70](#page-20-7)} IQ,^{[5](#page-18-17)} Alzheimer disease (AD),⁷¹ Parkinson disease (PD),⁷² and global surface area (GSA) and average thickness from ENIGMA study^{[4](#page-17-1)} with following adaptations: (1) we obtained common variants found both in genotype files from our study and in GWAS summary statistics; (2) we calculated z-score by dividing the beta coefficient by the standard error if the beta coefficient was available in the summary statistics, or dividing the natural logarithm of odds ratio by the standard error if odds ratio was given in the summary statistics; (3) we matched the sign of the z-score based on the allelic directionality of weights from FUSION software.

To perform TWAS analysis, we tested the association between the predicted gene expression/splicing (w) and brain traits listed above (Z) by implementing the algorithm $Z_{TWAS} = w' Z/sqrt(w'Dw)$ where D is the LD matrix as the covariance among all cis-variants from the FUSION software[.78](#page-20-15),[83](#page-20-20) Since the population structure of our dataset was different from European neuropsychiatric GWASs, we performed TWAS analysis separately with different LD estimates computed based on our study or European population from 1000 Genomes Phase 3 as the covariance. For variants missing in GWAS summary statistics which existed in our study's genotypes, we implemented IMPG imputation⁸⁴ allowing imputation of maximum 40% of missing variants within the FUSION algorithm.

To identify genes/intron junctions not driven by co-expression, we defined jointly independent genes/intron junctions through performing summary-statistic-based joint analysis, 85 where we replaced SNPs with genes/intron junctions as described in previous work^{[83](#page-20-20)} within the FUSION software. Implementing genes/intron junctions to the model one at a time in decreasing order of significance, we evaluated whether the conditional TWAS test remained significant. Those with significant conditional TWAS association were defined as jointly independent.

Results

Transcriptomic profiles of primary human progenitors and neurons recapitulates cell-type-specific characteristics of cortical development

We established an in vitro culture of primary human neural progenitor cell (phNPC) lines derived from genotyped human fetal brain tissue ($n = 89$ unique donors) at 12-19 post conception weeks (PCW) (14–21 gestation weeks), that recapitulates the developing human neocortex $26,86-88$ $26,86-88$ ([Figure 1A](#page-3-0), [Material and methods](#page-1-0)). Immunofluorescence of the cells showed that undifferentiated progenitors were PAX6 and SOX2 positive (90%–95%), consistent with a ho-mogeneous culture of radial glia^{[89,](#page-21-0)[90](#page-21-1)} [\(Figure 1](#page-3-0)B). At 5 weeks post-differentiation, phNPC cultures were transduced with a virus which expresses EGFP in neurons (AAV2-hSyn1- EGFP), which enabled us to isolate neurons via FACS sorting at 8 weeks post-differentiation [\(Figures 1](#page-3-0)A, 1B, [S1A](#page-17-2), and S1B, [Material and methods\)](#page-1-0).

We acquired transcriptomic profiles of progenitors and neurons via RNA sequencing, observing a strong correlation of libraries from the same donor cultured at different

times [\(Figure S1](#page-17-2)C). After correction for technical confounds [\(Figure S1D](#page-17-2)), progenitors and neurons clustered separately by principal component analysis (PCA) of global gene expression, indicating global transcriptomic differences by cell type ([Figure 1](#page-3-0)C). Both cell types showed expected expression of a variety of known cell-type-specific markers ([Figure S1](#page-17-2)E). Next, we identified differentially expressed genes, which were enriched in cell cycle and neurotransmission gene ontology terms, upregulated in progenitors and neurons, respectively [\(Figures 1D](#page-3-0) and [S1](#page-17-2)F, [Table S1\)](#page-17-2).

We evaluated how well the *in vitro* progenitors and neurons we generated model in vivo neurodevelopment. We implemented the transition mapping (TMAP) approach for a global assessment of transcriptomic overlap between in vitro cultures and in vivo post-mortem human brain sam-ples, as described in our previous work^{[26](#page-18-10)} [\(Material and](#page-1-0) [methods\)](#page-1-0). We compared the transition from progenitor to neurons with laser capture microdissection of cortical laminae from postmortem human fetal brain at 15–21 PCW.⁴¹ We observed the strongest overlap in the transition from progenitors to neurons with the transition from outer subventricular zone (oSVZ) to intermediate zone (IZ) or subplate zone (SP) ([Figure S1G](#page-17-2)), supporting the *in vivo* fidelity of our culture system representing neurogenesis during mid-fetal development.

Cell-type-specific genetically altered gene expression via local expression quantitative loci (eQTL) analysis

To investigate the impact of genetic variation on gene expression, we performed a local eQTL analysis by testing the association of each gene's expression levels with genetic variants residing within ± 1 Mb window of its transcription start site $(TSS)^{62,91}$ $(TSS)^{62,91}$ $(TSS)^{62,91}$ $(TSS)^{62,91}$ ([Figure S2A](#page-17-2), see [Material and](#page-1-0) [methods\)](#page-1-0). We implemented a linear mixed effects model (LMM) to stringently control for population stratification using a kinship matrix as a random effect with inferred technical confounders as fixed effects, separately for each cell type (λ_{GC} for progenitor = 1.028 and λ_{GC} for neuron $= 1.007$; see [Material and methods,](#page-1-0) [Figures S2B](#page-17-2)–S2E). After retaining associations that were lower than 5% false discovery rate with a hierarchical multiple testing correction $46,47$ $46,47$ [\(Material and methods](#page-1-0)), we obtained conditionally independent eQTLs ([Figures S3A](#page-17-2) and S3B, see [Material](#page-1-0) [and methods](#page-1-0)). We identified 1,741 eGenes with 2,079 eSNP-eGene pairs in progenitors and 840 eGenes with 872 eGene-eSNP pairs in neurons ([Figure S3](#page-17-2)C and [Table](#page-17-2) [S2](#page-17-2)). As a complementary analysis, we performed eQTLs us-ing a linear model approach (FastQTL)^{[61](#page-19-28)} followed by an adaptive permutation. We detected 90%/93% of eGenes and 87%/90% of primary eSNP-eGene pairs discovered via the LMM approach in progenitor/neuron were also identified using the standard linear model, indicating that our LMM approach was highly robust and reproducible [\(Figure S3D](#page-17-2)).

To determine whether our detected eQTLs were driven by in vitro artifacts, we tested whether eGenes were enriched in genes with discordant expression between our in vitro culture and the in vivo brain. We selected low-fidelity genes as those with opposing directions of differential expression effect size between in vivo oSVZ versus SP and in vitro progenitor versus neuron [\(Figure S1G](#page-17-2)). We did not observe an enrichment of cell-type-specific eGenes within this low fidelity gene list in neurons or progenitors ([Figure S4A](#page-17-2)). This observation suggests that the potential confounding effect of in vitro conditions in our model system was not a major driver of cell-type-specific eGene discovery.

We next evaluated QTL sharing across cell types using multiple different methods to increase confidence in the findings: (1) LD-based overlap, i.e., high LD between significant index SNPs indicates a shared effect, (2) *m*-values, 92 i.e., posterior probability of the shared effect, and (3) π_{1} , 63 63 63 i.e., the proportion of QTLs selected in one dataset that are true positives in another. We observed that 14.8%/ 35.5% of progenitor/neuron conditionally independent eSNP-eGene pairs were shared with the other cell type using LD-based overlap [\(Figure S3C](#page-17-2)). 53.1%/69.3% of progenitor/ neuron primary eSNP-eGene pairs were shared with the other cell type with *m*-value^{[92](#page-21-3)} > 0.9 ([Figure S4](#page-17-2)B). Also, the fraction of progenitor/neuron primary eSNP-eGene pairs that are true associations in neuron/progenitor eQTLs (π_1) was 76.9%/91.4%, when subset to gene-SNP pairs that were detectable in both datasets ([Figure S4C](#page-17-2)). A higher shared effect for neuron primary eQTLs with progenitor eQTLs than progenitor primary eQTLs with neuron eQTLs suggested similar genetic effects on transcriptomes in immature neurons with their parent cells, whereas parent progenitor cells have unique features, such as proliferation ability, that are not present in neurons.

We determined whether eSNPs were enriched in specific functional chromatin annotations in fetal human brain^{51} [\(Figure 2A](#page-6-0)). Both progenitor- and neuron-specific eSNPs were enriched in promoters and actively transcribed sites present in the fetal brain, and progenitors were enriched in enhancers regions and depleted in quiescent chromatin regions. Importantly, 40.8%/38.8% of progenitor/neuronspecific significant eQTLs (restricted to variants tested for allele-specific expression [ASE] analysis), respectively, were supported by cell-type-specific ASE, that is less susceptible to cross donor technical confounding, like population stratification^{55[,62](#page-19-29)[,93](#page-21-4)} ([Figures S4](#page-17-2)D–S4G, [Table S2\)](#page-17-2). For the significant eQTLs tested but unsupported by ASE, low power in the ASE analysis where only heterozygous donors were tested may have masked their significant detection in the ASE data. Also, the eQTLs supported by ASE sites were highly concordant in effect size and direction [\(Figure 2B](#page-6-0)), providing further confidence in the identified allelic effects on gene expression.

Comparing cell-type-specific eQTLs to bulk eQTLs

We aimed to determine the utility of our cell-type-specific eQTL study by comparison to pre-existing bulk brain eQTL studies. Comparing our results to a bulk fetal cortical

wall eQTL dataset from a previous study using a partially overlapping set of donors, 19 we observed that 26.2%/45% of progenitor/neuron conditionally independent eSNPeGene pairs were shared with the fetal bulk eQTL using the LD-based overlap [\(Figure S5A](#page-17-2); odds ratio test between cell type sharing with fetal bulk: p value: 6.5×10^{-25}). 45.9%/67.1% of progenitor/neuron primary eSNP-eGene pairs were also detected in the fetal bulk eQTLs ([Figure 2](#page-6-0)C, m -value > 0.9 indicates shared effects; odds ratio test between cell type sharing with fetal bulk: p value: $2.47 \times$ 10^{-27}). Also, the fraction of progenitor/neuron primary eSNP-eGene pairs that were true associations (π_1) in fetal bulk eQTLs were 74.9%/92% when subset to gene-SNP pairs that were detectable in both datasets ([Figure 2D](#page-6-0); see [Figure S5B](#page-17-2) for results with imputed missing eSNP-eGene pairs). Taken together, our observations show that although many genetic effects on gene expression are observed in both bulk and cell-type-specific eQTL data, novel regulatory mechanisms can be identified using cell-type-specific eQTLs, especially in progenitors, which can provide additional information beyond existing prenatal datasets.¹⁸⁻²⁰

We next explored the temporal specificity of cell-typespecific eQTLs by utilizing adult brain bulk cortical eQTL data from the GTEx project.^{[25](#page-18-9)} We observed $18.9\%/28.3\%$ of conditionally independent eSNP-eGene pairs in progenitors and neurons, respectively, were also found in adult brain eQTL data (LD-based overlap; [Figure S5](#page-17-2)C). That suggests substantial independent genetic mechanisms regulating genes from development to adulthood, as observed previously[.20](#page-18-19)

Cell-type-specific splicing quantitative trait loci (sQTL)

Given the previously known impact of genetic variation on alternative splicing, $9,11,19,94$ $9,11,19,94$ $9,11,19,94$ $9,11,19,94$ we next performed a splicing quantitative loci (sQTL) analysis separately within progenitors and neurons. We quantified alternative intron excisions as percent spliced in (PSI) by implementing the LeafCutter software, an annotation free approach that al-lows for discovery of novel isoforms.^{[59](#page-19-26)} We found $35,238$ and 36,070 intron excisions present more often in progenitors and neurons, respectively ($|log2FC| > 0.5$, see [Material](#page-1-0) [and methods,](#page-1-0) [Table S3\)](#page-17-2). As a specific example, we found a differential alternative splicing site within the DLG4 (MIM: 602887) encoding the postsynaptic density protein 95 (PSD-95). An exon skipping splice site supporting nonsense-mediated decay (splice 1, ENST00000491753) was upregulated in progenitors; while another splice site supporting multiple protein coding transcripts (splice 2) was upregulated in neurons ([Figure 3A](#page-11-0)). Post-transcriptional repression of PSD-95 expression in neural progenitors via nonsense mediated decay at splice site 1 has been previously experimentally validated, $95,96$ $95,96$ giving strong confidence in the cell-type-specific splicing calls.

For the sQTL analysis, we implemented an association test between PSI of each intron excision and genetic variants located within a ± 200 kb window from the start and end of the splice junctions [\(Figures 1A](#page-3-0) and [3](#page-11-0)B). We retained significant associations which were lower than 5% false discovery rate by implementing a hierarchical multiple testing correction (see [Material and methods\)](#page-1-0) and applied conditional analysis to identify independent sQTLs [\(Figures S3A](#page-17-2) and [S6](#page-17-2)A–S6C). We identified 4,568 intron excisions associated with 5,900 conditionally independent sSNPs-intron junction pairs in progenitors and 3,870 intron excisions associated with 4,396 conditionally independent sSNPs-intron junction pairs in neurons ([Figure S6](#page-17-2)D, [Table S3\)](#page-17-2). Similar to the eQTL analysis, we additionally performed sQTLs using the standard linear model (FastQTL) 61 61 61 followed by an adaptive permutation, and we detected 79.8%/78.7% of significant introns and 77.3%76.5% of primary sSNP-intron pairs discovered via the LMM approach in progenitor/neuron were also identified using the standard linear model [\(Figure S6E](#page-17-2)).

Regarding the cell-type specificity of sQTLs, we found that 22.4%/30% of progenitor/neuron conditionally independent sSNP-intron junction pairs were shared with other cell types using the LD-based overlap ([Figure S6](#page-17-2)D). 59.4%/ 57.3% of progenitor/neuron primary sSNP-intron junction pairs were shared with m -value > 0.9 ([Figure S7](#page-17-2)A). The fraction of primary progenitor/neuron sSNP-intron junction pairs that are true associations in neuron/progenitor sQTLs (π_1) was 87.3%/85.3% when subsetting to sSNP-intron junction pairs that were detectable in both datasets compared [\(Figure S7](#page-17-2)B). However, this analysis may have overestimated sQTL sharing, because 21.5%/30.2% of progenitor/neuron primary sSNP-intron pairs were not detectable in neuron/progenitor sQTL data, which was a higher missing data rate as compared to eQTLs where 6.3%/11% of progenitor/neuron primary eGene-eSNP pairs were not detectable in neuron/progenitor eQTL data. To account for this, we also computed π_1 accounting for the missing data [\(Figure S7B](#page-17-2)), which suggested substantially more celltype-specific sQTLs.

As an example, we found that the indel variant rs11382548 creating a canonical splice acceptor sequence impacted two different intron excisions supporting alternative 3' splice sites for TMEM216 (MIM: 613277) ([Figure 3C](#page-11-0)). Deletion of the A nucleotide at a canonical splice acceptor site of the last exon of TMEM216 leads to disruption of the alternative splicing event for transcript ENST00000334888 and increased usage of transcript ENST00000398979 and ENST00000515837 in both progenitors and neurons. This sQTL may be relevant to neurogenesis because knockdown of the TMEM216 reduces division of both apical and intermediate progenitor cells during corticogenesis.^{[97](#page-21-8)}

Interestingly, many splice sites were previously unannotated in the gene models we used (Ensembl Release 104). We detected $8.2\%/10.6\%$ cryptic at the 5' end, $11.4\%/$ 11.5% cryptic $3'$ end, and $8.8\%/10.8\%$ cryptic at both ends for significant intron excisions within progenitors/ neurons.

Leveraging RNA binding sites of 172 RNA-binding proteins in total from CLIP-seq databases, 60 we also found

Figure 3. Cell-type-specific sQTL analysis

(A) Differential splicing of two intron junctions within DLG4. Splice 1 (chr17:7,191,358–7,192,945) supports a previously validated nonsense-mediated decay transcript (ENST00000491753) with higher expression in progenitors, whereas splice 2 (chr17:7,191,358– 7,191,893) has higher expression in neurons.

(B) A schematic illustrating splicing QTL mapping. Association of variants locating within 200 kb distance from each end of intron junctions were tested. The T allele is associated with more frequent splicing of the shorter intron junction.

(C) Two intron junctions supporting an alternative 3' splicing site for TMEM216 regulated by variant rs11382548 located at the splice site. The regional association of variants to two introns is shown in the genomic tracks on the left colored by pairwise LD r^2 relative to variant rs11382548, association p values on the y axis, and genomic location of each variant on the x axis. Dashed line indicates significance threshold. Gene model of TMEM216 is shown in the upper right with the position of the variant rs11382548 (closest variant to the splice site), green box indicates the splice site. Boxplots in the lower right show quantile normalized PSI values for splice 1 (chr11:61,397,975–61,398,261) and splice 2 (chr11:61,397,975–61,398,270) at variant rs11382548.

(D) Enrichment of cell-type-specific sSNPs within RNA-binding protein (RBP) binding sites based on a CLIP-seq dataset. The significantly enriched RBPs based on -log10(enrichment p value) are listed on the y axis, and the x axis shows the effect size from enrichment test with 95% upper and lower confidence interval, where data points colored by -log10(p value) from the enrichment test and cell-typespecific RBPs are colored with purple for progenitors at the left, and as green for neuron at the right.

(E) Overlap percentage of cell-type-specific sSNP-intron junction pairs shared with fetal bulk sQTLs for progenitors and neurons at mvalue > 0.9 . Odds ratio (OR) test p values are shown.

that 37 RNA-binding proteins were enriched in progenitor sQTLs and 23 RNA binding proteins were enriched in neuron sQTLs^{[60](#page-19-27)} ([Figure 3D](#page-11-0), [Table S3\)](#page-17-2). Strikingly, 24 and 10 of these RNA-binding proteins were specifically enriched in progenitor- and neuron-specific sQTLs, respectively. Among RBP binding sites specifically enriched for progenitor sQTLs, we found TARDBP, prominently ex-pressed in neural progenitors^{[98](#page-21-9)} and known to play a role in neural progenitor proliferation.^{[99](#page-21-10)} In neurons, we detected enrichment of the EZH2 which regulates neuronal differentiation.^{[100](#page-21-11)} These observations suggest that sQTLs interfere with the binding sites of RBPs that play celltype-specific splicing roles during neural development.

To determine whether variants associated with alternative splicing also alter expression of the same genes, we compared cell-type-specific sQTLs with cell-type-specific eQTLs. Only 16.6% and 5.8% of sGenes, the genes that harbor intron excisions, were also eGenes for progenitors and neurons eQTLs, respectively [\(Figure S7](#page-17-2)C, upper panel). Furthermore, we also found that only 2.8% and 1.3% of conditionally independent sSNP-sGene pairs overlapped (pairwise LD $\mathbb{R}^2 > 0.8$) with conditionally independent eSNP-eGene pairs for progenitors and neurons, respectively [\(Figure S7](#page-17-2)C, lower panel). Also, we found that 5.9%/4.4% of progenitor/neuron primary sSNP-sGene pairs were shared with progenitor/neuron eQTLs with the *m*-value > 0.9 , and the fraction of progenitor/neuron primary sQTLs that are true associations in progenitor/ neuron eQTLs (π_1) was 45%/43% when subsetting to SNP-Gene pairs that were detectable in both datasets. These results indicate that sQTLs generally function through independent mechanisms from eQTLs.

We next examined whether cell type specificity provides additional identification of sQTLs beyond what has previously been detected with bulk RNA-seq. 37.2%/42% of progenitor/neuron sSNP-intron junction pairs were also de-tected in the fetal bulk sQTLs [\(Figure 3](#page-11-0)E, m -value > 0.9 indicates shared effects; odds ratio test between cell type sharing with fetal bulk: p value: 1.5×10^{-8} , see [Figure S7](#page-17-2)D for LD-based overlap for conditionally indepen-dent sSNP-intron junction pairs and [Figure S7](#page-17-2)E for π_1 based overlap). A smaller overlap of progenitor sQTLs with bulk cortical fetal tissue as compared to neuron sQTLs indicated that our cell-type-specific model system allowed for novel discovery of progenitor sQTLs. Also, we found 5.8%/7% of conditionally independent sSNP-intron junction pairs in progenitors and neurons, respectively, were shared with adult brain bulk cortical sQTL data from $GTEx^{25}$ $GTEx^{25}$ $GTEx^{25}$ (LD-based overlap; [Figure S7](#page-17-2)F), showing temporal specificity of cell-type-specific sQTLs.

Using cell-type-specific e/sQTLs to propose regulatory mechanisms of brain-related GWASs

We sought to explain the regulatory mechanism of individual loci associated with neuropsychiatric disorders, brain structure traits, and other brain-relevant traits by leveraging genetic variants regulating cell-type-specific gene expression and splicing. We co-localized GWAS loci of these traits with cell-type-specific eQTLs and sQTLs using a conditional analysis to ensure the loci were shared across traits^{[67](#page-20-4)} (see [Material and methods](#page-1-0) for the list of GWASs used for this analysis).

We discovered 41, 13, and 20 GWAS loci that co-localized specifically with progenitor eQTL, specifically with neuron eQTLs, or with both cell types, respectively ([Figure 4A](#page-13-0), [Table S4\)](#page-17-2). These observations show that the same genetic variants impact gene expression, neuropsychiatric traits, and brain structure in a cell-type-specific manner. Importantly, 98 trait associated loci-gene pairs (one locus could be associated with multiple different genes) were not found using fetal bulk cortical tissue eQTLs, where tissue heterogeneity may have masked their detection [\(Figure 4](#page-13-0)B).

Next, we leveraged our cell-type-specific chromatin accessibility QTL (caQTL) dataset^{[17](#page-18-5)} together with eQTLs in order to explain the regulatory mechanism underlying GWAS loci associated with brain relevant traits. As a specific example, we found a colocalization of a locus within the CENPW (MIM: 611264) across caQTLs, eQTLs, and GWASs for global surface area (GSA) and for educational attainment (EA) [\(Figure 4C](#page-13-0)). The progenitor index eSNP rs4897179 that was not detected in bulk cortical fetal tissue eQTLs (nominal p value $= 3.26 \times 10^{-7}$ in progenitors, nominal p value $= 0.068$ in neurons, and nominal p value $= 0.26$ in fetal cortical bulk tissue), for the CENPW eGene, was colocalized with variant rs9388490, which is the index SNP for both GSA and EA GWAS (nominal p value $=$ 4.95 \times 10^{-12} in GSA GWAS, and nominal p value = 1.43×10^{-8} in EA GWAS). Also, we found that a SNP (rs9388486) located within a chromatin accessible peak region 107 bp upstream of TSS of the CENPW was colocalized with the index eSNP. We therefore consider rs9388486 as the potential causal variant and noted that the C allele disrupts the motifs of the transcription factors CREM, ATF2, ATF4, and ATF1 [\(Figure 4D](#page-13-0)). CENPW is required for appropriate kinetochore formation and centriole splitting during mitosis, 101 and increased CENPW levels lead to apoptosis in the devel-oping zebrafish central nervous system.^{[102](#page-21-13)} Overall, these observations propose a cell-type-specific mechanism whereby the C allele at variant rs9388486 disrupts transcription factor binding and diminishes accessibility at the CENPW promoter, resulting in decreased CENPW expression levels in progenitors ([Figures 4](#page-13-0)E and 4F), presumably altering neurogenesis or reducing apoptosis, leading to increased cortical surface area and higher cognitive function.

We also aimed to examine cell-type-specific splicing QTLs colocalized with GWAS loci. We observed 29, 20, and 34 GWAS loci in total that co-localized with specifically progenitor/neuron sQTLs and sQTLs present in both cell types [\(Figure 5A](#page-14-0), [Table S4](#page-17-2)). Similar to eQTL colocalizations, we observed that 111 trait-associated loci-intron junction pairs were detected only with cell-type-specific sQTL (one locus could be associated with multiple intron junctions), but not fetal bulk cortical sQTLs [\(Figure 5](#page-14-0)B). Interestingly, we detected a progenitor-specific sSNP (rs1222218) regulating a novel alternative exon skipping event for ARL14EP (MIM: 612295) was colocalized with a SCZ index SNP $(rs1765142)^1$ $(rs1765142)^1$ $(rs1765142)^1$ [\(Figure 5C](#page-14-0)). The risk allele for SCZ led to more frequent skipping of the exon, supporting expression of a novel isoform [\(Figures 5](#page-14-0)D and 5E). The cryptic splice junction has been previously discovered in

Figure 4. Colocalization of cell-type-specific eQTLs with GWAS for brain-related traits

(A) Number of GWAS loci colocalized with progenitor (purple)- or neuron (green)-specific eQTLs or both cell types (orange). Each GWAS trait is listed on the y axis (SA, surface area; TH, thickness).

(B) LD-based overlap of colocalized GWAS loci-gene pairs per trait combinations across progenitor, neuron, and fetal bulk eQTL colocalizations for the traits listed in (A).

(C) Genomic track showing regional association of variants with educational attainment (EA), global surface area (GSA), and CENPW expression in progenitors and neurons, -log10 of association p values on the y axis, and genomic location of each variant on the x axis. Progenitor eSNP rs4897179 (3rd row) was coincident with index SNP (rs9388490) for both EA (1st row) and GSA GWAS (2nd row), and conditioning progenitor eSNP rs4897179 on rs9388490 showed colocalization of the two signals (5th row). Also, rs4897179 was colocalized with another variant (rs9388486) located in the chromatin accessibility peak at the promoter of CENPW (6th and 8th rows). Genomic tracks were color-coded based on LD r^2 relative to the variant rs9388486. Dashed line indicates significance threshold.

(D) Plot showing the chromatin accessibility peak (chr6:126,339,531–126,340,960) in progenitors across different genotypes of rs938848. The C allele of rs9388486 disrupted binding motifs of transcription factors including CREM, ATF1, ATF2, and ATF4.

(E) Boxplots showing chromatin accessibility across rs9388486 genotypes in progenitors (purple) and neurons (green) (top). Boxplots showing VST normalized CENPW expression across rs9388486 genotypes in progenitors (purple), neurons (green), and fetal bulk (blue) (bottom).

(F) A schematic showing that one or more of the implicated transcription factors (TF) has decreased preference to bind at the C allele, which results in lower CENPW expression, increase in global surface area, and educational attainment.

Figure 5. Colocalization of cell-type-specific sQTLs with GWAS for brain-related traits

(A) Number of GWAS loci colocalized with progenitor (purple)- or neuron (green)-specific sQTLs or both cell types (orange). Each GWAS trait is listed on the y axis (SA, surface area; TH, thickness).

(B) LD-based overlap of colocalized GWAS loci-intron junction pairs per trait across progenitor, neuron, and fetal bulk sQTL colocalizations for the traits listed in (A).

(C) Genomic tracks color-coded based on pairwise LD r^2 relative to the variant rs1222218 showing regional association of variants with SCZ and an unannotated alternative splicing event for ARL14EP in progenitors and neurons, association p values on the y axis, and genomic location of each variant on the x axis. A cryptic exon skipping splice site (chr11:30,323,202–30,332,866) was associated with progenitor sSNP (rs1222218) colocalized with SCZ GWAS index SNP (rs1765142). Dashed line indicates significance threshold. (D) Sashimi plots with the gene model of ARL14EP and the genomic position of the unannotated splice site (blue) overlapping with AR-L14EP. Average INT normalized PSI values for the splice site are shown for each genotype group. Schizophrenia risk allele G increases the frequency of the exon skipping event in progenitors.

(E) Boxplots showing INT normalized PSI values for splice across rs1222218 genotypes in progenitors and neurons.

GTEx within a variety of tissues including adipose and lung, but not in the adult brain.^{[25](#page-18-9)} ARL14EP has been shown to play a role in axonal development in the mouse neurons.^{[103](#page-21-14)} Here, we propose a novel transcript of this gene with expression in progenitors as a risk factor for SCZ.

Genetic imputation of cell-type-specific GWAS susceptibility genes and alternative splicing

Next, we imputed genes and alternative splicing associated with brain-related traits by integrating the polygenic impact of cell-type-specific regulatory variants with GWAS risk variants in a transcriptome-wide association study (TWAS) approach.^{[78](#page-20-15)} We found $1,703/973$ genes and 6,552/6,578 intron junctions as significantly cis-heritable in progenitors/neurons (heritability p value < 0.01). We found the cis-heritable impact of 124/102 genes and 372/370 intron junctions in progenitor/neuron significantly correlated with at least one brain-related trait ([Table](#page-17-2) [S5](#page-17-2)). Of those significant TWAS genes/introns, we separated conditionally independent genetic predictors from the co-expressed ones and defined them as jointly independent.^{[83](#page-20-20)} We performed cell-type-specific TWASs on both gene expression and splicing for schizophrenia (jointly independent genes: 23/26; jointly independent introns: 65/ 62 in progenitor/neuron), IQ (jointly independent genes: 25/24; jointly independent introns: 42/63 in progenitor/ neuron), and neuroticism (jointly independent genes: 13/15 neuron; jointly independent introns: 39/34 in progenitor/neuron) ([Figures 6A](#page-15-0)–6C and [S8A](#page-17-2)–S8C). Also, we found novel loci not discovered in colocalization analysis per trait, demonstrating the additional power of TWASs compared to a single-marker testing approach.

We evaluated the reproducibility of TWAS results to ensure that the cell type and temporal specificity discovered

- Detected also in GWAS colocalization
- Nearest gene to GWAS locus
- \bullet Nearest gene to GWAS locus detected also in GWAS colocalization Novel discovery using TWAS
- \triangle Increase in gene expression associated with increased disease risk/trait
- □ Decrease in gene expression associated with increased disease risk/trait

Figure 6. Prediction of differential gene expression during human brain development via TWAS

(A) Manhattan plots for schizophrenia, IQ, and neuroticism TWAS for progenitors (purple-gray, top) and neurons (green-gray, bottom) where the LD matrix used was based on a European population. Each dot shows -log10 (TWAS p value) for each gene on the y axis, gene names were color coded based on discovery also in colocalization analysis (orange), defined as the nearest gene to GWAS locus (dark pink), being in both these two categories (blue), and discovered only in TWAS analysis (black). Only joint independent genes are labeled (positively and negatively correlated genes represented by triangle and square, respectively, and red line used for TWAS significant threshold).

(B) Manhattan plots for IQ TWAS, as described in (A).

(C) Manhattan plots for neuroticism TWAS, as described in (A).

(D) IQ TWAS results for B3GALNT2, regional association of variants to IQ trait shown at the top, and statistics from each TWAS study shown at the bottom (red line used for genome-wide significant threshold 5×10^{-8}).

were not merely due to the sample size of our cell-type-specific QTL study. We observed that SCZ TWAS results using weights from a smaller sample sized adult brain eQTL data from GTEx (n = 118)^{[62](#page-19-29)} showed a high correlation with TWAS results performed with weights derived from the independent CommonMind Consortium (CMC) adult brain eQTL ($n = 452$), ¹⁴ whereas low correlation was observed between SCZ TWAS with weights derived from adult brain as compared to fetal bulk brain or cell-type-specific eQTL data ([Figure S9A](#page-17-2)). Similarly, SCZ TWAS results with weights calculated from two fetal bulk eQTL datasets down-sampled to the size of progenitor ($n = 85$) and neuron ($n = 74$) datasets showed a high correlation indicating that reproducible TWAS is achievable in these sample sizes ([Figure S9](#page-17-2)B). These results provide evidence that the limited size of our study

was not the major driver for the observed cell-type- and temporal-specific TWAS results. Also, despite the difference in population structure between our dataset and European neuropsychiatric GWASs, we observed that TWAS genes/introns were highly overlapped when different LD estimates were used [\(Figure S10](#page-17-2)A).

We next compared our cell-type-specific TWAS approach to TWAS analyses performed using weights calculated from bulk cortical fetal tissue¹⁹ and adult brain e/sQTLs from the CMC. 14,83 14,83 14,83 Most TWAS findings were specific to a cell type or temporal e/sQTL dataset, rather than broadly detected, indicating that different developmental or cell type e/sQTL datasets contribute complementary information about genes influencing risk for neuropsychiatric disorders or other brain traits ([Figure S10](#page-17-2)B and [Table S5](#page-17-2) for

comparison). As an example, despite IQ GWASs falling short of the genome-wide significance threshold at B3GALNT2 (MIM: 610194) locus, we detected that genetically imputed B3GALNT2 expression was significantly correlated with IQ in progenitors, but not in neuron, fetal bulk tissue or in CMC adult brain tissue ([Figure 6](#page-15-0)D). Mutations in the B3GALNT2 play a role in glycosylation of α -dystroglycan and were associated with intellectual disability in individuals with congenital muscular dystrophy (MDDGA1 [MIM: 615181]). 104 104 104 Overall, here we showed that an increase in B3GALNT2 expression in progenitors is associated with lower IQ, suggesting this gene's early cell-type-specific impact on cognitive function.

Within the cell-type-specific splicing TWAS, we found an intron junction of MRM2 (MIM: 606906) more frequently spliced that was associated with increased risk for schizophrenia specifically in progenitor cells (TWAS-Z: 6.54), but it was not significantly cis-heritable within neuron, fetal bulk, or adult bulk data ([Figure S10](#page-17-2)C). MRM2 is a mitochondrial rRNA methyltransferase, 105 and was found to be associated with intellectual disability^{[106](#page-21-17)} and mitochon-drial encephalopathy (MELAS [MIM: 540000]).^{[105](#page-21-16)} We propose a cell-type-specific developmental basis for alternative splicing of the MRM2 associated with risk for schizophrenia.

Discussion

Here, we investigated the influence of genetic variation on brain-related traits within a cell-type-specific model system recapitulating a critical time period of human brain development, neurogenesis. Our analysis discovered features of gene regulation that will be complementary to previous eQTLs and sQTLs identified in bulk human brain in that: (1) we identified thousands of novel eQTLs, ASEs, and sQTLs during brain development that are enriched in regulatory elements present during neurogenesis; (2) most e/ sQTLs in progenitors/neurons were not identified in previous fetal bulk post-mortem tissue datasets using LD-based overlap indicating the importance of cell type specificity for identifying genetic influences on gene regulation; (3) using this resource, we are able to propose cell-type-specific variant-gene/transcript-trait(s) pathways to further explore molecular and developmental causes of neuropsychiatric disorders; (4) by integrating the polygenic effects across traits and gene expression, we are able to impute celltype-specific gene expression/alternative splicing dysregulation in individuals with neuropsychiatric disorders in time periods prior to disease onset.

As one example of a cell-type-specific variant-gene-trait pathway, we discovered a locus near the CENPW colocalized across cell-type-specific caQTL, eQTL, brain size, and cognitive function. Through the integration of multiomic gene-to-trait databases, we hypothesize that the C allele at rs9388486 leads to decreased TF binding of up to four transcription factors (ATF1/2/4, CREM) in progenitors, resulting in decreased chromatin accessibility at the promoter peak, decreased expression of CENPW, leading to increased cortical surface area, and increased cognitive function. CENPW has a strong role in proliferation, as it is required for kinetochore formation during mitosis. 107 This is consistent with progenitor proliferation influencing surface area, as described in the radial unit hypothesis. 108 Increased levels of CENPW may cause death of progenitor cells either by directly being an apoptotic inducer or by triggering apoptosis in response to an imbalance in cell ho-meostasis with excessive mitotic activity.^{[102](#page-21-13)} In all, we demonstrate how integration across multi-level biological data can be used to propose functional mechanisms underlying complex traits, and future studies may be able to develop computational models to propose causal pathways across multi-omic QTL data.^{[9](#page-18-20),[109,](#page-21-20)[110](#page-21-21)} Such information will be crucial to both design efficient functional validation experiments as well as to leverage GWAS loci to advance treatment targets for neuropsychiatric disorders.

Though the most commonly proposed regulatory mechanism by which non-coding genetic variation influences complex traits is through gene expression levels, 91 our data also support mechanisms by which genetic variants associated with cell-type-specific alternative splicing influence complex brain-relevant traits. Importantly, we observed sQTLs impacting previously unannotated celltype-specific alternative splicing events that are also colocalized with brain-relevant GWASs. For example, we found a progenitor-specific sSNP regulating one unannotated exon skipping splice site for the ARL14EP also colocalized with an index SNP for schizophrenia GWAS, indicating a developmental molecular pathway contributing to schizophrenia risk.

Our cell-type-specific TWAS analysis identified that alteration in expression of multiple genes and transcripts are associated with risk for different neuropsychiatric conditions. We followed a unique TWAS approach allowing us to explore cell type and temporal specificity by leveraging existing fetal brain bulk and adult e/sQTLs together with the cell-type-specific data we generated here. This type of analysis allows the imputation of the genetically regulated component of differential expression within cell types years prior to disease onset. As such, it allows the knowledge of gene expression differences that cannot be gained from post-mortem tissue of affected individuals versus control subjects, which must be acquired after diagnosis. This window into developmental gene expression differences may be particularly important to understand disease risk, as these results are not subject to confounding by medication use or the altered experiences of the environment of individuals living with a neuropsychiatric illness.^{[111](#page-21-22)} Nevertheless, further support for such data could be gained from iPSC lines modeling early developmental time periods from large populations of affected individuals versus control subjects.

With our cell-type-specific model, we propose how and when genetics influence brain-related traits through gene expression and splicing. The sample size of our study

 $(n = 89$ independent donors) is consistent with other previously published cell-based QTLs, 21,24,112,113 21,24,112,113 21,24,112,113 21,24,112,113 21,24,112,113 21,24,112,113 and cell-type resolution may have led to novel and higher powered eQTL discovery masked in bulk tissue. However, it is also possible that the novel loci identified here contain false positives due to relatively low sample size as compared to post-mortem datasets $19,114$ $19,114$ or are caused by *in vitro* cell culture artifacts. eGenes identified in this study are not enriched in genes with low fidelity in our in vitro system, nevertheless the replication of the cell-type-specific study using scRNA-seq from developing fetal brain tissue or cell-type-specific iPSC-derived eQTL datasets^{[24](#page-18-21)[,115](#page-21-26)} of independent donors derived from a multi-ancestry population will be crucial to mitigate these concerns. This in vitro system has particular utility in that, in the future, it may be used to determine the impact of genetic variation in response to activation of specific pathways or response to environmental stimuli. 23 By pursuing cell type, temporal, and environmental specificity of eQTLs, we expect that a greater degree of mechanisms underlying risk for neuropsychiatric disorders and brain-relevant traits can be uncovered.

Data and code availability

Data will be available within dbGaP upon publication with study accession number phs002493.v1.p1, and code is available at [https://bitbucket.org/steinlabunc/](https://bitbucket.org/steinlabunc/expression_splicing_qtls_public/src/master/)

[expression_splicing_qtls_public/src/master/](https://bitbucket.org/steinlabunc/expression_splicing_qtls_public/src/master/).

Supplemental information

Supplemental information can be found online at [https://doi.org/](https://doi.org/10.1016/j.ajhg.2021.07.011) [10.1016/j.ajhg.2021.07.011](https://doi.org/10.1016/j.ajhg.2021.07.011).

Acknowledgments

This work was supported by NIH (R00MH102357, U54EB020403, R01MH118349, R01MH120125), Brain Research Foundation, and NC TraCS Pilot funding to J.L.S. D.H.G. was supported by NIH (R37 MH060233, R01 MH094714, UO1MH116489, and R01 MH110927). The following core facilities were utilized for this project: UNC Neuroscience Center Microscopy Core (P30NS045892), UNC Mammalian Genotyping Core, CGIBD Advanced Analytics Core (NIH grant P30 DK034987), UNC Flow Cytometry Core Facility, UNC Vector Core, and UNC Research Computing. Additional core facilities utilized for this project were: UCLA CFAR (5P30 AI028697) and the UCLA Neuroscience Genomics Core. We thank Dr. Karen L. Mohlke and Dr. Yun Li for helpful comments, Dr. Eric Wexler for the idea of the phNPC eQTL, and Dr. Stephen Montgomery for clarifying the eigenMT method.

Declaration of interests

The authors declare no competing interests.
