Nonalcoholic fatty liver disease (NAFLD) represents a spectrum of chronic liver disease ranging from simple steatosis (NAFL) to nonalcoholic steatohepatitis (NASH). However, the molecular mechanisms of NASH progression remain incompletely understood. White adipose tissue (WAT) has emerged as an important endocrine organ and contributes not only to the initial stage of NAFLD, but also to its severity. In the current study, through transcriptomic analysis we identified increased expression of Sparcl1, a secreted glycoprotein, in the WAT from NASH mice. Plasma Sparcl1 levels were similarly elevated and positively correlated with hepatic pathological features in NASH patients. Functional studies showed that both chronic injection of recombinant Sparcl1 protein and overexpression of Sparcl1 exaggerated hepatic inflammation and liver injury in mice. In contrast, genetic ablation of *Sparcl1*, knockdown of Sparcl1 in WAT, and treatment with a Sparcl1-neutralizing antibody dramatically alleviated diet-induced NASH pathogenesis. Mechanistically, Sparcl1 promoted the expression of C-C motif chemokine ligand 2 (CCL2) in hepatocytes through binding to Toll-like receptor 4 (TLR4) and activation of the NF-**κ**B/p65 signaling pathway. Genetically or pharmacologically blocking the CCL2/CCR2 pathway attenuated the hepatic inflammatory response evoked by Sparcl1. Thus, our results demonstrated an important role for Sparcl1 in NASH progression, suggesting a potential target for therapeutic intervention.

Introduction

In the past decade, the prevalence of obesity has substantially increased in both the adults and children (1) due to rapid changes in lifestyle. Obesity is associated with high risk for many metabolic disorders, such as type 2 diabetes mellitus, nonalcoholic fatty liver disease (NAFLD), and hyperlipidemia. NAFLD comprises a spectrum of liver conditions ranging from simple steatosis (NAFL) to the more serious nonalcoholic steatohepatitis (NASH) (2, 3). Although NAFL is considered benign, 10%–20% of patients can progress to NASH, which has become the most rapidly growing indication for liver transplantation in the United States ([4\)](#page-14-0).

A hallmark of NASH is the prominent hepatic inflammatory response [\(5](#page-14-1), [6](#page-14-2)). Animal studies have shown that inflammation in hepatocytes is an important link between the initial metabolic stress and subsequent hepatocyte death, liver injury, and fibrogenesis in NASH [\(7\)](#page-15-0). In particular, while patients with simple steatosis

exhibit a benign clinical course, hepatic inflammation and its main consequence, fibrosis, is a key determinant of long-term adverse outcomes [\(8,](#page-15-1) [9\)](#page-15-2). Nevertheless, the cellular and molecular mechanisms underlying the activation of hepatic inflammation remain largely unknown. One of the key factors in hepatocytes is the membrane protein Toll-like receptor 4 (TLR4) (10), which functions as a receptor for endotoxins such as lipopolysaccharide (LPS) (11). However, abundance of these endogenous ligands is already elevated at the NAFL stage. LPS levels in plasma and hepatocytes were higher in patients with NAFL or NASH and correlated with NF-κB activation, as compared with normal subjects (12). However, no difference was found between patients with NAFL and NASH (12). In addition, another study showed a positive association between LPS-binding protein and hepatic fat deposition, but not with the severity of lobular inflammation or fibrosis (13). These direct and indirect pieces of evidence strongly suggest that molecules or proteins that selectively activate TLR4 signaling during NASH progression remain to be identified.

One of the key risk factors for obesity-associated diseases is attributed to the expansion of white adipose tissue (WAT). Decades of studies have established WAT not only as an inert energy-storage site, but also as a major endocrine organ with metabolic regulatory roles. WAT dynamically participates in the pathogenesis of all aspects of NAFLD through release of fatty acids, proinflammatory cytokines, and multiple polypeptides

1

(14, 15). These polypeptides are collectively termed adipokines, with multipotent physiological and pathophysiological effects on chronic liver diseases (14–16). Among them, leptin and adiponectin are the best-studied adipokines that are associated with the development and progression of NAFLD (17). It has been reported that plasma leptin levels were higher in NASH patients than those in NAFL patients or controls (18, 19), while hypoadiponectinemia correlated with the severity of liver pathology in NASH (20, 21). In addition, adipose tissue–expressed neuregulin 4 (Nrg4) can protect hepatocytes from cell death, thereby attenuating diet-induced NASH in mice (22). As such, identification of novel adipokines in NASH progression may help to reveal its molecular mechanisms and provide a potential therapeutic strategy for treatment.

In the present study, through transcriptomic analysis we found that secreted protein acidic and rich in cysteine-like protein 1 (Sparcl1) is upregulated in the WAT of diet-induced NASH mouse models. More importantly, elevated plasma Sparcl1 levels correlated with severity of NASH in a human cohort. Sparcl1 is a secreted glycoprotein belonging to a large family of matricellular proteins. It is implicated in the regulation of cell proliferation and migration, by which it regulates embryogenesis, tissue remodeling, and tumorigenesis (23, 24). This family also includes several other molecules, including Sparc, thrombospondin 1 and 2, osteopontin, and tenascin C and X, which have been linked to the development of insulin resistance, chronic liver diseases, and diabetic retinopathy and nephropathy (25–28). However, whether Sparcl1 plays a role in obesity-associated metabolic abnormalities has not yet been explored.

Results

Construction of mouse models for NAFL and NASH. Murine dietary models of NAFLD/NASH widely vary in their effects. Although many models exhibit hepatic lipid accumulation, their histological appearance may not resemble human NASH (3). C57BL/6J mice usually do not develop steatohepatitis or fibrosis on a high-fatdiet (HFD), while mice fed a methionine- and choline-deficient diet lose rather than gain weight and are not insulin resistant (3). Therefore, these mouse models might not be appropriate for the study of obesity-associated NASH. Recent studies described that long-term consumption of HFD additionally containing high fructose and high cholesterol (HFHC diet) can induce obesity, hepatic steatosis, and liver inflammation and injury, which appears to closely resemble human NASH (22, 29). Thus, C57BL/6J male mice were fed a normal chow diet or HFHC diet for 2 different periods: 12 weeks and 28 weeks [\(Supplemental Figure 1](https://www.jci.org/articles/view/144801#sd)A; supplemental material available online with this article; https://doi. org/[10.1172/JCI144801DS1](https://doi.org/10.1172/JCI144801DS1)). Compared with mice fed a normal chow diet, mice fed an HFHC diet for 12 weeks developed obesity and liver steatosis [\(Supplemental Figure 1,](https://www.jci.org/articles/view/144801#sd) B–E). However, plasma levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST), two markers of liver injury, were unaffected [\(Supplemental Figure 1,](https://www.jci.org/articles/view/144801#sd) F and G). mRNA levels of the majority of genes involved in hepatic inflammation and liver fibrosis were unaltered ([Supplemental Figure 1H](https://www.jci.org/articles/view/144801#sd)). In agreement, staining of F4/80, a unique marker of murine macrophages, was comparable between the 2 groups of mice ([Supplemental Figure](https://www.jci.org/articles/view/144801#sd) [1I](https://www.jci.org/articles/view/144801#sd)). In addition, we compared HFHC mice with HFD mice at the

same age, as described in our previous studies (30, 31). We found that body weight, hepatic triglyceride (TG) content, and mRNA expression levels of lipogenic genes were comparable between these 2 obesity models (data not shown). These results suggest that mice fed a 12-week HFHC diet may have similar hepatic metabolic changes to those of HFD mice at the same age.

On the other hand, in addition to the exaggerated body weight, liver/body weight ratio, and hepatic TG retention ([Supplemental](https://www.jci.org/articles/view/144801#sd) [Figure 2](https://www.jci.org/articles/view/144801#sd), A–D), mice fed an HFHC diet for 28 weeks exhibited higher plasma ALT and AST levels ([Supplemental Figure 2,](https://www.jci.org/articles/view/144801#sd) E and F). Moreover, F4/80 staining and expression of genes related to hepatic inflammation and liver fibrosis were significantly upregulated ([Supplemental Figure 2](https://www.jci.org/articles/view/144801#sd), G and H). These observations indicate that short-term feeding (12 weeks) of HFHC diet may induce simple steatosis (NAFL) in mice, whereas long-term feeding (28 weeks) can cause NASH.

Identification of Sparcl1 as a WAT-secreted protein in NASH mice. WAT, especially visceral adipose tissue (vAT), has been considered a crucial contributor to NAFLD development through multiple mechanisms (32). Classically activated proinflammatory macrophages during vAT expansion may influence systemic insulin sensitivity and hepatic inflammation through delivery of inflammatory mediators. Moreover, white adipocytes are capable of secreting not only fatty acids but also a class of secretory proteins that modulate the homeostasis of distant organs, including the liver (16, 17, 33). To identify potential WAT-enriched secretory factors involved in NASH progression, we firstly compared the expression profile of epididymal WAT (eWAT) from mouse models of NAFL and NASH mentioned above by RNAsequencing (RNA-Seq) analysis ([Supplemental Figure 3](https://www.jci.org/articles/view/144801#sd)A). Then, using a *P* value of 0.05 and fold change greater than 1.5 as cutoff points, we undertook intersection analysis of the 2 groups of dysregulated genes (differentially expressed genes, DEGs). While 392 genes were dysregulated in both mouse models, a total of 823 and 1420 genes were selectively dysregulated in the eWAT of NAFL and NASH mice, respectively (Figure 1, A and B, and [Supplemental Table 1\)](https://www.jci.org/articles/view/144801#sd). Functional enrichment analysis showed that many DEGs in NASH mice were enriched in extracellular matrix remodeling (Figure 1C), indicating the disorganization of basement membrane components in obese adipose tissues, as described previously (34).

Then, these 1420 DEGs in NASH mice were compared with a previously published mouse cytokine database (GSE10246, NCBI Gene Expression Omnibus), which contains a set of mouse genes predicted to carry an encoded signal peptide for secretion. As a result, 54 cytokines were increased and 64 cytokines were decreased in the eWAT of NASH mice (Figure 1, D and E). We observed downregulation of Nrg4 (Figure 1E), a newly identified adipokine, which is consistent with the results from a recent study (22). In addition, we observed upregulation of Sparc (Figure 1D). Sparc expression has been shown to be predominant in adipose tissues and correlated with fat mass in humans (35). Animal studies confirmed that abnormal expression of Sparc plays an important role in metabolic disorders and hepatic injury (25, 36). The downregulation of Nrg4 and upregulation of Sparc in the NASH group were further confirmed by quantitative real-time PCR (qRT-PCR) analysis [\(Supplemental Figure 3](https://www.jci.org/articles/view/144801#sd)B). Interestingly, we

found that *Sparcl1*, a member of the Sparc family (23), was also increased (Figure 1D). Analysis by the cytoHubba plugin in Cytoscape also showed that Sparcl1 was involved in the top hub genes ([Supplemental Figure 3](https://www.jci.org/articles/view/144801#sd)C). Moreover, we found a correlation between Sparcl1 and the DEGs as illustrated by MCODE (Molecular Complex Detection) based on the PPI (protein-protein interaction) network [\(Supplemental Figure 3](https://www.jci.org/articles/view/144801#sd)D). Collectively, these results suggest that *Sparcl1* might be a candidate gene that exerts a pathogenic effect on the development of NASH.

Examination of the Sparcl1 expression pattern revealed that *Sparcl1* mRNA was enriched in inguinal WAT (iWAT), eWAT, and brown adipose tissue (BAT), whereas its expression in other organs such as the liver and kidney was relatively low ([Supplemen](https://www.jci.org/articles/view/144801#sd)[tal Figure 4](https://www.jci.org/articles/view/144801#sd)A). Compared with stromal vascular fractions, *Sparcl1* expression was enriched in mature adipocytes ([Supplemental](https://www.jci.org/articles/view/144801#sd) [Figure 4B](https://www.jci.org/articles/view/144801#sd)). Moreover, its mRNA level was highly induced during differentiation of 3T3-L1 white adipocytes along with PPARγ2, an established adipogenic marker [\(Supplemental Figure 4](https://www.jci.org/articles/view/144801#sd)C). Consistent with the RNA-Seq data, our qRT-PCR analysis confirmed that the expression levels of *Sparcl1* in iWAT and eWAT were significantly increased in NASH mice (Figure 1F), but remained unaltered in mice with NAFL (Figure 1G). Interestingly, upregulation of *Sparcl1* was more evident in the iWAT of NASH mice than it was in the eWAT (Figure 1F). Although vAT has been confirmed to be associated with NASH development and progression (14, 15), our findings suggest that more attention should be paid to exploring the role of subcutaneous fat in chronic liver diseases. Furthermore, qRT-PCR revealed 1.42- and 2.17-fold upregulation of *Sparcl1* mRNA levels in the livers of mice with NAFL or NASH, respectively ([Supplemental Figure 4](https://www.jci.org/articles/view/144801#sd)D), suggesting that the liver itself could produce Sparcl1 during development to NASH. In agreement, plasma Sparcl1 concentrations, measured by enzymelinked immunosorbent assays (ELISAs), were also selectively increased in NASH mice (Figure 1H).

Plasma Sparcl1 levels were associated with hepatic pathological features in NASH patients. To determine the clinical relevance of our animal-based observations, plasma Sparcl1 levels were measured in normal individuals and liver biopsy–proven NAFLD patients [\(Supplemental Table 2](https://www.jci.org/articles/view/144801#sd)). Plasma Sparcl1 levels were positively correlated with ALT, AST, and γ-glutamyl transferase (GGT) levels in the overall cohort (Figure 2, A–C), and gradually increased with the steatosis, ballooning, and lobular inflammation (Figure 2, D–F). We further distinguished NAFL and NASH patients according to the fatty liver inhibition of progression (FLIP) algorithm evaluated by a pathologist blinded to clinical data (39, 40). As a result, we also found that plasma Sparcl1 levels were significantly higher in NASH patients compared with normal individuals or NAFL patients (Figure 2G). To further evaluate the potential utility of Sparcl1 as a biomarker for the diagnosis of NASH, the area under the receiver-operating characteristic (AUROC) curve was calculated based on the FLIP algorithm. Plasma Sparcl1 exhibited a high accuracy for distinguishing patients with NASH from NAFLD patients (AUROC = 0.861, *P <* 0.001) and from the overall cohort (AUROC = 0.853, *P <* 0.001; Figure 2, H and I). Moreover, the Sparcl1-ALT-AST model showed an improved accuracy in identifying NASH patients compared with the ALT-AST model (AUC = 0.859 vs. 0.564, *P <* 0.001; Figure 2J).

Acute injection of recombinant Sparcl1 protein activates the hepatic inflammatory response and promotes liver injury in steatotic mice. To study Sparcl1 function in NASH development, male C57BL/6J mice were fed an HFHC diet for 12 weeks to induce liver steatosis as mentioned above, and then intraperitoneally administered with a single treatment of recombinant Sparcl1 protein or vehicle control (saline). A dose of 0.2 mg/kg was chosen for these experiments because this dose can mimic the increased plasma levels of Sparcl1 observed in long-term HFHC diet–induced NASH mice [\(Supple](https://www.jci.org/articles/view/144801#sd)[mental Figure 5A](https://www.jci.org/articles/view/144801#sd)). As a result, acute Sparcl1 treatment led to an increase in plasma ALT and AST levels in HFHC-fed mice ([Sup](https://www.jci.org/articles/view/144801#sd)[plemental Figure 5](https://www.jci.org/articles/view/144801#sd), B and C). Expression of hepatic inflammatory genes was dramatically increased in HFHC-fed mice treated with Sparcl1 [\(Supplemental Figure 5](https://www.jci.org/articles/view/144801#sd)D). Plasma ALT and AST levels and expression of hepatic inflammatory genes were also strongly increased in HFD mice treated with Sparcl1 ([Supplemental Figure](https://www.jci.org/articles/view/144801#sd) [5](https://www.jci.org/articles/view/144801#sd), E–G). However, treatment with Sparcl1 did not induce remarkable changes in the normal mice ([Supplemental Figure 5,](https://www.jci.org/articles/view/144801#sd) H–J). In addition, we found that Sparcl1 expression was not altered in other mouse models with liver injury: alcohol-treated mice ([Supplemen](https://www.jci.org/articles/view/144801#sd)[tal Figure 6,](https://www.jci.org/articles/view/144801#sd) A–F) and carbon tetrachloride–treated $(CCl₄$ -treated) mice [\(Supplemental Figure 6,](https://www.jci.org/articles/view/144801#sd) G–J). Acute Sparcl1 treatment had no additional effect on CCl₄-induced liver injury and inflammatory response ([Supplemental Figure 6](https://www.jci.org/articles/view/144801#sd), K–M). Collectively, these results suggest that Sparcl1 can activate the hepatic inflammatory response in the presence of steatosis, leading to liver injury and elevated expression of hepatic inflammatory cytokines.

Chronic exposure to Sparcl1 promotes hepatic steatosis and inflammation. The hepatic inflammatory response plays a central role in the initiation and progression of NASH [\(5\)](#page-14-1). The finding that liver inflammation was activated in the acute Sparcl1–treated steatotic mice prompted us to explore the effects of chronic exposure to Sparcl1. Therefore, after 12 weeks of HFHC diet feeding, mice were intraperitoneally injected with saline or recombinant Sparcl1 protein (0.2 mg/kg) every other day for 3 weeks (Figure 3A). This treatment did not alter body weight, food intake, or fat content (data not shown). However, chronic exposure to Sparcl1 increased the liver/body weight ratio and hepatic TG content, accompanied with upregulation of lipogenic genes (Figure 3, B–D). Subsequent liver histology showed an increase in lipid accumulation in the livers of Sparcl1-treated mice compared with saline-treated mice (Figure 3E). Chronic Sparcl1 treatment resulted in the accumulation of F4/80-positive macrophages (Figure 3, F and H), indicating enhanced hepatic inflammation. Moreover, hepatocyte death was observed by an increase in TUNEL staining in Sparcl1-treated mice (Figure 3, G and H), which was also reflected by elevated plasma ALT and AST levels (Figure 3I). Plasma concentrations of HMGB1, which is predominantly released from hepatocytes during liver injury (41), were also elevated in Sparcl1-treated mice (Figure 3J). Chronic Sparcl1 treatment also resulted in liver fibrosis, as shown by Sirius red staining and measurement of liver hydroxyproline content (Figure 3, K–M). In addition, mRNA expression of genes related to hepatic inflammation and liver fibrosis was upregulated in the livers of Sparcl1-treated mice (Figure 3N).

To further confirm the pathogenic effects of Sparcl1, we took advantage of adenoviral delivery techniques, which have been shown to efficiently upregulate genes of interest selectively in the WAT of mice (42-44). Given that the upregulation of Sparcl1 was more evident in the iWAT of NASH mice (Figure 1F), adenovirus expressing Sparcl1 (Ad-Sparcl1) or GFP was injected into iWAT of HFHC diet–fed steatotic mice. Forced expression of Sparcl1 in iWAT resulted in a 2.3-fold increase in plasma Sparcl1 levels [\(Supplemental Figure 7](https://www.jci.org/articles/view/144801#sd)A). As a result, Sparcl1 overexpression increased hepatic TG content and plasma levels of liver injury makers in steatotic mice ([Supplemental Figure 7](https://www.jci.org/articles/view/144801#sd), B–E). Abundance of F4/80-positive macrophages was increased accompanied with upregulation of genes involved in hepatic inflammation ([Sup](https://www.jci.org/articles/view/144801#sd)[plemental Figure 7](https://www.jci.org/articles/view/144801#sd), F and G). Consistently, hepatic hydroxyproline content, Sirius red staining, and mRNA expression of genes related to fibrosis were enhanced in Ad-Sparcl1–expressing mice [\(Supplemental Figure 7,](https://www.jci.org/articles/view/144801#sd) H–J). Taken together, our findings clearly demonstrate that chronic exposure to Sparcl1 could accelerate the pathogenesis of NASH in the presence of steatosis.

Sparcl1 activates the hepatic inflammatory response through induction of CCL2. To elucidate the molecular basis of Sparcl1-

mediated NASH progression, we conducted RNA-Seq analysis for DEGs using the livers of chronic recombinant Sparcl1 protein– or saline-treated mice ([Supplemental Figure 8A](https://www.jci.org/articles/view/144801#sd)). We found that 1888 genes were upregulated and 624 genes were downregulated (fold change > 1.5, *P <* 0.05; [Supplemental Table](https://www.jci.org/articles/view/144801#sd) [3](https://www.jci.org/articles/view/144801#sd)). Among them, we identified a pronounced overexpression of CCL2, a member of the C-C chemokine family, in the livers of Sparcl1-treated mice ([Supplemental Figure 8](https://www.jci.org/articles/view/144801#sd)B). The increased expression of CCL2 in the livers and plasma was confirmed by qRT-PCR and ELISA analysis (Figure 4, A–C). In agreement, compared with normal or NAFL patients, plasma CCL2 concentrations were significantly increased in NASH patients (Figure 4D) and correlated with ALT, AST, and GGT levels (Figure 4, E–G). Importantly, plasma Sparcl1 and CCL2 levels were positively correlated in humans (Figure 4H). We examined this further in Hepa1-6 cells, in which Sparcl1 alone failed to induce CCL2 expression but did so in the presence of palmitate [\(Sup-](https://www.jci.org/articles/view/144801#sd) [plemental Figure 8,](https://www.jci.org/articles/view/144801#sd) C–E). However, preincubation with palmitate did not induce an inflammatory response or CCL2 expression in Hepa1-6 cells [\(Supplemental Figure 8,](https://www.jci.org/articles/view/144801#sd) F–H). In addition, our RNA-Seq analysis found that Cxcl1, Cxcl2, and Cxcl5 were also significantly upregulated in the livers of Sparcl1-treated mice ([Supplemental Figure 8B](https://www.jci.org/articles/view/144801#sd) and [Supplemental Table 3\)](https://www.jci.org/articles/view/144801#sd), which was confirmed by qRT-PCR analysis (Figure 4I). These chemokines have been shown to mediate the recruitment of neutrophils through their common receptor CXCR2 ([45](#page-15-4), [46\)](#page-15-5). Consistently, immunohistochemistry and qRT-PCR analysis showed that Ly6G, a neutrophil marker [\(47\)](#page-15-6), was increased in the livers of mice with chronic Sparcl1 treatment (Figure 4, J and K). SB225002, a pharmacological inhibitor of CXCR2 ([48\)](#page-15-7), markedly inhibited Sparcl1-evoked neutrophil infiltration and Ly6G expression (Figure 4, L–N). Thus, our results indicate that hepatic infiltration of neutrophils might be, at least in part, attributable to the induction of Cxcl1, Cxcl2, and Cxcl5.

To test whether CCL2 mediates the role of Sparcl1 in the activation of the hepatic inflammatory response, we used 3 approaches to block CCL2 function and then examined the effects of Sparcl1. First, we generated an adenoviral shRNA targeting *CCL2* to inhibit its expression in the liver. HFHC-fed steatotic mice were administered with control shRNA or *CCL2* shRNA and then injected with a single treatment of recombinant Sparcl1 protein or saline [\(Supplemental Figure 9,](https://www.jci.org/articles/view/144801#sd) A and

B). As a result, knockdown of *CCL2* substantially blocked the hepatic inflammatory response and liver injury induced by Sparcl1 treatment ([Supplemental Figure 9,](https://www.jci.org/articles/view/144801#sd) C–E). In addition, HFHC-fed mice were administered cenicriviroc, a pharmacological inhibitor of the CCL2 receptor [\(49](#page-15-8), [50](#page-15-9)). Consistently, cenicriviroc also largely attenuated the ability of Sparcl1 to induce liver inflammation and injury in steatotic mice [\(Supplemental](https://www.jci.org/articles/view/144801#sd) [Figure 10](https://www.jci.org/articles/view/144801#sd), A–D). In addition, adeno-associated virus 8–mediated

Figure 4. Sparcl1 induces CCL2 expression to promote NASH progression. (**A** and **B**) Relative mRNA levels (**A**) and protein concentrations (**B**) of CCL2 in the livers from mice chronically treated with saline or recombinant Sparcl1 protein. (**C**) Plasma CCL2 levels in the 2 groups of mice. (**D**) Plasma CCL2 concentrations in patients with NAFL (*n =* 76) or NASH (*n =* 141) and normal healthy individuals (*n =* 228). NAFLD patients were divided into NAFL and NASH according to the FLIP algorithm. (**E**–**H**) Individual correlations between circulating CCL2 concentrations and ALT (**E**), AST (**F**), GGT (**G**), and Sparcl1 (**H**) levels. (**I**) Relative mRNA levels of Cxcl1, Cxcl2, Cxcl5, Cxcl6, and Cxcl8 in the livers of the 2 groups of mice. (**J**) Ly6G staining of liver sections and quantification of images. (**K**) Relative mRNA levels of Ly6G in the livers from the 2 groups of mice. (**L**–**N**) C57BL/6J mice were fed an HFHC diet for 12 weeks, starting at 8 week of age. Then, mice were intraperitoneally injected with vehicle control (saline), Sparcl1 (0.2 mg/kg), or Sparcl1 plus SB225002 (0.5 mg/kg) for 3 weeks. *n =* 6 per group. Ly6G staining of liver sections (**L**) and quantification of images (**M**). Relative mRNA levels of Ly6G in the livers from 3 groups of mice (**N**). n = 6 per group (A-C and I-N). Data are represented as mean ± SEM. *P < 0.05, **P < 0.01, ***P < 0.001 by 2-tailed Student's t test (A-C and I-K), 1-way ANOVA (**D**, **M**, and **N**), or Spearman's correlation (**E**–**H**). Original magnification, ×200 (**J** and **L**).

Figure 5. Sparcl1 activates TLR4 to upregulate CCL2 expression. Hepa1-6 cells were transfected with adenovirus expressing Flag-tagged vector control or Flag-tagged Sparcl1 for 36 hours. Protein lysates were immunoprecipitated using anti-Flag M2–agarose. The immunoprecipitates were then eluted with Flag peptide and immunoblotted using anti-Flag and anti-TLR4 antibodies. The immunoprecipitation of Flag-Sparcl1 interacting protein was visualized by Coomassie blue staining. (**B**) Protein-protein interaction of Sparcl1 and TLR4. HEK293T cells were transfected with Flag-tagged Sparcl1 and HA-tagged TLR4 for 48 hours. Cell lysates were immunoprecipitated with either anti-Flag antibody or anti-HA antibody, and the immunocomplexes were probed with the indicated antibodies. (**C**–**E**) Relative luciferase activity (**C**), relative mRNA level of CCL2 (**D**), and NF-κB binding to the CCL2 promoter (**E**) in Hepa1-6 cells after incubation of Sparcl1, in the absence or presence of CLI-095 (1 μM) or JSH-23 (20 μM). (**F**–**H**) Relative luciferase activity (**F**), relative mRNA level of CCL2 (**G**), and NF-κB binding to the CCL2 promoter (**H**) in Hepa1-6 cells after incubation with Sparcl1, in the absence or presence of TLR4 siRNA. (**I**) TLR4 activation in terms of SEAP activity in TLR4-MD2–overexpressing HEK Blue hTLR4 cells in response to Sparcl1 in the presence or absence of CLI-095. (**J**) Western blots showing phosphorylated p65 (P-P65) and total (T-P65) in the livers of HFHC diet–fed mice treated with Sparcl1 or saline. (**K**) Western blot showing phosphorylated p65 and total p65 in Hepa1-6 cells treated with Sparcl1 or saline. (**L**) Subcellular distribution of endogenous p65 in Hepa1-6 cells treated with Sparcl1 or vehicle control for 2 hours. (**C**–**I** and **K**–**L**) Hepa1-6 cells were preincubated with palmitate (0.2 mM) for 12 hours. Data are represented as mean ± SEM. **P <* 0.05, ***P <* 0.01 by 1-way ANOVA (**C**–**I**).

(AAV8-mediated) knockdown of *CCL2* was performed. After 12 weeks of HFHC diet feeding, mice were administered *CCL2* shRNA or control shRNA through tail vein injection. One week later, mice were intraperitoneally injected with saline or recombinant Sparcl1 protein (0.2 mg/kg) every other day for another 3 weeks ([Supplemental Figure 11](https://www.jci.org/articles/view/144801#sd), A–C). As a result, the pathogenic roles of Sparcl1 in NASH progression, including hepatic steatosis and inflammation, increased plasma levels of ALT, AST, and HMGB1, and changes in expression levels of genes involved in liver inflammation and fibrosis, were largely attenuated by knockdown of CCL2 ([Supplemental Figure 11](https://www.jci.org/articles/view/144801#sd), D–J). Taken together, these findings suggest that Sparcl1 contributes to the hepatic inflammatory response and NASH progression, at least in part, through induction of CCL2.

Sparcl1 regulates CCL2 expression through binding to TLR4 and activation of the NF-κB pathway. Next, we investigated the molecular basis by which Sparcl1 upregulates *CCL2* expression in hepatocytes. Hepa1-6 cells were transfected with adenovirus expressing Flag-tagged Sparcl1 or empty vector (control). Protein lysates were immunoprecipitated with anti-Flag M2–agarose. The immunoprecipitates were then eluted with Flag peptide, resolved by SDS-PAGE, detected by Coomassie blue staining, and identified by liquid chromatography–tandem mass spectrometry (LC-MS/MS). Based on this analysis, TLR4, a pattern recognition receptor (10,

Figure 6. Sparcl1 deficiency protects mice from diet-induced NASH. *Sparcl1* wild-type (WT) and knockout (KO) male mice were fed an HFHC diet for 28 weeks, starting at 8 weeks of age. *n =* 5 per group. (**A**) Liver triglyceride (TG) content. (**B**) H&E staining of liver sections. (**C**–**E**) Plasma levels of ALT (**C**), AST (**D**), and HMGB1 (**E**). (**F**) F4/80, TUNEL, and Ly6G staining of liver sections. (**G**) Quantification of the F4/80, TUNEL, and Ly6G staining images. (**H**) Sirius red staining and its quantification. (**I**) Liver hydroxyproline content. (**J** and **K**) Relative mRNA levels of genes involved in liver inflammation and fibrosis. (**L**) Relative mRNA levels of CCL2 in the livers from the 2 groups of mice. (**M**) Plasma concentrations of CCL2 from the 2 groups of mice. Data are represented as mean ± SEM. ***P <* 0.01, ****P <* 0.001 by 2-tailed Student's *t* test (**A**, **C**–**E**, and **G**–**M**). Original magnification, ×200 (**B**, **F**, and **H**).

11), was found to co-purify with Sparcl1 (Figure 5A). We confirmed the physical interaction of Sparcl1 with TLR4 in transiently transfected HEK293T cells using a coimmunoprecipitation approach (Figure 5B). We then tested the biological relevance of the Sparcl1- TLR4 interaction. It has been well established that NF-κB/p65 mediates TLR4 activation to regulate the transcription of multiple cytokines and chemokines, including CCL2 [\(51\)](#page-15-10). Therefore, Hepa1-6 cells were incubated with Sparcl1 in the absence or presence of CLI-095 (a TLR4 signaling inhibitor) or JSH-23 (an NF-κB signaling inhibitor), followed by the examination of luciferase reporter assays, gene expression analysis, and chromatin immunoprecipitation (ChIP) assays. As a result, Sparcl1 could dosedependently activate the NF-κB luciferase reporter, upregulate the expression of *CCL2*, and enhance the occupancy of p65 on the *CCL2* promoter (Figure 5, C–E). However, incubation with CLI-095 or JSH-23 largely attenuated the activation of NF-κB signaling by Sparcl1 treatment (Figure 5, C–E). In agreement, transfection of specific siRNA targeting TLR4 could also block Sparcl1's activation of the NF-κB reporter and induce *CCL2* expression (Figure 5, F–H). Additionally, we employed genetically engineered

HEK Blue hTLR4 cells, which contain a TLR4/NF-κB–secreted embryonic alkaline phosphatase (SEAP) reporter system to detect TLR4/NF-κB activation. As expected, incubation with Sparcl1 enhanced SEAP activity, which was inhibited by CLI-095 (Figure 5I). Finally, phosphorylation of p65 was increased in the livers of mice or Hepa1-6 cells treated with Sparcl1 (Figure 5J and 5K). Consistently, in response to Sparcl1 treatment, endogenous p65 was translocated into the nucleus in Hepa1-6 cells (Figure 5L). Collectively, our results suggest that Sparcl1 could upregulate *CCL2* expression through activation of TLR4/NF-κB signaling.

Sparcl1 silencing suppresses hepatic steatosis, inflammation, and fibrosis. Having established that Sparcl1 upregulation is causally linked to the development of NASH, we next explored whether inhibition of Sparcl1 is sufficient to ameliorate diet-induced NASH in mice. To test this hypothesis, *Sparcl1*-knockout (*Sparcl1*-KO) mice were generated and their wild-type (WT) littermates were utilized as controls [\(Supplemental Figure 12](https://www.jci.org/articles/view/144801#sd), A–D). Under normal chow diet, there was no significant difference in the body weight, food intake, body composition, and hepatic TG content between WT and *Sparcl1*-KO mice ([Supplemental Figure 12](https://www.jci.org/articles/view/144801#sd), E–H). We then

Figure 7. Knockdown of Sparcl1 in iWAT improves NASH pathogenesis in mice. (**A**–**M**) C57BL/6J mice were fed an HFHC diet for 28 weeks, starting at 8 week of age. Then, 5 × 10¹⁰ pfu of either shCon (AAV-scrambled shRNA) or shSparcl1 (AAV-Sparcl1 shRNA) was injected bilaterally into the inguinal fat pads of mice for 4 weeks. *n =* 6 per group. (**A**) Relative mRNA levels of Sparcl1 in the iWAT, liver, SKM, and BAT from the 2 groups of mice. (**B**) Plasma Sparcl1 concentrations. (**C**) Liver triglyceride (TG) content. (**D**–**F**) Plasma levels of ALT (**D**), AST (**E**), and HMGB1 (**F**). (**G**) F4/80 and Sirius red staining of liver sections. (**H**) Quantification of the F4/80 and Sirius red staining images. (**I**) Liver hydroxyproline content. (**J** and **K**) Relative mRNA levels of genes involved in liver inflammation and fibrosis. (**L**) Relative mRNA levels of CCL2 in the livers from the 2 groups of mice. (**M**) Plasma concentrations of CCL2 from the 2 groups of mice. Data are represented as mean ± SEM. **P <* 0.05, ***P <* 0.01, ****P <* 0.001 by 2-tailed Student's *t* test (**A**–**F** and **H**–**M**). Original magnification, ×200 (**G**).

fed WT and *Sparcl1*-KO mice with HFHC diet for 12 weeks or 28 weeks. Under 12 weeks of feeding, hepatic TG content, plasma ALT and AST levels, and mRNA expression of genes involved in liver inflammation and fibrosis were similar between the 2 groups of mice [\(Supplemental Figure 13](https://www.jci.org/articles/view/144801#sd), A–E). However, after feeding HFHC diet for 28 weeks, Sparcl1-deficient mice had lower liver

TG content, reduced lipid droplets in hepatocytes, and lower plasma ALT, AST, and HMGB1 levels (Figure 6, A–E). Immunofluorescence staining revealed that the abundance of F4/80 macrophages, TUNEL-positive hepatocytes, and infiltration of neutrophils were lower in the *Sparcl1*-KO mice (Figure 6, F and G), indicative of attenuated liver inflammation. In support of this,

Figure 8. Neutralization of Sparcl1 improves NASH pathogenesis in mice. (**A**–**M**) C57BL/6J mice were fed an HFHC-diet for 28 weeks, starting at 8 week of age. Then, mice were injected intravenously with IgG or anti-Sparcl1 antibody (5 mg/kg) twice per week for 4 weeks. *n =* 8 per group. (**A**) Confirmation of anti-Sparcl1 antibody binding by Western blotting. (**B**) Plasma Sparcl1 concentrations in the 2 groups of mice. (**C**) Liver triglyceride (TG) content. (**D**–**F**) Plasma levels of ALT (**D**), AST (**E**), and HMGB1 (**F**). (**G**) F4/80 and Sirius red staining of liver sections. (**H**) Quantification of the F4/80 and Sirius red staining images. (**I**) Liver hydroxyproline content. (**J** and **K**) Relative mRNA levels of genes involved in liver inflammation and fibrosis. (**L**) Relative mRNA levels of CCL2 in the livers from the 2 groups of mice. (**M**) Plasma concentrations of CCL2 from the 2 groups of mice. Data are represented as mean ± SEM. ***P <* 0.01, ****P <* 0.001 by 2-tailed Student's *t* test (**B**–**F** and **H**–**M**). Original magnification, ×200 (**G**).

liver fibrosis and hepatic hydroxyproline content were reduced in the *Sparcl1*-KO mice (Figure 6, H and I). Consistently, mRNA expression of genes involved in inflammation and fibrosis was markedly downregulated in the livers of knockouts (Figure 6, J and K). In addition, hepatic mRNA expression and plasma concentrations of CCL2 were lower in the knockouts (Figure 6, L and M). To further confirm these results, 2 groups of mice were fed with HFHC diet for 36 weeks. As a result, Sparcl1 deficiency protected mice from prolonged-time HFHC diet feeding–induced key pathogenic events of NASH and liver fibrosis [\(Supplemental Figure 14,](https://www.jci.org/articles/view/144801#sd) A–L).

Recent studies have shown that viral delivery techniques could efficiently downregulate genes of interest selectively in the iWAT of mice ([52](#page-15-11)–[55\)](#page-15-12). Therefore, AAV8-shRNA targeting *Sparcl1* or negative control (scrambled shRNA) were generated and injected into iWAT depots of HFHC diet–induced NASH mice. As a result, *Sparcl1* shRNA treatment reduced *Sparcl1* mRNA expression in the iWAT and plasma Sparcl1 concentrations, compared with negative control shRNA–injected mice ([Figure 7](#page-9-0), A and B). In agreement, metabolic studies and gene expression analysis showed that shRNA-mediated knockdown of *Sparcl1* improved NASH patho-

Figure 9. Sparcl1 disrupts systemic glucose metabolism in NASH mice. (**A**) Western blots showing the insulin-stimulated phosphorylated AKT (P-AKT) and GSK3β (P-GSK3β) in Hepa1-6 cells treated with Sparcl1 (100 ng/mL) or vehicle control (PBS). Cells were preincubated with palmitate (0.2 mM) for 12 hours. (**B**–**D**) Blood glucose levels (**B**), plasma insulin levels (**C**), and insulin tolerance test (**D**) in HFHC diet–fed mice with chronic treatment of Sparcl1 or saline. *n =* 6 per group. (**E**–**G**) Blood glucose levels (**E**), plasma insulin levels (**F**), and insulin tolerance test (**G**) in *Sparcl1*-WT and -KO mice fed an HFHC diet for 28 weeks. *n =* 5 per group. (**H**) F4/80 crown-like structures in the iWAT sections from HFHC diet–fed mice after chronic treatment with Sparcl1 or saline. (**I**) Relative mRNA levels of proinflammatory cytokines. *n =* 6 per group. Data are represented as mean ± SEM. **P <* 0.05, ***P <* 0.01, ****P <* 0.001 by 2-tailed Student's *t* test (**B**, **C**, **E**, **F**, and **I**) or 1-way ANOVA (**D** and **G**). Original magnification, ×200 (**H**).

genesis and reduced CCL2 expression in NASH mice [\(Figure 7,](#page-9-0) C–M). These findings further demonstrated that WAT might be an important source of Sparcl1 during development to NASH.

Finally, to evaluate in vivo the potential therapeutic effects of suppressing Sparcl1 in treating NASH, we developed a neutralizing antibody to interfere with Sparcl1 and administered it to HFHC diet–induced NASH mice. According to the methods described in recent studies [\(56](#page-15-15)–[58\)](#page-15-16), NASH mice were treated with either anti-Sparcl1 neutralizing antibody or control IgG antibody twice per week for 4 weeks. The specificity and efficiency of the neutralizing antibody were confirmed by Western blotting and ELISA, which showed that plasma Sparcl1 concentrations were markedly reduced by this treatment (Figure 8, A and B). Compared with NASH mice treated with IgG controls, hepatic TG content and plasma levels of ALT, AST, and HMGB1 were markedly decreased in NASH mice treated with Sparcl1-neutralizing antibody (Figure 8, C–F). In addition, the abundance of F4/80-positive macrophages, liver fibrosis, and hepatic hydroxyproline content were reduced (Figure 8, G–I). In agreement, expression of genes involved in hepatic inflammation and fibrosis was downregulated (Figure

8, J and K). Additionally, mRNA expression and plasma levels of CCL2 were reduced (Figure 8, L and M). Collectively, these results demonstrated that inhibition of Sparcl1 with AAV8-shRNA or a neutralizing antibody could improve NASH progression in mouse models, suggesting that targeting Sparcl1 might be an effective therapeutic strategy for NASH.

Sparcl1 affects systemic metabolism at the whole-body level. Activation of TLR4/NF-κB signaling in hepatocytes has been shown to affect systemic metabolic homeostasis, resulting in hyperglycemia and insulin resistance [\(59](#page-15-13), [60\)](#page-15-14). Consistent with this hypothesis, we found that insulin-stimulated phosphorylation of AKT and its target protein, GSK3β, was repressed by Sparcl1 treatment in Hepa1-6 cells (Figure 9A). Chronic injection of recombinant Sparcl1 also induced fasting hyperglycemia and hyperinsulinemia and impaired insulin sensitivity in HFHC diet–fed mice (Figure 9, B–D), whereas *Sparcl1*-KO mice were partially protected from long-term HFHC diet–induced abnormal glucose homeostasis (Figure 9, E–G). Furthermore, Sparcl1 treatment could promote adipose tissue inflammation, as shown by crown-like structure formation and upregulation of inflammatory genes (Figure 9, H

and I). Therefore, Sparcl1 may have systemic effects at the wholebody level. Moreover, our results support the notion that NASH can further disrupt systemic glucose metabolism in the context of obesity or overnutrition [\(61](#page-15-17)).

Discussion

Typically, NASH is characterized by the presence of sustained hepatic inflammation, which is strongly associated with liver injury and fibrosis. Previous studies showed that inflammation can induce lipid accumulation during NASH progression and may precede steatosis (2, [5,](#page-14-1) [62](#page-16-7)), while alleviation of liver inflammation could improve hepatic TG retention and steatosis ([63,](#page-16-3) [64\)](#page-16-8). For instance, activation of hepatocyte TLR4 signaling due to *Tmbim1* deficiency substantially increased hepatic inflammation in mice fed an HFD for 24 weeks ([63](#page-16-3)). As a result, hepatic TG content was increased in the *Tmbim1*-deficient mice. On the other hand, suppression of hepatocyte TLR4 signaling by *Tmbim1* overexpression alleviated inflammation and reduced steatosis in mice fed a long-term HFD [\(63\)](#page-16-3). Moreover, Guo et al. showed that adipose tissue–enriched endocrine factor Nrg4 could reduce hepatic inflammation and preserve hepatocyte health (22). As a result, *Nrg4* deficiency exacerbated HFHC diet–induced hepatic TG retention, while overexpression of *Nrg4* protected mice from long-term HFHC diet–induced steatosis and inflammation (22). Therefore, these results support the notion that hepatic steatosis and inflammation are tightly associated in NASH progression. Nevertheless, the critical factors that drive the hepatic inflammatory response in NASH remain poorly understood. Initially, a 2-hit hypothesis was posited decades ago, which described that the first hit is steatosis while the second hit is from oxidative stress [\(65\)](#page-16-9). However, this view is now considered outdated (2, 3). A multiple-hit hypothesis involving a myriad of factors has been proposed, which includes lipotoxicity, insulin resistance, hepatocyte inflammasome activation, and alterations in gut microbiota (2, 3). Therefore, both the pathogenic drivers and molecular basis that underlie NASH progression are complicated and require more intensive studies. In this study, using HFHC diet–induced mouse models that encompass 2 time periods, we compared the WAT transcriptome and identified 118 cytokines selectively dysregulated in the WAT of NASH mice. Some of these cytokines have been shown to regulate adipogenesis (such as *Wnt10b* and *Angptl2*), adipose inflammation (such as *Gdf3* and *Cyr61*), and fat mass and energy expenditure (such as *Fgf10* and *Vegfb*) in adipose tissues ([66](#page-16-10)–[71\)](#page-16-11). Whether they play a role in the development of NASH through direct or indirect mechanisms remains poorly understood. Therefore, our transcriptome screening may provide a valuable resource to explore the molecular mechanisms of the WAT/liver endocrine axis underlying NASH progression for future studies.

We further investigated the pathogenic roles of Sparcl1 in NASH progression through several approaches. Both chronic recombinant Sparcl1 protein injection and adenovirus-mediated overexpression of Sparcl1 led to a hepatic inflammatory response and liver injury in mice in the presence of simple steatosis, as evidenced by elevated plasma concentrations of ALT, AST, and HMGB1. In addition, liver fibrosis was induced by chronic Sparcl1 treatment, as shown by Sirius red staining and increased hepatic hydroxyproline content. Comparison of chronic Sparcl1–treated mice (Figure 3 and [Supplemental Figure 7\)](https://www.jci.org/articles/view/144801#sd) to the 28-week HFHC diet–fed mice ([Supplemental Figure 2](https://www.jci.org/articles/view/144801#sd)) showed that the hepatic inflammatory response and liver injury were more severe in Sparcl1-treated mice. Therefore, exogenous Sparcl1 treatment in 12-week HFHC diet–fed mice can worsen liver disease toward NASH and achieve a similar state to that of the long-term HFHC diet–fed model. On the other hand, *Sparcl1*-deficient mice by gene knockout or knockdown were protected from long-term HFHC diet–induced NASH, as demonstrated by decreased hepatic steatosis and inflammation and reduced liver injury and fibrosis. Of pathophysiological significance, Sparcl1 expression was upregulated in the WAT of NASH mice, and plasma Sparcl1 concentrations were correlated with hepatic pathological features in NASH patients. Therefore, together with the use of neutralizing antibody, these findings suggest that blocking Sparcl1 signaling might be a promising therapeutic target for NASH treatment. Of note, our data showed that liver fibrosis could be reduced more than 50% after 4 weeks of treatment in mice, which was also observed in recent studies ([56–](#page-15-15)[58\)](#page-15-16). One possible explanation is that the diet-induced NASH phenotypes, especially liver fibrosis, might be mild. The mild symptoms of liver fibrosis in NASH mice might be easily reversed or ameliorated. Indeed, the diet-based models are refractory to fully progressing to severe fibrosis, even after long-term feeding [\(72](#page-16-0)). Therefore, further studies are still needed to explore the therapeutic effects of Sparcl1-neutralizing antibody in NASH models with severe liver fibrosis. We also found that *Sparcl1* mRNA levels were moderately increased in the livers of mice with simple steatosis or NASH ([Supplemental Figure 3](https://www.jci.org/articles/view/144801#sd)D). This is consistent with a recent study that showed a 2-fold upregulation of hepatic *Sparcl1* mRNA expression in a genetic mouse model of steatohepatitis and fibrosis ([73](#page-16-1)). Nevertheless, the basal expression level of *Sparcl1* was very low in the murine liver (23), which was also observed in our study ([Supplemental Figure 4A](https://www.jci.org/articles/view/144801#sd)). In addition, *Sparcl1* was found to be expressed in many organs such as the lung and gastrointestinal tract (23). Other tissue- and cell type–dependent expression of Sparcl1 may play a role in the NASH progression as well.

It has been well established that TLR4 is a critical link mediating obesity-associated hepatic steatosis and liver inflammation and injury ([74](#page-16-2)). In the liver, TLR4 is functionally expressed in hepatocytes and macrophages/Kupffer cells [\(63,](#page-16-3) [75,](#page-16-4) [76\)](#page-16-5). Our experiments also showed that Sparcl1 could activate TLR4 signaling in RAW264.7 macrophage cells [\(Supplemental Figure 15,](https://www.jci.org/articles/view/144801#sd) A and B). Therefore, we speculate that in addition to hepatocytes, Sparcl1 may also induce the production of inflammatory mediators through activation of TLR4 signaling in macrophages/Kupffer cells. However, through Kupffer cell depletion and bone marrow transplantation, Li et al. demonstrated that the activation of TLR4 signaling in hepatocytes was imperative, while TLR4 signaling in Kupffer cells was not necessary in diet-induced NAFLD ([76\)](#page-16-5). Furthermore, studies based on the Cre-loxP strategy further showed that ablation of *TLR4* in hepatocytes led to markedly decreased hepatic inflammation, and improved hepatic steatosis and liver injury ([77](#page-16-6)). In contrast, ablation of *TLR4* in myeloid cells did not protect mice from diet-induced hepatic steatosis, and even worsened the systemic inflammatory state ([77](#page-16-6)). Therefore, together with these reports, our data highlight the importance of hepatocytes in response to extracellular stimuli and distinct functions of liver cell populations in the development of chronic liver diseases.

Our in vitro experiments showed that Sparcl1 can bind with TLR4 in hepatocytes, suggesting that Sparcl1 might act as an endogenous ligand of TLR4. Functional studies demonstrated that the inflammatory response evoked by Sparcl1 is dependent on steatosis. Given that acute Sparcl1 treatment can aggravate liver injury and enhance the hepatic inflammatory response in both HFHC diet-fed and HFD-fed mice, but not in the CCl_{4} treated mice, our results suggest that the role of Sparcl1 in liver metabolism and inflammation might be dependent on a state of metabolic disorders, such as obesity and hyperlipidemia. It has been reported that free fatty acids (FFAs) are not direct TLR agonists and trigger the activation of TLR4 signaling pathway to elicit inflammatory response through indirect mechanisms ([78\)](#page-16-13). We found that incubation of palmitate at a dose of 0.2 mM did not induce NF-κB activation in Hepa1-6 cells. Our data are consistent with 2 previous reports showing that palmitate treatment at a dose of 0.25–1.0 mM cannot activate NF-κB signaling in human primary adipocytes, 3T3-L1 adipocytes, and mouse primary bone marrow–derived macrophages ([79,](#page-16-14) [80](#page-16-15)). Thus, we propose 2 possibilities regarding the involvement of FFAs and Sparcl1 in TLR4 activation: (a) the Sparcl1/TLR4-mediated hepatic inflammatory response may require the presence of FFAs, and (b) a physical association between FFAs and Sparcl1 might exist.

Mechanistically, we found that Sparcl1 can activate the transcription and expression of several chemokines, including CCL2, Cxcl1, Cxcl2, and Cxcl5. Chemokines are chemotactic proteins that act as chemoattractants for leukocyte trafficking, growth, and activation in inflammatory sites [\(81\)](#page-16-16). In the liver, hepatocytes can produce approximately 50 chemokines, while their receptors are typically expressed in immune cells and hepatic stellate cells ([82\)](#page-16-17). Extensive experimental and clinical studies have elucidated the pivotal roles played by the chemokine system in the progression of chronic liver diseases [\(83\)](#page-16-18). Expression levels of these chemokines are highly upregulated in human NASH, but not in human simple steatosis or HFD-induced fatty liver in mice [\(84](#page-16-19), [85](#page-16-20)). Notably, adenovirus-mediated overexpression of chemokines like Cxcl1 and CCL2 was sufficient to induce NASH phenotypes in obese mice ([85,](#page-16-20) [86](#page-16-21)). Moreover, CCL2 expression in hepatocytes has been shown to be associated with TG content both in a diet-induced mouse NASH model and human NAFLD livers ([86](#page-16-21), [87](#page-16-22)). Consistently, compared with the patients with simple steatosis, levels of circulating CCL2 were elevated in NASH patients, suggesting that the high CCL2 levels might be of importance for NASH progression [\(88](#page-16-23)). In contrast, genetic depletion or pharmacological inhibition of CCL2 in mice ameliorated steatosis progression, alleviated the hepatic inflammatory response, and reduced liver injury [\(89](#page-16-24), [90\)](#page-16-25). In our study, the exacerbating effects of Sparcl1 on the hepatic inflammatory response and liver injury were abrogated by either genetic knockdown of CCL2 or pharmacological inhibition of CCR2. Furthermore, suppression of CXCR2 markedly blocked Sparcl1-induced neutrophil infiltration and Ly6G expression. Thus, our results suggest that these chemokines might be the primary targets of Sparcl1 in NASH progression.

There are some limitations of this study that we would like to point out. First, as pointed out by a recent study, presumably healthy volunteers may have markers of NAFLD ([91](#page-16-12)). However, due to ethical requirements, it is not appropriate to perform liver biopsy and histopathological examination in healthy humans. Therefore, a strict ALT threshold was used to ameliorate this problem in our study [\(91](#page-16-12)). Second, multicenter clinical studies are needed to further confirm the association of plasma Sparcl1 concentrations and NASH severity. Third, although we have identified TLR4 as a receptor for Sparcl1, which part of Sparcl1 recognizes the TLR4 sequence remains to be determined. Further studies are still needed to answer these questions.

In conclusion, our results support the role of Sparcl1 as a regulator of NASH progression, at least in part, through TLR4/NF-κB– dependent activation of CCL2. Our findings provide a mechanism to explain how obesity promotes the development of chronic liver inflammation, injury, and fibrosis. In light of this, therapeutic interventions that suppress Sparcl1 function might represent a promising candidate for treating NASH.

Methods

Animal experiments. Male C57BL/6J mice aged 6 weeks were purchased from the Shanghai Laboratory Animal Company (SLAC). For NASH diet feeding, C57BL/6J mice were fed a diet containing 40% fat, 22% fructose, and 2% cholesterol (D09100310, Research Diets Inc.) for 12, 28, or 36 weeks. For HFD feeding, C57BL/6J mice were fed a diet containing 60 kcal% fat, 20 kcal% carbohydrate, and 20 kcal% protein (D12492, Research Diets Inc.) for 12 weeks. The *Sparcl1*-KO mice were generated by Biocytogen Co. Ltd. using the CRISPR/Cas9-based Extreme Genome Editing system. Two single guide RNAs (sgRNAs) were designed to target upstream of exon 3 and downstream of exon 7 in the nonconserved regions of *Sparcl1* using the CRISPR design tool ([http://www.sanger.ac.uk/htgt/wge/\)](http://www.sanger.ac.uk/htgt/wge/). The sgRNA plasmids with Cas9 mRNA were coinjected into C57BL/6J mouse zygotes, and surviving zygotes were transferred into pseudopregnant mice. The genotype of *Sparcl1*-KO mice was confirmed by PCR amplification and DNA sequencing. Tail tips of each mouse were collected to extract genomic DNA. The targeting region was amplified by PCR (forward 5′-GATTCTGCACCCACTCTGCTCACTT-3′, reverse 5′-TCTG-GTTGTTGTTGAGCCCCAGAAG-3′). For Sparcl1 treatment, recombinant mouse Sparcl1 protein (0.2 mg/kg) was intraperitoneally injected into mice. For cenicriviroc treatment, mice were treated daily with cenicriviroc (30 mg/kg) or vehicle control by intraperitoneal injection. Recombinant adenovirus for Sparcl1 overexpression was generated with GFP adenovirus as the negative control. AAV-delivered short hairpin RNA (shRNA) was constructed using an AAV8 Vector System (GeneChem), driven by CMV or the liver-specific thyroxine-binding globulin (TBG) promoter. For overexpression or knockdown of Sparcl1, 4×10^9 pfu of purified adenovirus or 5×10^{10} pfu of AAV-shRNA was injected bilaterally into the inguinal fat pads of HFHC diet–fed mice. For knockdown of CCL2, HFHC diet-fed mice were injected with 2 \times 10⁹ pfu of Ad-shRNA or 2×10^{11} pfu of AAV-shRNA by tail vein injection. The 2 shRNAs had the following target sequences: Sparcl1, 5′-GCAAG-CAAACCCAAGACTTAA-3′; and CCL2, 5′-GAAGTTGACCCGTA-AATCT-3′. For insulin tolerance tests, mice were injected with regular human insulin (Eli Lilly, 0.75 U/kg) after a 6-hour fast. Blood glucose was determined using a portable blood glucose meter (LifeScan).

Human studies. A total of 906 adult participants who had undergone liver biopsy were consecutively recruited at the First Affiliated

Hospital of Wenzhou Medical University from December 2016 to February 2019. Exclusion criteria were as follows: (a) alcohol consumption greater than 140 g per week in men and greater than 70 g per week in women; (b) presence of other liver diseases, including hepatitis B or C virus infection, autoimmune hepatitis, primary biliary cholangitis, and liver failure; (c) concomitant use of hepatotoxic drugs, including antibiotics, nonsteroidal antiinflammatory agents, steroids, calcium channel blockers, tamoxifen, amiodarone, isoniazid, and methotrexate; (d) chronic or acute kidney disease as well as presence of urinary tract infection; and (e) fatty liver infiltration less than 5% on liver histology or missing data. As a result, 689 subjects were excluded and 217 patients with biopsy-confirmed NAFLD were included in the present study. The diagnosis of NAFLD was based on the histopathological features of liver biopsy, including grade of steatosis, hepatocellular ballooning, and lobular inflammation. NAFL (simple steatosis) and NASH were diagnosed by the FLIP algorithm (39, 40). Two hundred twenty-eight gender- and age-matched healthy volunteers were enrolled simultaneously according to the following eligibility criteria: (a) BMI less than 25 kg/m^2 and a strict ALT cutoff of 19 U/L in females and 30 U/L in males, as described previously ([91\)](#page-16-12); (b) no diabetes, no history of cardiovascular disease, and no chronic kidney disease; (c) no clinical evidence of chronic liver diseases, as defined by history, ultrasound features, and biochemical examinations. The baseline characteristics of these individuals are shown in [Supplemental Table 2](https://www.jci.org/articles/view/144801#sd).

ELISA measurement of human Sparcl1. For NAFLD patients, plasma samples were collected on the day of liver biopsy. Gender- and age-matched healthy volunteers were enrolled simultaneously and plasma samples were collected on the same day. All plasma samples were stored in separate tubes at –80°C, and kept until ELISA analysis without repeated freezing and thawing. There was no difference in plasma Sparcl1 levels measured at different times in storage ([Sup](https://www.jci.org/articles/view/144801#sd)[plemental Figure 16](https://www.jci.org/articles/view/144801#sd), A–C). The standard curve of the ELISA assays is shown in [Supplemental Figure 16](https://www.jci.org/articles/view/144801#sd)D.

RNA-Seq. High-throughput RNA-Seq was performed by Cloud-Seq Biotech. Briefly, total RNA was used for removing the rRNAs with the NEBNext rRNA Depletion Kit (New England Biolabs) following the manufacturer's instructions. RNA libraries were constructed by using the NEBNext Ultra II Directional RNA Library Prep Kit (New England Biolabs) according to the manufacturer's instructions. Libraries were controlled for quality and quantified using the BioAnalyzer 2100 system (Agilent Technologies). Library sequencing was performed on an Illumina HiSeq 4000 instrument with 150-bp pairedend reads. Paired-end reads were harvested from the sequencer and quality controlled by Q30. After 3′ adaptor trimming and removal of low-quality reads using Cutadapt software (v1.9.3), the high-quality clean reads were aligned to the reference genome (UCSC mm10) with hisat2 software (v2.0.4). Then, guided by the Ensembl gtf gene annotation file, cuffdiff software was used to obtain the gene-level FPKM as the expression profile for mRNA, fold change and *P* values were calculated based on FPKM, and differentially expressed mRNAs were identified. All original data were deposited in the NCBI's Gene Expression Omnibus database (GEO GSE176681).

Statistics. All statistical analysis was performed with SAS version 9.3 (SAS Institute). Data are presented as mean ± SEM or mean ± SD or median (interquartile range). For animal and cellular experiments, a 2-tailed unpaired Student's *t* test was performed to compare 2 groups. 1-way ANOVA followed by the Student-Newman-Keuls test was used to compare more than 2 groups. For human studies, the correlation of plasma levels of Sparcl1 or CCL2 and clinical parameters was analyzed using Spearman's correlation. The NAFLD patients were classified into different groups according to the FLIP algorithm. A χ^2 test was used to compare categorical variables between groups. Receiver operating characteristic (ROC) curve analysis was applied to evaluate the utility of plasma Sparcl1 levels in diagnosing NASH. The differences in diagnostic performance were assessed by DeLong's test. Two-sided *P* values less than 0.05 were considered statistically significant. Statistical significance is displayed as $P < 0.05$, $*P < 0.01$, or $*+P < 0.001$.

Study approval. The human study was approved by the Ethics Committee of First Affiliated Hospital of Wenzhou Medical University (Wenzhou, China), in line with the ethical guidelines of the 1975 Declaration of Helsinki. Written informed consent was obtained from each individual. The animal protocol was reviewed and approved by the Animal Care Committees of Zhongshan Hospital, Fudan University (Shanghai, China).

Author contributions

Y Lu designed and directed the study. BL, LX, JJ, and Wei Liu performed animal and cellular experiments. Wenyue Liu, PZ, YJ, YH, and MZ contributed to the human study. YC, MX, and Y Liu conducted the statistical analysis for the human study. JL and XL contributed to the discussion.
